
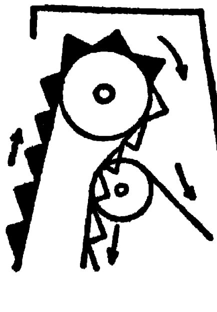

Fig 42. Perfect-discharge Elevator

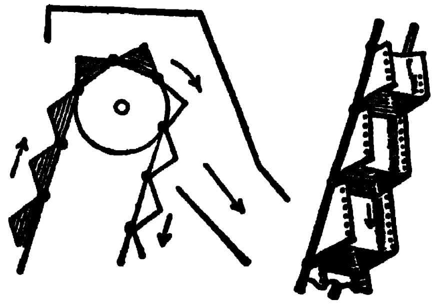

Fig 43. Continuous-discharge Elevator

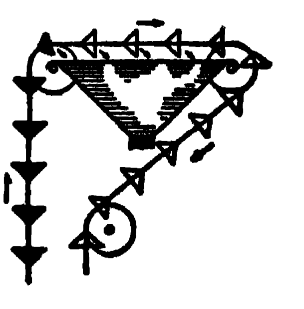

Fig 44. Gravity-discharge Elevator

making them strong enough to carry the concentrated pull of the entire conveyer. Unless very strongly built, trouble will follow from vibration and loosening of bolts. It is desirable to cross-connect the 2 take-up screws, to rotate together and keep shafts parallel; sprockets and chain are cheaper than bevel gears and shafts for this purpose.

Boots must receive material on rising side of chain. They can not be used for stuff harder than coal, excepting fine granular material. Timber boots, lined with sheet steel, are not so good as those made of C-I sides and sheet-steel body. In this case the take-ups are built into the boot. For ore and stone, the arrangement in Fig 45 works well. The elevator is preferably inclined at 60° from horiz. The delivery is high enough to keep one empty bucket below the chute to catch fines and lessen cleaning up. This design is cheap, and will not clog, jam, or freeze. There should be plenty of room around boot or loading chute for ease in repairing, and for safety.

Delivery chutes should not have their bottom line extended higher than the head shaft; 4-6 in lower is better for a clean delivery. If closed on top, the upper sheets should be hinged for quick access in case of a jam. Generous spacing of buckets (pitch) is desirable. Anthracite, if clean, will slide on a 15° polished chute. A little dirt, or worse, dry snow, necessitates 30°–35°; bituminous requires 45°. If the chute is hoppered, the corner angles of a 45° hopper will be flatter than 45°, and material will hang there. Some dirty and sticky ores require 60°. Bottom sheets should be bolted for easy renewal. Channel sections for sides are frequently the most economical, giving minimum of shop work with economy in metal. The cheapest and most durable chute bottoms are of hard tank plates.

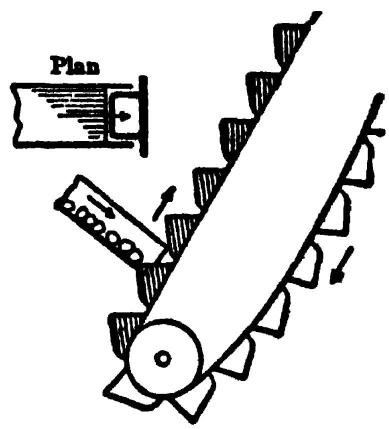

Fig 45. Bucket Elevator

Frames and casing. Modern construction, and because of fire risk of flames rapidly climbing, as in a flue, is justified. Good bracing is essential, but tension rods are undesirable. All braces should be angles. Drive supports should be proportioned for deflection and stiffness, regardless of unit stresses. Covering, if of black sheets, must be kept well painted; galvanized muck-bar iron is better. Panels on one side should be bolted for access, and lead washers under bolt heads will prevent rusting at holes. GUIDE WHEELS on the rising side should be set 5–7 ft apart, depending on size of elevator and its angle; short vert elevators require no guides. Number of guides on slack side depends on path of the chain, which approximates a parabola; 10 ft centers is close enough.

Power required is 2 to 3 times the net work of lifting the unbalanced load; or, motor hp = ton per hr × ft lift ÷ 990 × 2 or 3. Large capac, low speed, and short lift tend to economy. In estimating power, assume all buckets to be filled; but, in estimating capac of buckets, consider them not more than $^2/_3$ full for ordinary conditions of feeding. Elevators have been built for 120-ft lift. Exceptional care in unit stresses and loads is needed for all high-lift elevators.

11. BELT AND BUCKET ELEVATORS

Buckets (Art 10) are bolted to belt with special flat-head bolts.

Belts are canvas and rubber, 4 to 12 ply. Canvas should be 32-oz duck. For the best belts, the adhesion of the rubber covering, for a strip 1 in wide, should be 16 to 20 lb; 10–14 lb is good. Thickness of rubber is $^1/_8$–$^1/_4$ in. Splices are best made with metal hooks. Pierce all holes first with an awl, instead of driving the hooks through the solid belt. Width of belt should be 2 in more than width of buckets; width of drums, 2 in more than belt. Working stress on belt, per in width per ply, should not exceed 22 lb for high-grade belts having 30 to 32-oz duck plies. Reduce stress to 20 lb for 28-oz duck.

Drums. Coeff of friction is ordinarily 0.2 to 0.3 for a finished C-I pulley. Rubber-belt lagging, bolted on, will raise the coeff to 0 35 or 0.4. Certain kinds of dust raise the coeff, others lower it; sulphur dust is the worst. Oil and grease must be kept away from belt, as they dissolve rubber. The great advantages of belt and bucket elevators are that they are simple to install and maintain, and have no chain and sprocket troubles in gritty materials. They usually cost a little more than chain elevators. ARC OF CONTACT between drum and belt is 160°–180°, depending on angle to horiz. Slack side is permitted to hang in an easy parabolic curve, which is modified by the tension of lower take-up screws. When laying out, give ample clearance in the boot for the slack side, which at times may also oscillate a foot. The actual curve is more like a parabola than a catenary.

Frame should be well braced for transverse stiffness; but may be more flexible under beam load. As a column, 90 ($l \div r$) is a safe limit. Besides the dead load, the live load on head shaft and pillow blocks is the sum of the taut and slack tensions of the belt. The slack tension is usually 0.3 the taut tension, and may be 0.5 with take-ups set up. Put GUIDE IDLERS under taut side of belt, 5–7 ft apart; none under slack side.

Ratio of drum diam to belt thickness is important as affecting life of belt, the most expensive item in total cost. It is best stated in terms of belt plies; 5 in diam per ply of belt is advisable for permanent plants. Tendency is to use a smaller, cheaper drum, which revolves faster and requires less gear reduction. As drums and gears do not wear out in the life of an elevator and belts do, real economy lies with the high ratios. Lower drum is usually smaller than driver, because driving tension in belt is almost nil at that point, with only bending tension remaining. Guide idlers are often too small, do not turn easily, and drag on the belt.

For chain-bucket and other elevators for excavating earth, trenching, etc, see Sec 3; for gold dredging, see Sec 10; for tailing "sand-wheels" and ore concentrators, see Taggart, Handbook of Ore Dressing.

12. HELICAL CONVEYERS

Characteristics: low first cost, compactness, small capacity, large consumption of power for useful work done. To friction loss of load sliding through the trough, must be added the friction of screw turning within the mass. Low capacity is due to the need of keeping load line below the shaft center and bearings. For grain, a 30-in screw can deliver 100 tons 100 ft per hr, with 40 hp. This is about 20 hp per ton-mile, or 20 times as much power as for a belt conveyer. The disparity increases with wt of materials, or higher coeff of friction: for bituminous coal, about 25 hp-hr per ton-mile; ground cement, 30 hp; for rock and ore (with clean, lightly loaded trough), 25 to 50 hp per ton-mile. When finely-ground stuff is to be carried up an inclined belt (100 mesh, or less, like cement), a short length of screw conveyer is required as a feeder, to expel air and compact the material. Hot material is sometimes cooled in a screw conveyer. Conversely, some substances are heated in transit; or the screw may be cut into paddles for mixing heavy materials. Ordinary grades of concrete can be cheaply mixed; first-class concrete requires a batch mixer. Shafts are preferably tubular, for transverse stiffness due to large diam. Bearings should be babbitt lined, with grease cups. Spacing depends on wt of material and lateral bending of shaft, and may vary from 7 to 15 ft. Conveyers in series, if in line, should have flexible couplings; otherwise, angle or bevel gears. Gates are plain slides. Screws are usually of heavy sheet steel; for minerals, concrete, cement, and ashes, smoothly molded C I is more durable. Troughs are of sheet steel, curved to conform to screw. Generous clearance between screw and trough permits accumulation of a layer of fines, which protects the bottom from wear. Plank boxes, of rectangular section, lined with sheet steel, are not so good as half-round steel troughs. Careful lining up, and stiff supports are essential. Thrust bearings are plain shoulders on end of shaft, with C-I bearings; they require constant lubrication and are generally too small for long life. Long screw conveyers are apt to get out of line on timber supports, where beam loads cause changing deflections, just as this condition affects the good running qualities of long overhead line shafts.

13. FEEDERS, GRIZZLIES, GATES AND CHUTES

Feeders for continuous conveyers are essential when delivery is intermittent, as from cars, skips, and buckets. They act as equalizers, to smooth out the peak loads, and are also advantageous in feeding crushers and trommels, to prevent clogging, steady the motor load, and reduce size of motors. TYPES: (*a*) reciprocating troughs, inclined and level; (*b*) swinging plates, single and double; (*c*) plungers, with stationary troughs; (*d*) continuous aprons;

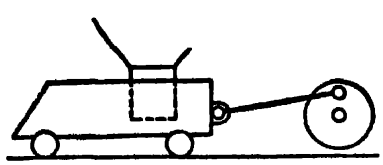

Fig 46. Reciprocating Feeder

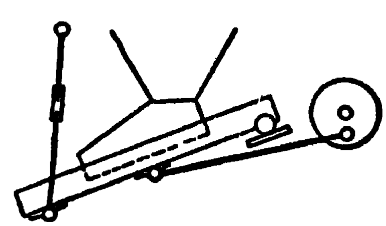

Fig 47. C. K. Baldwin Feeder

(*e*) automatic timed gates; (*f*) rotary plates; (*g*) revolving grizzlies; (*h*) roll feeders. SIMPLE INCLINED TROUGH, inclined 10°–15°, suspended by 4 adjustable rods, is apt to sway in an oval orbit and strain itself. LINK-BELT FEEDER obviates this by placing a reciprocating flat or inclined chute on 4 wheels (Fig 46). If inclined 15°, it can be made to empty itself. C. K. BALDWIN FEEDER has 2 rear wheels, with adjustable rods at front. It is always inclined to insure self-cleaning (Fig 47). In all of these, there is considerable vibration,

requiring stiff supports. Crank shaft should not rotate more than 80 r p m. All bearings should have bronze bushings. Long connecting rods are desirable; best made of pipe with forged ends. Throw is usually 12 in. Crank disks can be tapped for 3 radii of crank pin, to vary stroke. Stresses on moving mechanism and crank-shaft bearings are doubled

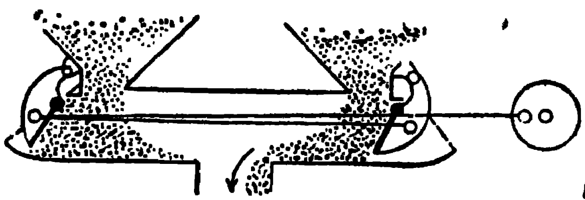

Fig 48. Duplex, Balanced Feeder (L. de G. Moss)

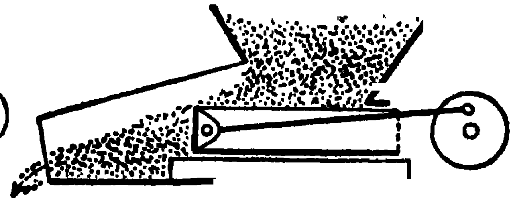

Fig 49. Dempcey's Plunger Feeder

for impact. Counterbalances in crank disks lessen vibration. Gear teeth may be cut on rims of disks to keep torsion out of crank shaft and save 1 gear wheel. Single and double swinging plates have been used by the writer, to reduce vibration of large masses. Fig 48 shows a duplex balanced form for a track hopper. Horiz chutes should be as short as possible, just so that material will not fall beyond angle of repose; speed, 100 r p m. Dempcey's plunger feeder (Fig 49) may be horiz or inclined. It can be made duplex under a large hopper. Plunger is hollow, preferably of C I, and slides on rails, which should be easily replaced, as they lie unprotected in the material; speed, 100 r p m. The throw of feeders can be varied while running, by a vibrating link-arm with constant throw, using a shifting slide on link to vary travel of reciprocating pan.

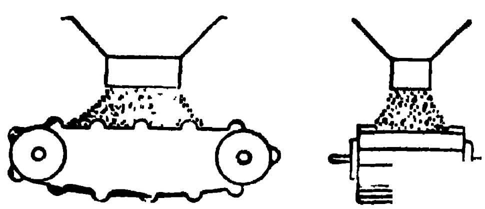

Fig 50. Apron Feeder

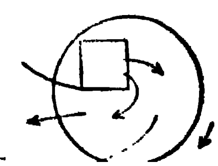

Fig 51. Action of Plate Feeder

Capacity can be calculated by displacement, main factor being breadth. Reciprocating feeders, if made as shown with a back plate, are really stationary pusher feeders. The incline does not increase capacity, but lessens work

Apron feeders make an excellent gate for ore (Wellman-Seaver-Morgan Co) and may be power-driven (Fig 50). No skirt-boards are used. Rotary plates, as in the Challenge feeder and Trump mixer, consist of circular plates, level or slightly inclined, with a plow. They will not sweep off the theoretical volume, owing to slip backwards on the plate (Fig 51).

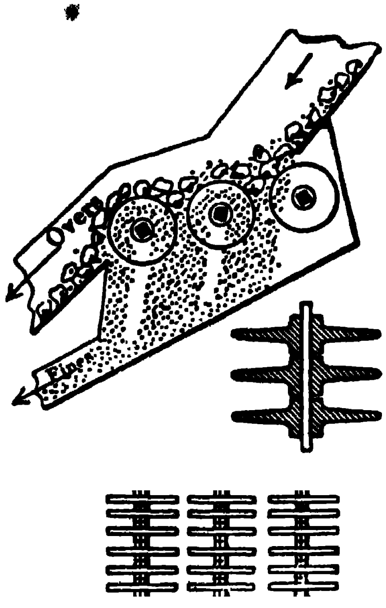

Fig 52. Stockwell Feeder

Revolving grizzlies were introduced by E. V. Stockwell, chief engr, Braden Copper Co (Fig 52). A single set or a series of rolls may be used. The C-I plates are tapered to prevent wedging of lumps, and loosely fitted on a square shaft to aid in freeing lumps. With sticky materials, stationary finger bars between disks will clear them. The spaces drop out the fines to a by-pass chute. These grizzlies now made by Robins Conveying Belt Co.

Roll-feeders, introduced by Hoover & Mason for ore and limestone, have a single hollow roller with C-I spiders and plate barrel (Fig 53); they also serve as gates. They feed too unsteadily for conveyers, but are good for filling cars. Variable-throw feeders are also used.

Gates of the undercut type are occasionally used for feeders; driven by shafting and cranks or eccentrics. Cranks are preferable, giving less trouble and using less power.

Gates of sliding type, though cheap, are often troublesome. They rust, jam with fines, and freeze tight in winter, often requiring a sledge to open them. Their length should be at least 1.5 × width. The single undercut gate is very satisfactory in sizes less than 20 in diam (Fig 54). Duplex undercut gates work well with fine material, but, for ore, should have offset jaws (Fig 55) to avoid jamming. The Briggs folding flap neither jams nor freezes, and is easily moved. Clearance between flap and sides must be small to avoid lodgment of spalls.

The flap may be external, as in Fig 56. Fig 57 is a combined gate and chute for large stone, subject to much freezing. Stationary grizzlies in chutes, for by-passing fines, are best made of tapered bars now in the market. Clogging at lower end of bars by gradual accumulation

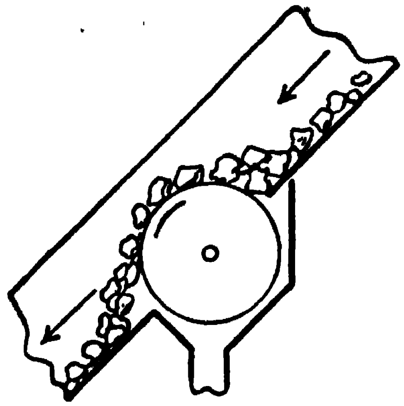

Fig 53. Roll Feeder

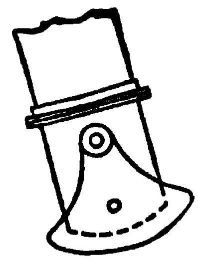

Fig 54. Single Undercut Gate

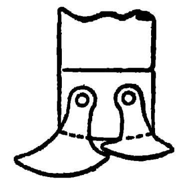

Fig 55. Hunt Undercut Gate

of spalls is avoided by curving the ends downward. C-I slotted spacing bars are preferred by many to through bars and washers, which offer more obstruction. Chutes and hoppers, subject to heavy falls of ore or rock, last well if lined with old rails instead of plate.

SECTION 28

BREAKING, CRUSHING, AND SORTING OF ORES

BY

ARTHUR F. TAGGART

PROFESSOR OF MINERAL DRESSING, SCHOOL OF MINES, COLUMBIA UNIVERSITY

Note.—Numbers in parentheses in text refer to Bibliography at end of this section.

BREAKING, CRUSHING, AND SORTING OF ORES

Ore is crushed at the mine to aid subsequent transport to the mill, or because a certain amount of fall is available, or to facilitate hand sorting. For some one of a variety of reasons, it may be desirable to perform these preliminary operations at the mine rather than at the treatment plant.

The usual crushing plant, whether located at mine or mill, is designed to produce feed to the grinding mills. As such it comprises jaw and gyratory crushers, classed as BREAKERS; and reduction gyratories, cone crushers, and rolls, called INTERMEDIATE CRUSHERS. Steam stamps are used only in the Lake Superior native-copper plants, as intermediate crushers; gravity stamps are found in many gold mills. It is unlikely that steam stamps will ever be generally used, and the gravity stamp is approaching obsolescence.

Size reduction, except in the smallest plants, involves two or more stages. Aver reduction in max size of lump in primary breakers is 4 : 1, in cones 5–6 : 1 and in rolls 4 : 1 in closed circuit and 2 : 1 in open circuit. Hence, to reduce 24-in run-of-mine ore to minus 1 in ball-mill feed, a primary breaker with 24-in effective gape followed by a cone with 6-in effective gape would serve; if minus 10-mesh (0.065 in) ball-mill feed were demanded, 3 or 4 stages would be necessary, for example, primary crusher to 6 in, standard cone to 1 in, short-head cone to 0.25 in, and rolls in closed-circuit with vibrating screens 0.25–0.065 in.

1. BREAKING BY HAND HAMMERS (24)

Hand sledges, 10-lb for soft rock and work at high altitudes, 12-lb for aver service, 16-lb for hard rock, are used to break ore through grizzlies in the mine and on ore-bins small enough to pass through chutes and gates; also to break large lumps so that they can be nipped by the primary breakers when these are too small for their service. CAPACITY figures are unreliable; but it is certain that sledging is almost always uneconomical, and that ore should either be broken smaller at the face, or that gates, chutes and primary crushers be made large enough to take the run-of-mine.

2. JAW CRUSHERS (24)

Jaw crushers. Best known type is the Blake, with movable jaw pivoted at top. The Dodge, with movable jaw pivoted at bottom, has relatively small capac. Single-toggle crushers with conventional plane jaw plates, or with either the swing-jaw plate or both jaw plates convex outward, are coming into use, principally as secondary crushers. Primary jaw crushers are usually of the Blake type. Table 1 gives essential data respecting Blake crushers (from makers' catalogs). For many sizes the figures have been checked against operating data, and found to be conservative.

Main frame, swing jaw and flywheels are of cast iron, semi-steel or cast steel; pitman, cast steel; toggles, cast steel with chilled ends, or alloy steels (life, 90 days to several yr); toggle seats, high-carbon steel or alloy steels (life, 90 days to several yr); shaft, high-carbon or alloy steel forgings, heat-treated, tempered, turned and polished; jaw plates, chilled iron or manganese steel (consumption of manganese steel 0.01–0.06 lb per ton crushed; of chilled iron, 0.1 lb per ton aver); cheek plates of same metal as jaw plates (consumption of manganese steel, about 0.01 lb per ton; of chilled iron, 2–3 times as much for same service). Modern trends are toward lighter crushers made of high-strength alloys. Too light a crusher will shake to pieces either itself or its foundation.

Reduction ratio in crushing is ratio between size of feed and of product; in coarse crushing max sizes should be considered. NIP ANGLE is the angle between jaw faces. Aver reduction ratio for jaw crushers of all sizes in Table 1, with minimum setting, is about 4.5, estimated on the basis of max feed size of about 85% of gape, and max product size 1.7–2 times open setting; for max setting, 2–2.5. Larger ratios are allowable in the smaller crushers, because the corresponding nip angle is smaller. Max nip angle for above ratios is less than 24°. In mills, the aver ratio for 20 crushers, ranging from 6 by 20-in to 66 by

84-in size, was about 3.7; max, 9; min, 1.5. Corresponding nip angles, 18–23° (max angle in largest crusher).

Capac of Blake-type crushers depends primarily upon character of ore, size of feed, and discharge opening; it is affected also by throw, speed and angularity of jaws, and shape and character of surface of jaw plates. Table 1 gives average capacities (from makers' catalogs) based on rock like limestone, easy to crush. But, capac figures are generally given in terms of a feed, none of which will pass through the crusher without breaking, whereas ordinary crusher feed contains much material that requires no breaking, but passes directly through.

Quartz, quartzose ores and firm brittle ores can usually be crushed at a rate equal to catalog figures. Tough ores, as basic silicates, traps and diorites, crush less readily. Hersam (1) shows that if the capac of a crusher on quartz is taken as 100, its capac on a granite such as he tested would be 89.5 and on trap, 83; mfrs usually drop these figures to 80–85 and 75 respectively. Minerals of low sp gr, as coal, fibrous minerals like asbestos, and clayey materials, can be crushed only at rates much below catalog figures. Choking by clayey materials may be lessened by a trickle of water run into the crusher with the feed; this lubricates the crushing faces, so that the compressed material slides forward as the jaw recedes, and thus works through the crusher. With slate, which cleaves easily and tends to pass through the crusher in slabs much larger in one or two dimensions than the jaw opening, the capacity may be much reduced, due to the measures necessary to prevent such discharge.

Table 1. Blake Crusher Data *(from Makers' Catalogs)*

Size of receiving opening, in	Approx capac, tons per hr to crushed sizes stated, in*										R p m	Hp	Weight, lb

* With straight jaws. With curved jaw-plates, convexed toward each other and approx parallel near the throat, speeds may be higher, with higher capac, but at expense of some reduction in size of largest particle that will be nipped.

Crusher capac increases progressively with decrease in reduction ratio, and with increase in speed to a certain limit, although not proportionately. Increase in nip angle decreases capac somewhat, but the effect is small for angles near those common in practice. With granite, Hersam (1) found that greater tonnage could be crushed with smooth than with medium or rough jaw faces, tonnage with medium faces being greater than with rough. Increase in jaw throw causes marked increase in capac, if same minimum opening be maintained. Curved jaw plates tend to permit crushed material to spread out in the fine-crushing zone, which decreases tendency to choke and increases capac.

Empirical formula for capac, relatively accurate for all except smallest and largest crushers, is $T = 0.6\,A + R = 0.6\,LS$; where T = ton per hr; A = area of receiving opening, sq in; R = reduction ratio; L = length of receiving opening, in, and S = width of discharge opening (SET), in. For small crushers the result will be high; for large crushers, low.

Power consumption per ton crushed is considerably greater in small crushers than in large. Tons per hp-hr ranges from 0.7 in smaller sizes to 1.0 in crushers with 30-in width of receiving opening (GAPE). For 36–60-in gape, tons per hp-hr increases to about 1.3–1.8. For 66-in gape, 2.5 tons per hp-hr is fairly conservative. These figures are all based on reduction ratio of 6 : 1 and on a continuously busy crusher. For smaller reduction, tons per hp-hr increase, roughly in inverse ratio. REDUCTION TONS PER HR = hourly tonnage × by max-particle reduction ratio. Reduction tons per hp-hr for crushers in Table 1 range from 2 for 7-in gape to 10 for 66-in gape. Practice shows variations of about 50% on both sides of these aver figures.

Fall through crusher itself is about twice the gape; to which must be added the drop necessary to get feed to the crusher and product away from it.

Lost time in mills, due to causes chargeable to the crushers, as repairs, renewals, clogging and its attendant difficulties, is less than 1%. Renewing jaw and cheek plates and re-babbitting bearings are chief causes of lost time. When crusher is planned to run only 1 or 2 shifts per day, as in a majority of mills, renewals and repairs are done in off shifts; in which case practically no delay is chargeable to the crushers.

Attendance. Usual practice is 1 man per crusher; rarely, 1 man to 2 crushers. Principal duty of attendant is to regulate feed and pick out powder, steel and waste. When crusher is fed by dumping car- or skip-loads directly into the jaws, no picking is possible, but attendant must see that the ore does not bridge, and break up such jams as occur.

Feeding. Jaw crushers should be fed regularly and up to capac, if possible. But they should not be " buried," since bridging at the mouth often occurs and necessitates digging out to start the flow of ore again. A power-actuated hook, or similar device, for removing lumps from crusher jaws is an economy. Ample provision should be made to prevent pieces of ore from dropping into the actuating mechanism.

Breaking points are provided in most coarse crushers, to take care of excessive loads caused by entrance of steel or other foreign material. In Blake crushers the usual breaking point is a toggle. Without this provision, the usual effect of stoppage under full working load with power on is to crush the pitman babbitt, or throw off the belt, or both. If the belt does not throw off, and there is no satisfactory overload circuit breaker on the driving motor, the motor will burn out.

Size of product. With straight jaw plates, product will all pass a square-mesh testing sieve having aperture equal to 1.7–2 times open setting; 65–85% will pass an aperture equal to open setting, the lower percentage for tough or slabby rock, the higher for relatively friable rock that breaks granularly; 25–40% will pass an aperture equal half the open setting, the lower perçentage with sized feed, the higher with run-of-mine rock. The size showing max wt is usually at or near the open setting. With curved plates and higher speeds, apply the above percentages to the mean of the open and closed settings.

Cost of jaw crushers (1938) was 10.5–12¢ per lb for small machines; 9–10¢ for large, when fitted with chilled-iron; add 10–20% if fitted with manganese steel. OPERATING COST is best estimated from data given on power consumption, attendance and wear; these items making about 90% of total cost. For rough estimates, 8–10¢ per ton for small crushers, to 2–3¢ for large, are outside figures.

3. GYRATORY CRUSHERS (24)

Gyratory crusher consists of a fixed crushing surface, in form of a frustum of an inverted cone, around the axis of which gyrates a movable crushing surface, having the shape of a conical frustum in erect position. The feed passes into the downwardly converging annular space between the crushing surfaces, and is crushed when the surfaces approach; falling through when they recede. There are 3 types: suspended-spindle, supported-spindle, and fixed-spindle type. The first is most used; the second is fast disappearing. The third is the newest form, and has been satisfactorily installed as a primary or secondary

coarse crusher in many plants. Its relatively small height lends itself to rugged construction and the short spindle reduces the clear height above the crusher required for convenience in repair work. The fact that the length of stroke is the same for both large and small pieces of ore is advantageous for crushing soft, tough ore, but this is unnecessary and may be disadvantageous for hard and brittle materials.

Sizes are indicated by the gape of receiving opening, in inches. Length of receiving opening is the circumference of the outer edge of receiving opening (between adjacent faces of the spider arms) × number of spider arms. This length is approx 8 times the gape in lever-type crushers in sizes below 18-in, and 7 times the gape in larger sizes.

Details. SHELL is of C I; high-test iron or cast steel; SPIDER, C I in small crushers and high-test iron or cast steel in large; SPINDLE, hammered open-hearth steel, heat-treated, turned and polished; SUSPENSION BEARING varies in detail, the principle being to bring the suspending surface as near the point of no-movement as possible; ECCENTRIC SLEEVE should be large and lubricated by forced feed; GEARS, cast high-carbon steel, or forged steel with cut teeth; COUNTERSHAFT BEARING, long and rigid; OUTBOARD BEARING, ball-and-socket; DRIVE PULLEY, of such size as to transmit 1 h p per in width, at 600-750 ft per min; CONCAVES and MANTLES are usually manganese steel (life 90 days-2 years). Modern practice inclines toward roller bearings and tex-rope drives.

Adjustments: (*a*) WIDTH OF DISCHARGE OPENING is changed by raising or lowering the breaking head. Range of this adjustment is limited, because the nip angle is markedly increased by wear of the breaking head. This increase in nip angle causes great decrease in discharge capac. If more than a small adjustment is required, it must be got by making the concaves and breaking head thicker and shorter. THROW, less than in jaw crushers, is adjustable only by changing eccentric sleeves. It should be greater in large crushers than in small; greater for relatively soft and tough ores than for hard and brittle ores. SPEED may be varied between wide limits. Increased speed does not cause the marked increase in vibration and shock that occurs in jaw crushers. Lowest speed compatible with required capac is most economical within certain operating limits. A tendency to clog when crushing sticky ores may often be overcome by increase in speed, thus increasing the sharpness with which the head recedes from the concaves.

Speed, throw, capac, reduction ratio, and power consumption are closely related. Reduction ratio increases when crusher is working near max capac. Crusher speed must be increased to keep up capac; this being accompanied by considerable increase in power consumption. If the crusher is sufficiently over-motored, so that the change brings no perceptible strain on the driving equipment, it is well to watch for heating of the eccentric, as any marked increase in speed and capacity over the figures recommended by the makers is likely to cause burned-out bearings. Increase in reduction ratio, without mechanical troubles, should be accompanied, with straight liners, by decrease in speed and decrease in amount of material in the crushing zone. With curved liners, ratio may

a Crusher size is designated by gape. *b* Top of hopper to lip of discharge chute. *c* Usual gear ratio is approx 1 : 2.5. *d* Run of mine rock. *e* Convexly-curved concaves and a concavely-curved mantle can be fitted to any of the crushers listed, and have (1938) been used on sizes to 42-in gape, with capac increases from 25% to 60%, according to makers' claims.

be increased without decrease of speed; in fact, speed and capac may both be increased somewhat without corresponding increase in power consumption, due to non-choking characteristics of curved liners.

Reduction ratio, based on max sizes of feed and product, ranges, according to makers' ratings from a minimum of 1.5 to max of about 4; general aver, 2.5–3. A greater ratio is recommended for large crushers than for small. These are just about the range and aver for reported practice.

Angle of nip in gyratory crushers is 21°–23°; aver very near 22°.

Capacity depends primarily upon character of ore, size of feed, and discharge setting. Throw, speed, angularity of jaws, and shape and character of crushing surfaces have material effect. Table 2 gives capacities for different sizes, according to makers' catalogs. See Art 2 for discussion of applicability of these figures to different ores.

The discussion (Art 2) of effect of various factors upon capac of jaw crushers holds also for gyratories. No simple formula expresses results of gyratory crushing, as does that given for jaw crushing. Capacities in makers' tables are often far exceeded in mills, although the excess capac usually results from feeding material much smaller than the max that the crusher will take, with consequent freedom from bridging and clogging, or from the use of curved liners, or both.

Power consumption. Reduction tons per hp-hr range from 1 for smallest machine to 28 for a 42-in machine, according to makers' ratings; reported field performances tend to run 10–20% below these figures.

Fall through crusher proper is about 10 times the gape, up to 12-in gape; for larger crushers, the fall decreases with increase in gape from 8 to 6.

Lost time in mills, due to causes chargeable to the crushers, as repairs and renewals, clogging and its attendant delays, averages less than 1%. Renewal of mantles, concaves, and chute liners, and re-babbitting the eccentric bearing are the chief causes stated. Most of the crushers reported were planned to work 1 or 2 shifts per 24 hr, thus leaving 1 shift free for minor repairs. With good planning and ample supply of repair parts, such operation practically eliminates lost time.

Attendance. Usual practice, 1 man per crusher to 2 or 3 crushers per man. Where the gyratory is the primary crusher, there should be 1 man for each to remove waste; where it is secondary, little or no attendance, apart from oiling and watching for trouble, is necessary.

Feeding should be regular, and as nearly as possible up to capac. If feed contains pieces near the largest the crusher will receive, it is wise not to bury the crusher, as bridging easily occurs and may require laborious digging out. But bridging is much less likely to occur in gyratories than in jaw crushers, and many gyratories are fed so as to be buried. At most plants crushers are fed by chutes or over stationary grizzlies; belt or pan conveyers, drum feeders and shaking grizzlies are also used. Pan conveyers are probably best for feeding initial crushers. Chain feeders are useful to prevent "bounding" with bouldery feed from bins. Chute-fed crushers mostly occupy a secondary position in the mills, taking feed from primary crushers.

Breaking points are usually omitted in modern gyratories. Large gyratories will pass almost any piece of steel that enters, without stalling or breakage; small ones will generally slip a belt before breaking, and, if motor is properly safeguarded against overload, this is fairly satisfactory. For direct-connected crushers, overload circuit-breakers are probably best for providing against damage.

Size of product. For primary crushers with straight liners, all the product will pass a square-mesh testing sieve of aperture equal 1.7–2.2 times the open setting; 70–90% will pass an aperture equal the open setting; and 30–50% will pass an aperture equal half the open setting; the higher percentage in both cases corresponding to relatively friable run-of-mine rocks that break granularly. The size showing max wt is at or slightly above the open setting. For curved liners in primary service, substitute the mean of open and closed settings for the open setting in the above text.

Cost of gyratories in 1938 was 8.5¢ per lb for a 42-in machine; 10.5¢ for a 16-in, and 16¢ for an 8-in. These prices are for crushers chilled-iron fitted; add 10–20% for manganese-steel fitting. Over 90% of OPERATING COST is for power, labor, and wearing parts. If crushers are run to capac, cost should range below 6–8¢ per ton for small crushers and 1.5–2.5¢ for large.

4. COMPARISON OF JAW AND GYRATORY CRUSHERS

Table 3 compares crushers of the two types of one maker. It shows that, when worked to capac, the price of a gyratory is 27–77% that of a jaw crusher capable of same reduction in particle size; also, that in same circumstances, the gyratory will crush

J = Blake-type jaw crusher. G = Suspended-spindle gyratory. * Compare sixth line above, where price per hourly ton is computed on G capac.
(a) Prices are as of 1925. Add about 1¢ per lb for 1938. Comparative price relationships in remainder of table are substantially unchanged.

1.7–4.3 times as much as the jaw crusher per installed h p. But, when the quantity of rock to be crushed per hr is within capac of 1 jaw crusher of proper gape, price of a gyratory for same work is 1.3–2.5 times that of a jaw crusher. Power for a jaw crusher when idling is about 50% of that at full load, and full-load consumption is about 50% of installed h p; corresponding percentages for the gyratory are 30 and 60%. Applying these figures to Table 3, it appears that for machines crushing to 4 in or less, power consumption per ton is less in the jaw crusher. In coarser crushing to 5–12 in, power per ton crushed is less for gyratory than for jaw crusher. Repairs, cost of installation, and loss of head are all greater for gyratory than jaw crushers for all sizes. Hence, it may be concluded that, for quantities that can be handled by 1 jaw crusher, the jaw crusher is the more economical on all counts; also that, for coarse crushing, the gyratory consumes less power per ton, but costs more to buy, install and keep in repair, and for elevating the material. The gyratory is advantageous in allowing expansion in capac, it can be set higher than a jaw crusher, due to absence of vibration, and can be fed from all sides. But, if the rock is clayey or fibrous or does not break freely, it is more likely to clog. The shape of the gyratory's crushing zone prevents discharge of large unbroken slabs, such as can pass through a jaw crusher; hence gyratory product is more uniform than that of a jaw crusher.

Following empirical relation, based on analysis of good practice, indicates roughly the proper crusher to use, considering tonnage and size only: if hourly tonnage to be crushed, divided by the square of the gape in inches, yields a quotient less than 0.115, use a jaw crusher; otherwise, a gyratory.

5. GRIZZLIES (24)

Grizzly bars are best of taper section, to prevent choking; sometimes of special cross-sec, such that when worn out there will be minimum waste. Bars are threaded on rods and distanced by thimbles. Their slope must exceed the angle of friction (usually greater than 32°); when less than 40°, the ore must sometimes be helped forward by hand. They are generally used for separating fines from breaker feed. Grizzly dimensions are determined more by mode of feeding and using, than by tonnage treated; capac should greatly exceed demands. An aver figure for capac is 125 ton per sq ft per 24 hr per inch of aperture, with proportionately greater (or less) capac with greater (or less) bar spacing.

Heavy, coarse woven-wire screen or punched plate is often used instead of bars; especially for flat, shaking grizzlies. Roller grizzlies, consisting of a number of spaced circular disks on a horiz revolving shaft, or rings on a cylindrical cage; and traveling grizzlies, composed of parallel bars, spaced between corresponding links of parallel chains, making a continuous apron running over head and tail sprockets, are also used as combined feeders and screens ahead of coarse crushers.

6. REDUCTION GYRATORY. CONE CRUSHER

Reduction gyratory, a new type, for intermediate crushing, is made both in the suspended-spindle and the pillar-shaft (fixed spindle) types. The latter is similar to the pillar-shaft breaker, except that the flare of the breaking head is greater in the reduction gyratory, and the concaves flare downward, instead of converging, to maintain the required nip angle. Suspended-spindle machines are fitted with convexed bowl liners (concaves) having chords vertical or flared downwardly. Head has straight surface elements, or is concaved near bottom (bell-head). Speeds are higher than for primary machines. Combination of high speed, long discharge opening and substantially parallel-sided fine-crushing zone tends to eliminate choking and to size the discharge nearer to closed setting of crusher. Machines are rated according to the bottom diam of crushing head. Performance data, as estimated by mfrs, are given in Table 4. Structural materials correspond to those described for primary gyratories.

Size of product. Machines in typical fine-reduction service (fine bowls, closed settings of 0.5-in or less and small throws of 0.25–0.38-in), make products all of which will pass a square-mesh screen of 2–3 times the closed setting; 50–65% is finer than closed setting and 25–35% finer than half the closed setting. This construction has advantage of giving a large discharge area for a given set of the crusher, and consequently a larger capac. Usual sizes are 4-, 6- and 10-in gape. Capac of this new machine is not established; as given by one maker, it ranges from 24 ton per hr to 0.75 in, to 48 ton to 1.5 in, for a 6-in crusher, and from 80 ton per hr to 1.5 in to 135 ton to 2.5 in for a 10-in crusher.

Cone-type crusher is of the flaring-bowl gyratory-type of intermediate crusher. The crushing head, flat-conical or hemispherical in shape, is supported on a large bearing of special design (hemispherical, roller, etc) and is gyrated by a long, ball-supported eccentric, driven by bevel gearing. The stationary crushing surface (bowl) is attached to the main

frame by bolts acting against a nest of springs, which compress and allow the head to lift when an uncrushable body enters. Set may be adjusted while running, by loosening lock nuts and revolving the bowl. Sizes, capac and power consumption, as stated by one maker, are given in Table 4.

Reduction ratio, based on max sizes of feed and product, ranges, on some 20 field reports, from 3 to 18, with the aver between 5 and 6. High reduction ratios are possible only with coarse and medium bowls, annularly corrugated near mouth; short-head machines work at lower ratios in open circuit, but can be pushed to 8 or 10 by closed circuiting, in which case circulating loads may be upwards of 100% and new-feed capac will be somewhat reduced.

Angle of nip at mouth in short-head machines is about 10° or less, and decreases in fine-crushing zone; in the standard machine, the coarse bowl apparent angle in coarse-crushing zone is about 35°, but this is decreased to between 25 and 30 by annular corrugation of bowl.

Capacity is a function of area of discharge opening and of crushing surface. A relationship, reasonably safe for purposes of estimate for standard crushers taking primary crusher discharge with a max particle size 75–85% of crusher gape, is

$$C = 7 + \left(\frac{S - 0.05}{0.11}\right) d^2$$

in which C = ton per hr, S = set, in and d = rated size of crusher (diam of head at bottom in ft). With sized feeds, smaller reduction ratios (max feed particle about 50% of gape), and settings of 0.5 in and under (usual short-head practice) add 25–50% to formula capacities, the larger figure for the larger crushers. Nordberg Mfg Co call attention to the fact that cone-crusher capac on a given ore may vary 50%, according to moisture and clay content, and the like, and they therefore do not approve the use of a formula for their machine.

Power consumption. Reduction tons per hp-hr range from about 2.5 for 2-ft cones with fine bowls to 8 for 7-ft cones with coarse bowls, or roughly a little more than the cone-size rating in ft.

Size of product. In open-circuit crushing the product will all pass a square-mesh screen of aperture 1.8–2.2 times the closed setting of the crusher; 20–25%, on the aver, is coarser than the closed setting; range is 10–65, being greater, in general, with coarser settings; about 35–40% is finer than half the closed setting. These figures are based on sizing tests from some 20 random field performances. In closed-circuit work the limiting size may be substantially equal to the closed setting, with upwards of 60% of the product finer than half the closed setting.

(a) Short-head. Capacities given are for closed-circuit operation.

Feeding should be regular, and as nearly as possible up to capac at the speed at which the machine is operated. Reduction of speed, from catalog figures, will save some power in consistently underloaded crushers. Symons cone has a circular feed plate, mounted on a pedestal on top of crushing head, from which plate the material spills off evenly all around, if feed stream is brought to it vertically and near the center. Side-directed entry of feed stream overloads one side and underloads other; much oversize is discharged on underloaded side. If bridging does not occur, due to slabby oversize, cone-type crushers may be buried, but this practice involves much digging after emergency shut-downs.

Wear on head mantles and bowl liners is remarkably uniform; as a result manganese-steel fittings may sometimes be run down to 0.5 or 0.38 in before scrapping, the residue then comprising only 20–25% of the original wt. Reported lives of Mn-steel fittings range from 50 000 to 850 000 ton; steel consumption, 0.005–0.05 lb per ton crushed, aver near 0.02 lb per ton.

Attendance. Special attendance, such as is required for primary crushers, is not needed. In general, one attendent can take care of the secondary-crushing section of a plant of any size, except where screens require constant attention due to moisture, or to an excess of wood chips or other fibrous waste.

7. ROLLS (24)

Rolls are of two general types, rigid and spring. RIGID ROLLS, the older, are now rarely used. Their bearings are rigidly fixed on the frame, so that the rolls must stall, or their shafts bend or break when an uncrushable particle enters.

Spring rolls. Table 5, generalized from catalogs of the principal makers, gives sizes, weights, speed and power consumption of standard rolls. Weight of a given size of roll, as offered by different makers, varies widely. The lighter rolls should be chosen only for small tonnage, or very easy crushing, or where first cost is paramount. Heavy rolls for heavy service repay the greater first cost in a short time, in lower repair costs and continuity of operation.

Shells are of high-carbon steel, rolled like locomotive tires; of forged chrome-steel, rolled or bored to size and taper; or of manganese-steel, ground to proper shape. For light service, rolled high-carbon shells are excellent; it is claimed that, because the surfaces are not extremely hard, their nip is more assured than with harder shells; also, cracking less readily, they can be worn very thin before replacing.

Life of shells is in general 20 000–50 000 tons crushed for small (less than 36-in) fine-crushing rolls, of chrome or high-carbon steel, and 300 000–1 000 000 tons for large rolls in coarse crushing, tonnage in both cases including circulating loads. Manganese and high-carbon steel are best for coarse crushing. Thickness of new shells is 2.5–4 in for rolls to 36-in diam, and 3.5–6 in for larger; thickness when discarded is generally 0.5–1.5 in. Shells are rarely worn as thin as $^3/_8$ in, which can be done only in fine crushing and with very tough steel. Consumption of shells, including waste, is 0.01–0.1 lb per ton.

In a mill where rolls crush to different sizes, partly worn shells from fine rolls may be transferred to coarse rolls, if of the same size, since the loss of effic in coarse rolls, due to slight pitting, is much less than in fine. Flanging and pitting of shells are prevented or materially lessened by proper attention to lateral adjustment. Emery bricks held constantly against the back of the rolls diminish corrugation. At Van Roi mill (3), use of emery bricks tripled life of fine-roll shells. In S E Missouri, flanged shells are taken off and ground or turned down in a lathe, according to whether they are manganese or rolled steel. A 54- by 20-in shell can be turned down in 20–30 hr, dependent upon extent of corrugation (4).

Adjustments possible in well designed rolls are: (*a*) distance between roll faces (set); (*b*) lateral adjustment of one or both roll shafts. ROLL SETTING is done by pinning the nuts at one end of tension rods, and so arranging the nuts at other end that they are both moved equally and dependently by the adjusting mechanism. This mechanism also provides for backing the movable roll away from the fixed roll, to free them in case of clogging. LATERAL ADJUSTMENT. To prevent FLANGING, the range of this adjustment must be such that either edge of both rolls can be made to run, a part of the time, on the face of the other roll. To prevent CORRUGATION, rolls should be shifted about 0.6 the diam of largest particles in feed. Lateral adjustment is manual or automatic. Objection to manual adjustment is that it may be forgotten or purposely neglected by roll operator; a short period of neglect may ruin the surface of the shells. The objection to automatic adjustment is the difficulty of making a simple, durable and certain shifting mechanism.

Angle of nip is angle formed by tangents to roll faces, at their points of contact with particles to be crushed; it rarely exceeds 25°. The range in a number of mills was 5° 36′

to 35° 30′; averaging 23° 21′ for feeds coarser than 2 in.; 19° 26′ for feeds of 1–2 in, 14° 38′ for feeds of 0.5–1 in and 11° 25′ for smaller than 0.5 in. The variation is due to use of large rolls with small feeds for getting capacity, and the angles with coarse feeds may be taken as a safe aver.

(*a*) Catalogs of 5 principal makers are summarized. This column gives the number of these makers who manufacture a given size. (*b*) lightest and heaviest of the size listed. (*c*) Not usually by same maker. Low speeds usually correspond to light-weight rolls. (*d*) The lower figure responds to light rolls at low speed and *vice versa.* (*e*) Two motors.

Angle of nip varies with diam of rolls, diam of particle and set of rolls. For large particles, large diam rolls must be used, or the reduction ratio must be small. When feed of given size is not being nipped, it is usual to install larger rolls or increase distance between them, and consequently the size of product. An expedient at one plant is to cut a transverse groove in one shell; which, of course, increases the nip angle at that point. At American Graphite Co, smooth shells would not nip; overcome by drilling 8 sets of four 1.5-in holes at equal angular distances around the faces (5). Shells with transverse corrugations are sometimes used for coarse crushing, but the practice is not well established.

Diam of rolls (Table 6). Largest commercial roll is 78 in diam; sis naller than 24-in are rare except in laboratories.

Speed should be lower for hard, tough rock than for soft and brittle rock, less for dry than for wet feed, less for coarse feed than for fine, and less for a large reduction ratio than for a small, nip being the controlling factor in each case.

Table 6. Diameter of Rolls for Different Sizes of Feed

0.25	9	8	8	7	5
0.12	4	4	4	3	2

(a) Allowing 25° nip angle.

Reported speeds are from 382 ft per min for 24-in rolls, to 2 060 ft for 72-in. More or less independently of the other factors, practice tends to keep below 900 ft per min for rolls to 36 in diam, below 1 000 ft for 42-in, and not above 1 500 ft for 56- and 72-in; higher speeds are dangerous to springs, shafts, frames and foundations. At Miami Copper mine, 55-in rolls taking −3.5-in feed run 100 rpm; same size with −2-in feed, at 115 rpm.

Capacity of rolls is, theoretically, the wt of a ribbon of ore, the length of which is the peripheral travel per unit of time; breadth, the width of face; thickness, the set, or distance between roll faces. With open setting, actual capac never reaches the wt of "theoretical ribbon;" which is more nearly approached the smaller the set.

For rolls set coarser than 1 in, about 5% of theoretical ribbon is to be expected; for sets between 0.25 and 1 in, aver performance is 15–20% of theoretical; for sets less than 0.25 in, aver is 20–30% of theoretical, with free feeding. With choke feeding, in closed circuit with a screen, from 100 to 250% of theoretical ribbon is to be expected, the set being assumed as the screen aperture × 0.3. Rolls may be in actual contact, or with a small space between faces; mean cross-sec of ribbon is, of course, greater than the set, since the rolls recede against the spring pressure at short, irregular intervals. Percentage of theoretical ribbon that can be crushed is about 50% greater for soft, easily crushed rock than for hard, tough rock.

Reduction ratio, based on max sizes, in open-circuit crushing averages about 2; when circuit is closed with screens, ratio may run as high as 12, but averages near 4. Circulating load with high ratios may run to 300–400%, against 50–100% with aver ratio; in general, large circulating loads mean choke crushing.

Power consumption, based on amount of new feed per h p-hr, depends upon kind of rock, size reduction, size of product, and the circulating load, if any. Averages: 0.4 ton per h p-hr to less than 0.25-in size; 0.6 ton per h p-hr to sizes between 0.25 and 0.75 in; 0.75 ton per h p-hr to sizes between 0.75 and 1 in; 1.6 ton per h p-hr, for sizes between 1 and 1.5 in, and 2.8 ton between 1.5 and 2 in. Reduction tons per h p-hr aver 1 in open-circuit and 2 in closed-circuit crushing, ranging from 0.3 for 24-in rolls to 3.5 for 78-in in open-circuit, and from 0.3 to about 5 in closed-circuit work for same size range (30 mills reporting).

Feeding. For max capac and effic, rolls must be fed at a constant rate and with stream distributed over full width of face. In FREE-FEED there is freedom of movement between particles resting in the V of the rolls prior to nipping; in CHOKE-FEED, the particles in the V are piled up to such depth that no free movement exists. In free feeding each particle is broken substantially individually, and crushing is almost continuous; in choke feeding masses of material pass through intermittently, the roll faces springing apart to permit their passage; there is much abrasion between particles, resulting in less granular product than with free feeding. Except for the largest rolls, choke feeding is practicable only with material already crushed to 0.25-in or less. Rolls are ordinarily run dry.

The lower limit of size for effic crushing is not clearly established. If a product passing 10-mesh is all that is desired, it is economical to complete the crushing in rolls. For a finer product, ball- or rod-mills are more economical. Preponderant practice (1938) is to feed ball mills with material of max size, ranging from 0.25-in to 10-mesh, and to use rolls in closed circuit with vibrating screens to produce this material. Much test work is being done with short-head cones to displace rolls in this service, because of the larger reduction ratio possible, and results of some tests are promising. At Nevada Consol (6) rod mills taking minus 0.75-in feed are reported to show an advantage of 2.5¢ per ton over rolls for making minus 10-mesh feed for ball mills. Rolls can crush to 20-mesh or

finer, but to do so must be set close and choke-fed. This is very uneconomical, due both to wear and tear and to power consumption.

Graded crushing reduces particle size by a series of crushers, each with a smaller discharge aperture than the preceding, and material fine enough to pass the next crusher is removed between the crushing steps. This minimizes production of slimes. Size reduction in the successive steps is usually small; of the order of 2 or 3, based on aver size. The alternative extreme is to break down with as big steps in reduction ratio as size and strength of the crushers permit; with no removal of fines between the crushers, except that the last one is in closed circuit with a limiting screen.

Before the application of flotation processes to base-metal milling, when minimum sliming was essential to max recovery, graded crushing was assumed necessary, apparently with little experimental evidence. But, an exhaustive investigation by N J Zinc Co, in crushing by rolls a sphalerite ore with granitic gangue from 1 in to 0.1 in max size, showed that the amount of −0.025 in size produced was the same, within a range of about 2% of the weight crushed, irrespective of number of steps or presence or absence of intermediate screening. Tests in Columbia School of Mines laboratory have shown that the sizing test of product of rolls with a given set is practically the same with a given ore, irrespective of size of feed; provided only that the rolls are free crushing, that they nip the particles, and that the feed contains no undersize. The significance of the last restriction lies in the fact that, if different feeds contain different amount of undersize, these will affect the screen tests of products, even though they pass through the rolls without breaking. These facts seem to establish definitely that, in free crushing in rolls, there is no advantage in graded crushing and intermediate screening.

Character of roll product. Two cases arise: (*A*) rolls are set with a definite distance between faces; (*B*) faces are set close. In case (*A*) the feed is generally more than 75% coarser than the set (aver of 19 random cases, 83%); in the cases investigated, the product ranged from 4% coarser than the set to 78% coarser (aver 45%) which gives 45% aver reduction in percentage of material coarser than the set. In the same operations, the percentage of material finer than half the roll setting averaged 30, and ranged from 2 to 66% when there was an aver of less than 5% of such material in the feed. In case (*B*) the aver reduction in max particle is close to one-half, this aver applying as well where max feed size is 20 mm as for 1.5 mm. Aver percentage of material in the product smaller than half the max particle is about 60; range, 30–80; smaller than half the set, aver 20% in open-circuit crushing and 30% in closed-circuit. In the cases investigated this aver represented an increase in such material over that present in the feed of about 2.5 times. Applying these generalizations to specific problems: (*a*) For a feed containing 75% of +1-in material to be crushed in rolls set 1 in, the aver product would contain 41% +1-in and 30% −0.5 in. (*b*) For a feed containing 5% of +20-mm, to be crushed in rolls set close, the aver product would contain about 5% of +10-mm and about 60% of −5 mm size.

Applicability. Rolls are the most widely used intermediate crushers for feeds smaller than 1.5 in, and delivering products down to 0.1 in. In such service they have large capac, low power consumption and relatively low repair costs. They are rugged, reliable, simple in construction and easy to repair.

Cost of roll crushing. The elements are power, labor, repairs and lubrication. For power consumption see Table 5. One man can attend to 3–12 sets of rolls; aver in 20 plants was 6, where roll tender had no other duties. Repairs may be estimated at about twice the cost of shells. Consumption of lubricant is 2–30 lb per 24 hr. On these bases, cost of crushing to −0.25-in should not exceed 7¢ per ton in small rolls (36-in or smaller), nor 4.5¢ in large. Coarse crushing costs considerably less, due to smaller power consumption and labor cost.

8. GRAVITY STAMPS (24)

Gravity stamps are now used only in mills in which they are already installed and their discard and replacement are not economically justified on the basis of expected life of the mine, or in very small gold mills where plant capac is insufficient to justify installation of a 4-ft diam ball mill. In large mills, stamps are now run as an intermediate crusher, with open front or 0.75 to 1-in screen; in small mills, as intermediate and final crusher, with fine screen and primary-crusher product as feed.

Weight. Stamps are rated on the wt of the falling part: in American mills, 1 250–1 500 lb; in South Africa, 1 500–2 000 lb are more usual; old California practice, 850–1 050 lb, many of which are still found.

Life of parts. Dies and shoes are of chilled C I, semi-steel, forged steel, chrome steel and manganese steel. Consumption of C-I dies ranges from 0.15 to 0.30 lb per ton crushed; for

chrome-steel dies, 0.10–0.20. Corresponding consumption of shoes is 2 to 3 times as great. STEMS are of hammered iron or mild steel, turned and polished, and tapered both ends to make them reversible when broken. Amount of breakage depends upon length, position and condition of guides, and wt of tappet. Broken ends may be turned down and the stem again used, if not too short. Annealing before turning down defers subsequent breakage. SCREENS are subject to considerable wear; their life depends upon hardness of ore, acidity of water, the screen material, type of screen, and kind of perforation. Discharge through screen depends upon kind of perforation, and percentage and size of opening. Present practice, where large capac with coarse discharge is sought, is to use woven wire, which has a high percentage of opening. Brass, copper, bronze and steel wire are common. Steel wears best, but fails quickly in acid water. Screens for fine-crushing stamps are usually renewed before failure, due to increased size of aperture from wear; hence, for fine crushing, heavy plate and coarse wire are not very economical, especially because they reduce the area of opening, and therefore the capac; they are also more subject to clogging. Capac requirements dictate screens of moderate wt, even if more frequent replacement becomes necessary. Percentage of opening varies but little for medium-weight wire-cloth screens, irrespective of aperture. It is greater for fine cloth than for fine punched plate, but the latter is stronger. Life is extremely variable, ranging from 2 or 3 days to perhaps 2 weeks for fine screens, and 2 weeks to 2 months for coarse.

Height of drop is variable within small limits with a given cam, by changing position of tappet on the stem. Amount of variation is small if the tappet is to be picked up at the point on face of cam for which it was designed. Height of drop is usually 6 to 8 in; it increases as dies and shoes wear; it is kept as nearly constant as possible by changing position of tappet on the stem to compensate wear.

Drop sequence. Cams are spaced equally on cam shaft, with their arms 36° or 72° apart, depending upon whether the shaft carries 10 or 5 cams. Sequence of drop in any one mortar has marked effect on the work done. Rules governing sequence: (*a*) no two adjacent stamps should fall in succession; (*b*) when one stamp is falling its neighbor should be rising.

Common sequences aimed to satisfy these rules are: HOMESTAKE, 1, 3, 5, 2, 4, which, stated backward, is 1, 4, 2, 5, 3; CALIFORNIA, 1, 4, 2, 3, 5 = 1, 5, 2, 4, 3; and modifications of the latter, as 1, 5, 3, 4, 2 and 1, 5, 3, 2, 4. The Homestake sequence comes nearest to satisfying theoretical requirements, but many operators hold that the California distributes the pulp better on the dies, and its swash of pulp in the mortar best facilitates discharge through the screen. When a 10-stamp battery is used, the sequence 1, 3, 5, 2, 4 becomes 1, 7, 3, 9, 5, 2, 8, 4, 10, 6 and 1, 5, 2, 4, 3 becomes 1, 6, 5, 10, 2, 7, 4, 9, 3, 8.

Height of discharge is the vert distance from top of die to top of lower rail of screen frame. It increases as the dies wear. To keep it nearly constant, as should be done, CHUCK BLOCKS of different heights are used, which vary height from die to bottom of screen opening; for closer regulation, SLATS 1–1.5 in thick are placed between bottom of screen and top of chuck block. Height of discharge may also be varied by a false bottom under the dies, but this has an unfavorable effect on character of impact of the blow. High discharge tends to produce slime. If this is undesirable, a fine product can be made by lowering the discharge, and using a finer screen.

Duty is tonnage crushed per stamp per 24 hr. Representative figures: 1.8 ton for 750-lb stamp and 0.022-in screen; 21.1 ton for 1 550-lb stamp and 0.2–0.28-in screen; 30 ton for 2 000-lb stamp and 3/8-in screen.

Conditions affecting duty: character of ore, size of feed and product, wt of stamps, drops per min, height of drop, drop sequence, shape of mortar, mortar foundations, and condition of shoes and dies. Increase in capac with increase of FALLING WEIGHT is substantially uniform. Tests on a 1 050-lb stamp indicate max duty with FEED SIZE between 1 and 1.5 in; but, while this is true in general, the max point is not definitely fixed. Several plants using coarse battery screens and finishing in tube-mills report an increase in tonnage per h p-hr due to placing a by-pass screen ahead of the battery, with the same aperture as the battery screen. Clark (11) says a 900-lb stamp can handle 3-in feed, and that no gain follows decreasing size below 2 in.

Speed. Aver is close to 100 6 to 8-in drops per min with heavy stamps and somewhat longer drop with light stamps.

Power required varies with wt of stamp, height of drop, and number of drops per min. Theoretical power per stamp may be calculated by formula: $Hp = W H N \div (12 \times 33\,000)$; where W = wt of stamp, lb; H = height of drop, in; N = number of drops per stamp per min. Total theoretical power for a battery is the above figure × number of stamps. Actual power exceeds the theoretical by 16–70%. An allowance of 25–30% excess is safe for estimating. Aver tonnage per hp-hr is 0.074, with screen aperture finer than 0.05-in; 0.138 for apertures from 0.05 to 0.25; 0.25; 0.164 for apertures coarser than 0.25-in. Truscott states (12) that So African stamp-milling averages 0.05 ton per hp-hr,

from −2-in through 30- to 40-mesh screen, 0.1 ton through 12- or 16-mesh, and 0.2 ton, through 3- or 4-mesh.

Water. Current practice is confined to wet crushing. Reports from 6 mills show moisture in pulp discharged through the screen to range from 75–94%. Aver Rand practice is about 85%; range 50–90%. Quantity of water per ton is less with coarse screens than with fine, and decreases with height of discharge.

Feeding is always automatic, to secure proper regulation. Irregular feed decreases capac, and increases breakage of stems and cam-shafts. Challenge feeder is the commonest and most satisfactory, especially on wet and sticky ores.

Lost time is due to breakage of stems, shoes, cams and cam shafts; dropping of boss heads or shoes; slipping of tappets, pulleys, or cam-shaft collars; renewal of shoes, dies and screens; adjustments of height of discharge and of drop; and dressing or cleaning up amalgamating plates. The latter cause is not directly chargeable to crushing. The other losses range from 1 to 11%.

Cost of crushing by gravity stamps is from about 15 to 50¢ per ton, depending upon size of product discharged.

Fine crushing is done almost exclusively in ball-, tube- and rod-mills (see Taggart, Handbook of Mineral Dressing; also, Sec 33).

9. HAND SORTING (24)

General. Sorting or HAND-PICKING is the manual removal of selected grades from broken ore. The picked material is usually high-grade or SHIPPING ORE, or WASTE, or both. Due to its coarseness, sorted ore may be worth more per ton than mill concentrate; and, being eliminated thus early, is not subject to danger of loss in mill treatment.

Advantages of sorting are increased output from a given mine and mill equipment, and reduced wear on milling plant. On the other hand is the question of allowable production. Even if the increased mill capac is not utilized, effic may be increased, due to the reduced load on the mill. Shipping ore and waste are often picked simultaneously, the residue being MILLING ORE. High-grade complex ores may be separated into several classes; as many as 16 have been made at Clausthal (14). Such close work requires breaking with hammers, besides actual sorting. Breaking with heavy long-handle hammers is called SLEDGING; further breaking with light long-handle hammers, SPALLING; final breaking with light short-handle chisel-peen hammers, COBBING. Due to high wages, these operations are rarely practiced in U S, except at prospects and very small mines, but they are common in many foreign countries.

When the ore-treatment process is chemical, sorting serves to remove deleterious substances, that consume chemicals, hinder settling and filtration, adsorb and carry valuable solutes into tailing, etc.

Apart from necessity for removing refuse from mill feed, and deleterious substances from feed to chemical processes, the decision as to advisability and extent of sorting is purely economic. The cheaper the labor, and the more ineffic and expensive the mechanical treatment, the farther can sorting be carried and *vice versa*. Undoubtedly sorting could be introduced advantageously at many plants, but it is equally true that it is sometimes practiced where economy demands its discard or curtailment. For investigation of economics, see Art 11.

Sorting of some kind is a part of every mining and ore-treatment operation. In narrow orebodies with distinct walls, much country rock unavoidably broken is sorted out underground and may be used for filling. In mines containing segregations of pure valuable mineral, as in some Lake Superior native-copper deposits, the valuable mineral is picked out underground and sent to the surface. But underground sorting is usually uneconomic, because of restricted working places, poor light, poor presentation of material and obscuring effect of the fines present. Some sorting to remove wood, rope ends, powder and tramp steel is done ahead of the primary crusher in practically all mills; but this work is incidental to crushing, not to hand sorting proper.

If valuable mineral occurs in coarse aggregates, or if considerable waste is mined with the ore, and ore and waste are readily distinguishable by eye, the economics of sorting should always be investigated.

10. SORTING SURFACES AND OPERATIONS

Sorting is done on floors, stationary tables and grizzlies, and various kinds of moving surfaces, as revolving tables, pan or belt conveyers (Sec 27), shaking feeders, shaking screens or grizzlies (Sec 34, 35). In modern U S practice and on the Rand, material fed

to sorting surfaces is prepared mechanically, with little or no breaking during sorting, but in European and some Latin-American mills much spalling and cobbing is done.

Sorting floors are used where labor is cheap, or spalling and cobbing are practiced. In its crudest form a "floor" is a level surface that can be thoroughly swept, on which ore is dumped and picked. Contract work is customary. Each contractor is assigned a certain space; delivery of ore and collection of products being made by the company. Sorting floors have reached their highest development at some of the Rand gold mines. DISADVANTAGES: all material must be moved manually, and sorters work in a stooping, tiring position. ADVANTAGE is thorough inspection, because every piece of material must be turned over and pickers are not unduly hurried.

Tables for sorting permit pickers to sit or stand comfortably. They remove whichever separable component of the feed is present in smallest bulk, and drop it below them into proper receptacles, finally scraping the residue through an opening in the table surface.

Fixed chutes and grizzlies for sorting are of the usual types, with the limitations that their slope must be near the sliding angle of the ore (15°–25°), and width must not exceed that which is readily inspected and worked (about 24–30 in when worked from one side and 48 in when worked from both sides). If slope is less than sliding angle, material is moved along with rake or hoe; if greater, flow is stopped as desired by a board, hoe or shovel inserted into stream. These devices are not used when much of the total material is to be separated, nor for close sorting. They are chiefly useful when rope, wood, powder and tramp steel are being removed from the primary crusher feed to obviate mill trouble. A grizzly expedites selection, because of removal of fines; but, if particles are tabular or wedge-shaped, grizzlies clog badly at the low speeds at which the material passes and it is therefore difficult to control movement of material.

Moving surfaces for sorting (see beginning of this Art) eliminate manual handling of reject material. But, as this reject is not turned over by or for the picker, material that should be removed is overlooked; also, all material passes at a uniform rate, irrespective of the components that should be removed, with the result that pickers are sometimes unduly hurried and sometimes underworked, if aver speed of travel is right. Nevertheless, much hand sorting is now done on moving surfaces because of the advantage of mechanical transport of the reject.

Belt conveyers (Sec 27, 35) are the commonest picking surfaces. Width, 24–30 in for one row of pickers; 48 in for double row.

Stations for pickers are 3–6 ft apart, with a chute at each for the reject. These CHUTES are placed beside the picker or on opposite side of belt; the latter being probably best for sizes to 3 or 4 in, that can be thrown by a flick of the wrist; but pieces needing two hands are best drawn toward the picker, and it may be less tiring to draw one-hand pieces larger than 4 in to the picker's side than to throw them away. Chute mouths should be large, so that accurate throwing is not necessary, and so shaped that pieces will not bound out. SPEED of belts is 10–80 ft per min; aver, between 30 and 40 ft. The smaller the pieces and the greater the amount of reject, the slower the speed and the longer the belt. Tuttle (15) states that in coal picking (Sec 34) belts are usually 4 ft wide and run at 30–60 ft per min. For picking oversize of 1.5-in screen at 30 ton feed per hr he recommends a length of 15 ft, plus 10 ft for each 3% of waste removed. On 0.75 to 1.5-in sizes he recommends 30 ft per min travel and, for a feed rate of 20 ton per hr, 15 ft of belt for every 1.5% of material removed. For more than 4–6% impurity, washing is preferable to picking. Belt should be only slightly troughed, to prevent heaping-up in the middle. A wide, flat belt, with feed carried not nearer than 6 in to the edges, is often used. Belts are suitable for any size of feed that can be handled by pickers, but they will not stand much sledging, and wear excessively with feed coarser than 6–8 in, especially when, as should be the case, fines have been screened out.

Pan conveyer, used for coarse material, resembles the belt. Speed is usually slower, for mechanical reasons and because larger lumps are handled. Pan conveyer stands sledging and wears less than belt with large lumps. Best form is a shallow trough, with stationary sides; it permits better removal of large lumps than when articulated sides form part of the moving mechanism. Slope of belt and pan conveyers should not exceed 20°; they may be extended to elevate and convey as well as to provide sorting surface.

Revolving table is an annular iron picking surface, 16–25 ft outside diam, usually inclined toward one edge, and supported on a frame that also carries a circular track resting on wheels. It is revolved by gearing, at 20–40 ft per min. Feed enters at one point. Pickers stand or sit around the outer and inner peripheries and throw sorted material into chutes or boxes. Reject is moved by a scraper into another chute.

These tables are common in So Africa and Europe. Some are supported by ribs from a central spindle, thus preventing picking stations on the inner periphery. Another design has 2 decks, the upper being about half the width of lower and 6 in higher, and receiving the selected material; thus both reject and selected material are presented to the inspector. ADVANTAGES of revolving tables: compactness, with consequent ease of supervision and collection of products. DISADVANTAGE, as compared to rectilinear conveyers, is loss of elevation suffered by reject in passing over the table.

Shaking surfaces are widely used in collieries, but, except as primary-crusher feeders, not to any extent in metal-treatment plants. They are essentially chutes with perforate or imperforate bottoms, set on a slope of about 10° in direction of flow and shaken at 100–250 2- to 6-in throws per min by an eccentric.

With the Ferraris mode of suspension, the surface may be horiz. For careful work, these are the least satisfactory type of moving picking surface, but when screen bottoms are used, they are justified in serving the triple purpose of screens, conveyers and sorting surfaces.

Washing of feed is essential to rapid and accurate sorting. It is usually done in the screens removing undersize, but may be done by hose or sprays on floors or moving surfaces. Sprays on a troughed inclined belt, just above the feed point, will wash fines down the incline and over the tail pulley, where they can be collected.

Table 7. Performances in Hand Sorting at Different Mills

(*a*) Native copper. (*b*) Smelting ore. (*c*) Waste, wood and steel. (*d*) Rich ore and waste. (*e*) Lump ore and waste. (*f*) Waste. (*g*) Refuse (wood, steel).

At Britannia M & S Co (16) the ore is cupriferous pyrite in schist, carrying about 2.7% Cu, 8% Fe, 1.5% Zn, 6% S, 70% SiO_2, 25¢ Ag and trace of gold. Sizes from 1.5 to 3.5-in are picked on a belt; 4 men per shift on 2 belts pick shipping ore (and hard country rock for tube-mill pebbles) from the oversize of 600 ton per 24 hr. Shipping ore, assaying 10–18% Cu, comprises about 10% of total product, which includes concentrate from jigs, tables and flotation. Handy states (17) that the labor in a typical Coeur d'Alene sorting plant, handling 800 ton per day of 1.5 to 4-in size, yielding 50 ton shipping ore and 150 ton waste, consists of 20 sorters, with 5 bosses and repair men. Normal cost is 16¢ per ton of run-of-mine, or 65¢ per ton sorted out. Louis (18) gives data on coal picking on belts in England. At 2.1–17.5% picked out, each worker handled 0.03–0.35 ton per hr, the highest tonnage corresponding to largest percentage removed, adherence to this rule being general, though not exact. Huntoon (19) gives the cost at Tonopah-Belmont, 1911, of sorting 15–20% of waste on belts as 68¢ per ton of waste, and at Tonopah Mining Co, 80¢ per ton removed, when this comprises 11% of the feed.

Amount removed by sorting varies according to ore treated. With native copper ores of Lake Superior, the amount at Copper Range is as small as 0.001%. At Federal Mining and Smelting Co lead mines and at Witherbee Sherman magnetite mines, 20% total high-grade ore and waste are removed. At Alaska Juneau (20), 7.73% of total mill feed was picked as milling ore assaying $5.06, and 34.64% (the remainder of 2-in trommel oversize) rejected as 7-cent waste. On the Rand (21), material from 8 in to 1.75 in constitutes 50–70% of total hoisted. Waste picked out forms 10–30% (aver about

16%) of total hoisted, being about 50% of total waste hoisted. In IDAHO mills, treating coarsely disseminated lead ores, shipping ore picked out ranges to 60% of total concentrate produced.

Labor for sorting is generally unfit for heavier work: boys, girls, women, or old or crippled men. Boys and girls are the quicker and, if properly supervised, do best work.

Size of material sorted usually ranges from 2.5 to 12 in.

Smelting ore as fine as 0.75 in is picked at Morenci plant of PHELPS DODGE Co, and as coarse as 24 in at Ogdensburg plant of N J ZINC Co. The number of movements required to make tonnage on small sizes is so great that the pickers' capac is low, and difficulty in handling and judging 24-in lumps is likely to retard work below the rate on intermediate sizes. Wiard states (22) that best size for sorting is between 1 and 3 in; Richards (23), that max rate is on 3 to 4-in lumps; but Table 7 shows that the max per man-hr corresponds to feed averaging 6-12 in. Comparison between FEDERAL M & S Co and WITHERBEE SHERMAN MINES is especially instructive, since at both mines 20% of the feed is picked as shipping ore and waste, and the number of pickers indicates sorting to be the sole responsibility of the workers. At Witherbee Sherman mine 5 ton per man-hr of 4 to 16-in material is picked, against 0.34 ton per man-hr of 1 to 6-in material at Federal M & S plant.

Lighting. Daylight is best; but, as picking must usually proceed on all shifts, artificial light is necessary. Since luster and color are the chief guides in sorting, light should be good and steady, and placed to keep shadows off the material picked. Diffused or flood lighting is preferred, but incandescent lights, directly over the feed and shaded from pickers' eyes, are sometimes used. Experiment is the guide. Ore moist from recent washing is probably in best condition for quick and ready selection.

11. ECONOMICS OF SORTING (24)

Following formulas are useful for determining monetary saving to be expected from sorting, roughing or other treatment, in which a finished product, either concentrate or tailing, is to be removed in advance of the place for its removal in the treatment scheme taken as standard.

Removal of concentrate. When the material to be eliminated is finished concentrate: let F and f = wt in tons and assay of original feed; P and p = wt in tons and assay of concentrate to be produced by proposed operation; M and m = wt in tons and assay of residue from proposed operation; T = tons of final mill tailing, without the new operation: T' = tons of final mill tailing to be produced from M tons of residue from new operation, C = tons of mill concentrate under normal operation; C' = tons of concentrate to be produced from M tons of residue from new operation; c and t = assays of C, C' and T, T'; V = value in dollars per unit of metal in concentrate to be produced by new operation; V' = value in dollars per unit of metal in mill concentrate produced by either operation; R = cost of new operation in dollars per ton of concentrate (P) produced thereby; S = cost in dollars per ton of milling H tons of original ore; S' = cost in dollars per ton of milling M tons of residue from new operation.

The assumption that assays of tailing and concentrate from original and sorted ore would be the same is justified by experience; which means that relatively small changes in tonnage or assay of mill feed have little effect on assays of mill products. Values assigned to V and V' should be net, and take full account of penalties, freight and smelting charges.

By the proposed operation, the net return from P tons of concentrate produced is its value, less cost of production $= PpV - PR$. Return from milling M tons of residue $= C'cV' - MS'$, and total return $= P(pV - R) + C'cV' - MS'$.

If this operation is omitted and the total feed undergoes same treatment that M is subjected to above, the return $= CcV' - HS$. Saving in dollars (or loss, if sign is negative) to be expected from adopting the proposed operation $= [P(pV - R) + C'cV' - MS'] - (CcV' - HS)$.

$$\text{Saving per ton on original feed} = \frac{P}{H}(pV - R) - cV'\left(\frac{C}{H} - \frac{C'}{H}\right) - \frac{M}{H}S' + S \qquad (1)$$

But
$$P \div H = (h - m) \div (p - m); \quad C \div H = (h - t) \div (c - t);$$
$$M \div H = (p - h) \div (p - m); \quad C' = M(m - t) \div (c - t).$$

Then: $\dfrac{C'}{H} = \dfrac{M}{H}\left(\dfrac{m - t}{c - t}\right) = \left(\dfrac{p - h}{p - m}\right)\left(\dfrac{m - t}{c - t}\right)$; whence, by substitution of above values in equation (1), the saving per ton of original ore to be expected from the proposed process

$$= \frac{(h - m)(pV - R) - (p - h)S'}{p - m} - cV'\left[\frac{h - t}{c - t} - \frac{(p - h)(m - t)}{(p - m)(c - t)}\right] + S \qquad (2)$$

Removal of waste. If, instead of concentrate, W tons of waste assaying w are discarded, at cost of R dollars per ton; then, when the new operation is employed, the loss due to discarding waste is $= WwV' + WR$, and the return from milling the remainder $= C'cV - MS$. Net return $= C'cV' - MS - W(wV' + R)$. If the proposed operation is omitted, the net return $= CcV' - HS$; whence, saving (loss, if of negative sign) to be expected from installing the new operation $= C''cV' - MS' - W(wV' + R) - CcV' + HS$.

$$\text{Saving per ton of original ore} = S - cV'\left(\frac{C}{H} - \frac{C'}{H}\right) - \frac{M}{\mathrm{H}}S' - \frac{W}{\mathrm{H}}(wV' + R) \quad (3)$$

Substituting assay values, as above, the saving per ton of original ore

$$= S - cV'\left[\frac{h-t}{c-t} - \frac{(m-t)\,(h-w)}{(c-t)\,(m-w)}\right] - \frac{(h-w)\,S' + (m-h)\,(wV' + R)}{m-w} \quad (4)$$

SECTION 29

ORE SAMPLING

BY

THE LATE T. R. WOODBRIDGE

FORMERLY CONSULTING METALLURGICAL CHEMIST, U S BUREAU OF MINES

Note.—Numbers in parentheses in text refer to Bibliography at end of this section.

ORE SAMPLING

Definition. The correct sampling of a lot of ore is the process of obtaining from it a smaller quantity which contains unchanged percentages of all the constituents of that lot. The commercial object is accomplished when the ultimate sample meets these conditions within an allowable limit of error, has been obtained at a reasonable speed and cost, and is of the bulk, dryness and fineness required for the chemical or other determination of one or more of its constituents. This commercial sample needs not be exact. As there are limits to the accuracy of weighing and determining the constituents it is necessary only that the error in sampling be smaller than the error in assaying.

1. CONDITIONS CONTROLLING ORE-SAMPLING PRACTICE

Segregation of minerals. Constituents of an ore are rarely distributed uniformly, but are more or less segregated. This is especially true of gold and silver ores. At the mine most sulphides and other useful metals break finer than the gangue, and every subsequent handling (in transport, crushing or screening) increases segregation of the finer and richer particles. The ore to be sampled is therefore an imperfect mixture of fine and coarse particles, from 200 mesh or finer to pieces of several inches diam. A perfectly uniform mixture of different-sized particles is impossible, and re-shoveling or re-coning merely decreases the degree of segregation; while most hand-sampling methods, and the inclined chute, barrel-mixer and knee-joint chute, increase segregation. Accuracy of a sampling process depends upon whether it takes from a lot of ore the same proportion of all its different-sized particles. Any process that selects the finer or the coarser particles is incorrect. The success of the older sampling systems depends not so much upon intimate mixing as upon the uniformity of distribution of different-sized particles around the axis of a truncated cone. Later systems use mechanical means for taking frequent small samples from a stream of ore; this is called FRACTIONAL-SAMPLING, since the final sample is composed of many partially mixed portions, any one of which can not seriously affect the value of the sample, but which in aggregate approach the true average and are within the assaying error. (Sec 25, Art 4–10 and Sec 30, Art 3.)

Table 1. Smallest Permissible Wt of Sample for Different Crushing Sizes of Gold Ores

Size, diam, in	Lb
2	10 000
1 1/2	5 000
1	2 000
3/4	1 000
1/2	400
3/8	300
1/4	200
3/16	100
1/8	75
6 mesh	50
10 "	25
18 "	10
30 "	4
50 "	1

Degree of crushing is sufficient when the size of the largest particle does not exceed that permissible for the weight of sample obtained. Insufficient crushing, especially in the later steps of the process, probably causes most of the persistent unintentional errors in sampling. Table 1 shows relative sizes and weights adopted in the best sampling plants. For its mathematical derivation see Bib (2).

Psychology of sampling relates to the personal equation of the sampler, who, to protect his employer, may overlook possible slight causes of salting (Sec 30, Art 9), permits advantage to be taken of segregation, or jockies with assays. It is responsible for use of devices similar to knee-joint and inclined chutes (Art 5), under conditions causing irregularities and inaccuracies evident only to the expert. Improved methods and customs lessen its influence, but its existence must be recognised in any discussion of sampling.

2. REMARKS ON SAMPLING METHODS

General. Ore is sampled by hand or mechanical methods. HAND METHODS, the oldest and simplest, require merely shovel and wheelbarrow. They are applicable to all ores; and are preferable, usually necessary, with wet or sticky ores. In MECHANICAL METHODS, sta-

tionary or moving devices in the stream of ore automatically divert the desired proportion for the sample. Though first cost and maintenance of a mechanical plant are important items, its operation may be continuous and the preliminary sample obtained a few minutes after unloading; mixing the ore is less important and probably unnecessary; and, when correctly constructed and operated, liability to error is much less than with hand methods. Although a mechanical plant may be so constructed that a correct sample is impossible, thorough inspection always discloses any such condition.

Mechanical devices are of 2 kinds; stationary, which continuously divert certain portions of the stream for the sample; moving, which periodically divert the entire stream for the sample. They respectively take part of the stream all the time, and all the stream part of the time. Theoretically and actually, stationary are not as dependable as moving devices. Ore does not flow uniformly, but is composed of many streams of varying proportions of fine and coarse. Thus, corrugated roll shells permit passage of coarse particles at certain points, and in an inclined or angled chute, or barrel-mixer, the finer will seek the lower points. Therefore one or more compartments of a stationary device may steadily receive an undue proportion of coarse or fine. With properly constructed moving devices, passing across the entire stream, the manner of delivery is unimportant, even if the ore was previously sized, because the sample spout is under all sections of the stream for equal periods of revolution or oscillation.

Preliminary and final sample. Whether sampling is continuous, from first crushing to final grinding, or is a series of unrelated processes, the operation of obtaining the preliminary sample from wet original ore is distinct from that of obtaining the final sample for assay. The preliminary sample may be taken by either hand or mechanical methods.

3. PRELIMINARY SAMPLE: HAND METHODS

Grab and pipe sampling are the simplest hand methods, being similar to those used in mine examinations (Sec 25). They may be used in sampling plants on low-grade concentrates or for rough checking.

Coning and quartering is applicable to all kinds and grades of ores, needs no expensive plant, and keeps the sample constantly in sight (for details, see Sec 25, Art 4). Chief objections are large labor cost and ever-present opportunities for utilizing segregation to obtain a high or low sample. Even with a perfect cone particles graduate in size, from finest at the apex and around the axis to coarsest at the bottom, the sizing progressing with height of cone. When a cone is built by shoveling, even from rough piles of ore, each shovelful is in itself a rough cone or pyramid with the coarsest particles near the heel and in position to be thrown on the pile where desired. When shoveling is done from 2 or more adjacent cones, opportunities for selection are greatly increased. The apex of the rising cone is frequently shifted from the true center. If flattening is done by dragging ore with the shovel from center to outside, the finest is left as a top dressing and an occasional deeper drag places more fines in any selected sector. If flattening is done by a churning motion of the shovel, fines will work to the top, leaving the coarsest nearer the floor. As each movement of the shovel is a distinct operation, such inaccurate work is difficult to detect, and a watcher hesitates about complaining. In QUARTERING, lines may be drawn at one side of center, or so as to include fines previously placed in a certain sector. In shoveling out the reject, the face of the sample quarter will rest at an angle to the vertical, causing loss of the upper wedge of fines, and a gain of an approx equal amount of the lower coarse. To avoid inaccurate work, it may be requested, after quartering, that the removed quarters be used for the sample. Use of the iron or wooden cross lessens some of the errors during quartering, but does not insure accuracy elsewhere. BENCH or COBB SYSTEM is an excellent modification of the usual practice, lessening segregation and overcoming many inaccuracies of the single large cone. It consists of a series of cones of 50 to 100 lb each, each built on the flattened mass of the preceding cone: quartering is done only after the final cone has been flattened.

Fractional-shoveling is applicable to all ores, but is principally used as incidental to unloading ore at destination. During unloading every 2nd to 10th shovelful or any proportion desired, is thrown into a barrow or pile, to be removed later to the sampling room. Thus the bulk of the ore is promptly placed in storage bins, and sampling cost is reduced in proportion to the quantity discarded. As the reject is immediately thrown with other ores, preventing any check, this sampling is of equal if not greater importance than any later work. Much of the shoveling is done in open cars, with loss of dust and fine ore. With cheap labor the count for the periodic sample shovelful may be unreliable, whether left to the shoveler or to a signal from the foreman. Variations from the 3rd to the 11th, and from

the 6th to the 29th, shovel have been noted when a 0.1 sample was intended (7). This method should be used only on low-grade and finely-crushed ores.

Fractional-shoveling is also used as part of regular sampling in some mills and smelters, though possibilities of error are greater than in coning and quartering; notably so if the ore has previously been piled by passing over an inclined chute. A workman naturally shovels ore from the point nearest receiving receptacle; hence if one barrow is placed near the back, and another near the front, of a conical pile, the sample will be high or low depending on which barrow is used for the sample. Errors during fractional-shoveling, whether from pile, bin, or railroad car, are difficult to detect and prove, as each shovelful loses its identity as soon as delivered, and the workman may change his system between 2 shovelfuls. A mode of checking is to request that the reject be used for the sample, though this will not often be granted. An effectual protection against use of such unfair methods is to crush a low-grade ore very finely, mix this with coarsely-crushed high-grade ore, and ship as one lot. This is particularly effective in fractional-shoveling, whether the sampling be done from car, rough pile, or cone, and is useful in coning and quartering and even in some mechanical mills. When the buyer realizes the situation, the practice may be reversed. Because of lack of confidence in their own methods some plants screen all ores of suspected mixed values, sampling separately different sizes, and averaging according to the two weights.

4. PRELIMINARY SAMPLE: STATIONARY MECHANICAL DEVICES

Whistle pipe. Fig 1 represents an outline of this type. *A* is the housing, with front removed to show pipe; *B*, the sampler, is a vertical pipe with 5 notched openings cut halfway through, as at *C*, each being 90° horizontally from the one above. In the notches are rectangular steel sheets at 45° to the vertical, the top edges forming diameters of the pipe. Above each notch is a cast-iron liner *D*, narrowed at bottom to collect the ore in a smaller stream before striking the dividing edge. Ore delivered through hopper *F* falls on the first partition, approx one-half being rejected through *R*, while the sample-half continues to the second partition. With 5 partitions, as in Fig 1, the sample leaving the pipe at *S* is $^1/_{32}$ of the original lot. This device is cheap to build and operate, and rapidly and simply produces a small sample. For accuracy, the whole lot must be crushed to fineness necessary for weight of sample (Sec 30, Art 3). For, if the crushing is planned for the average 100 000 lb lot, and no change is made, the safe maximum size may cause serious error on a 20 000 lb lot. The apparatus is tightly housed, so that frequent examinations are inconvenient, and, as the openings are invisible during sampling, improper working may be unnoticed. With dry, free-running, and properly-crushed ore, an accurate sample is obtainable by this device; but with sticky ore one or more openings may become clogged and cause the final sample to be 0.1 or 10 times the calculated weight. Sample and reject openings may alternately become clogged and produce a sample of proper weight, but with too little of the first and too much of the last part of the lot. It is not suited for the general run of ores, and is used in but one part of the U S.

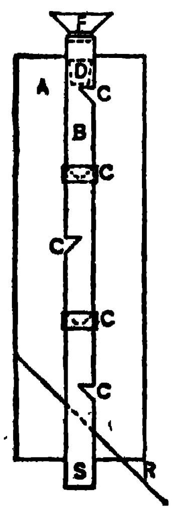

Fig 1. Whistle-pipe Sampler

Bank or combination riffles consist of 5 riffles set in a frame, the upper being placed over 2 lower ones, which are followed by 2 still lower sets. Fig 2 shows lines of flow. Ore fed to first riffle *A* is divided by vertical partitions into 20 or more streams, the odd and even-numbered falling on opposite sides of the riffle. These streams impinge on inclined iron aprons *B*, and are diverted to riffles *C*, similar to *A*. From these 2 riffles flow 4 sets of streams, each representing 0.25 of the lot. Two are rejected through *R*, and 2 diverted as above to aprons *D* and riffles *E*, and are again divided into 4 streams. Two unite and are rejected and 2, *SS*, each representing 0.125 of the lot, are united or treated as original and duplicate samples (Art 8). When the ore is slightly damp, rough cones form on the aprons. These may remain some time or be promptly dislodged; meanwhile the coarser ore is diverted to succeeding riffle divisions on each side, while the finer drops vertically. A small error on the first may be a serious accumulated error after passing 3 riffles. This danger is lessened by regular motion of the riffles across the stream; but to be effective this motion should be caused mechanically and not left to the workman's whim. Because of the tendency of the small divisions to clog, the device is applicable only to the drier and finer ores.

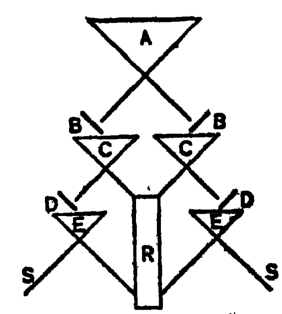

Fig 2. Bank or Combination Riffles

5. PRELIMINARY SAMPLE: MOVING MECHANICAL DEVICES

These are so constructed and operated that during 0.05 to 0.20 of a period of rotation or oscillation a division called the sample spout diverts the entire stream for the sample.

Snyder sampler (Fig 3) consists of a cast-iron plate *A*, revolving in a vertical plane on axis *B*, with an inclined sample spout *C* passing through it. As the spout passes through the stream it deflects for the sample such proportion as the arc of the spout bears to the circle of revolution. At other times the ore strikes the plate and is thrown back into the reject. These machines being of cast iron have no easily bent or twisted parts, and are accessible at all times. With one spout about 20 samples per min are taken, but this may be increased by constructing with 2 or more spouts. Sides of sample spout must be at right angles to the plate and in planes passing through center of revolution. Thus, as the edges wear, the spout will cut the same arc. With the usual inclined delivery chute any other construction will cause error. As the device revolves in a vertical plane, wet ore may stick to the plate for half a revolution and then drop into the sample spout, or from spout to the reject.

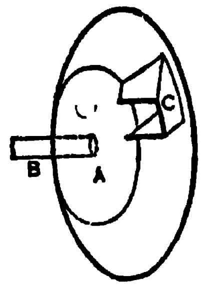

Fig 3. Snyder Sampler

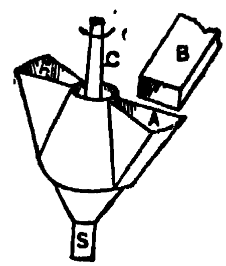

Fig 4. Vezin Sampler

Vezin sampler is used quite generally and in combination with many methods of sampling. There are many varieties, the type form being shown in Fig 4. Vertical shaft *C*, revolving with the arrow 10 to 40 rev per min, carries sampler spouts *AA* under delivery chute *B*, and diverts sample to center and through spout *S* at bottom. During remainder of revolution the ore falls into a reject receptacle.

Advantages: can be made accessible for cleaning and examination during sampling; frequency or proportion of sample is dependent on number or angular width of spouts; 2

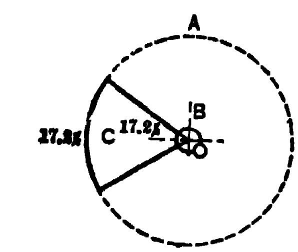

Fig 5. Vezin Sampler, Spout Edges Radial

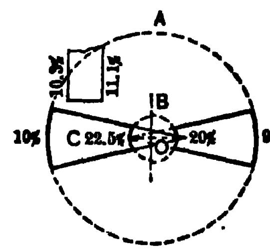

Fig 6. Vezin Sampler, Spout Edges Non-radial

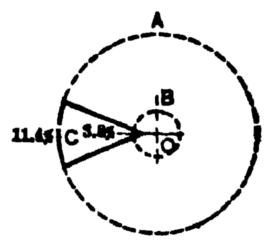

Fig 7. Vezin Sampler, Edges Non-radial

intermeshing machines may be operated for taking duplicate samples. Disadvantages: requires much head room; damp ore collects in or may fill the sample spout; the long upper edges of spouts quickly become bent, uneven, and worn. It is not patented and there are no restrictions on manufacture or use, though the inventor, H. A. Vezin, specified certain conditions as necessary for a correct sample. He insisted that sides of sample spout be in planes passing through center of shaft *C*, that feed chute should incline 58° from the horiz, with bottom edge radial to circle of revolution, and that speed of revolution should be the horiz speed of ore at spout edges, to lessen liability of particles to jump from or into sample spout. Chief cause of error is the position of sample-spout cutting edges, due to faulty construction, or wearing of non-radial sides. A variation from radial position, imperceptible with the machine in motion and proved only by careful measurements, may cause appreciable error, as illustrated in Fig 5, 6, and 7, which are horiz views of Vezin samplers in actual use. Fig 8 is from a photograph of a machine just before installation. If segregating delivery chutes are added, the error may be anything desired, as shown in Fig 9 (7). In the cuts: *B* is inside line of spout travel; *O*, center of carrying shaft; *C*, top of sample spout; *D*, bottom edge of inclined chute delivering ore to sampler; %, proportion taken for sample at points indicated. Fig 5 shows sides of spout radial, with equal arcs cut on *A* and *B*, assuring a correct sample regardless of segregation in the delivery chute. Angle between spout edges is too acute in Fig 6, 9, and too obtuse in Fig 7, 8. Percentages show

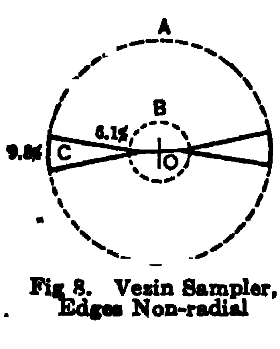

Fig 8. Vezin Sampler, Edges Non-radial

proportion taken for sample at inside and outside limits of spout, and also at extreme points on delivery chute. Even such machines might not cause commercial errors except for use of the inclined, and more especially the knee-joint chute (Fig 9). By adjusting the angle between D and D', and varying their lengths, control of distribution of coarse and fine is possible, as proved by samples taken across the chute. The chute shown in Fig 9 would probably cause a low sample in Fig 6, 9, and a high sample in Fig 7, 8.

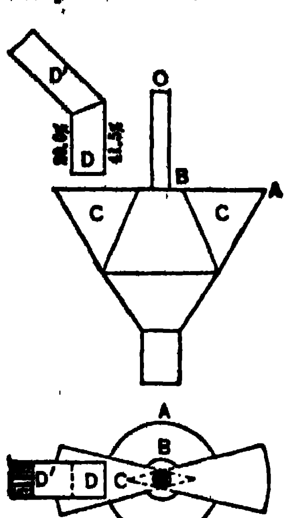

Fig 9. Knee-joint Chute, with Non-radial Vezin Sampler

There are many modifications of spout and chute that will cause this otherwise excellent machine to deliver an inaccurate sample. Previous to year 1900, machines were found with sample spouts intentionally leaky, causing loss of fines; delivery chutes dropped fines just beyond outer circumference of spouts; and sample spouts were made with parallel instead of radial edges, with ore feeding from outer circumference toward the center, and producing samples of 60% or less of the actual gold value. Since 1900, similar but more refined practices have been devised, so that it is wise always to inspect carefully every installation. The machine is generally conceded to work accurately if the spout edges are always radial and feeding chute is vert and at proper distance above the spout.

Chas. Snyder sampler is in principle similar to the Vezin, in that it revolves in a horiz plane and has spouts with radial edges (see Fig 10, lettered like Fig 6). It has a special annular, vertical delivery chute, covering an arc of 90° directly over the sample spout, and becoming narrower at top where it receives ore from elevators, rolls, or shaking trays. Within this spout are a number of short horiz iron rods, to scatter and delay the falling ore and destroy any previous segregation. The machine has 4 sample spouts, assuring continuous flow through them, instead of the intermittent flow of other devices. Errors of construction noted under Vezin sampler apply, but in less degree because of narrowness of spouts.

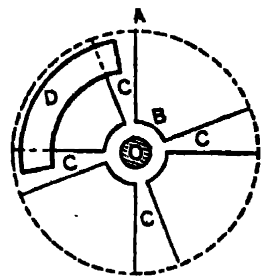

Fig 10. Chas. Snyder Sampler

Brunton vibrating sampler. Fig 11 shows front and side views. Ore is delivered through chute A, narrowing at lower end B. Operating mechanism drives arm C from positions C and C' and back again, diverting ore to the reject and sample sides R and S, respectively. Usual sample taken is 20%, but a simple adjustment permits any desired percentage. Correct feed is necessary for an accurate sample, and, as insisted upon by the inventor, D. W. Brunton, is assured by the narrowing chute or by use of shaking tray.

Possible inaccuracy, through cutting a large stream where particles are segregated, is indicated by Fig 12. As the diverting arm rests at C longer than at C', and takes an appreciable time to change positions, the reject R will receive more ore near C' than near C. Ore from rolls A, falling on inclined side of hopper B, is delivered over full area of chute D, the coarse scattering fairly uniformly while the fine slides to the opposite side. Therefore sample S might contain a fair proportion of coarse, but too much fine, and

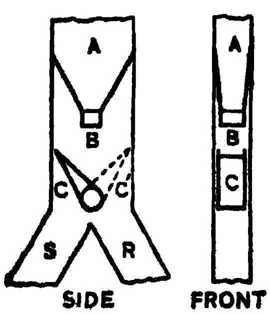

Fig 11. Brunton Vibrating Sampler

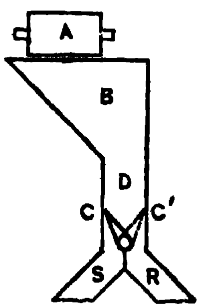

Fig 12. Vibrating Sampler (Incorrect Feed)

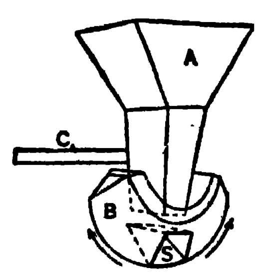

Fig 13. Brunton Oscillating Sampler

would probably be high in value. A change of angle of inclined side of chute, or a different length of portion D, might cause a high sample.

Brunton oscillating sampler (Fig 13). A is delivery hopper, and B is the moving portion suspended from shaft C, and oscillating in direction of arrows. Ore is diverted for the sample through spout S, and for the reject through oppositely-inclined spouts on both

sides of *S*. This machine is free from the undesirable features of earlier inventions. The receiving part of sample spout is rectangular, making it practically independent of segregation; cutting edges are removable and quickly replaced; it is accessible at all times; is operated at speeds (regulated by size of largest particles) sufficient to take 20 to 80 samples per min, with the greater accuracy due to small frequent samples; the rapid oscillating motion tends to free the spouts from wet ore or obstructions; its compactness permits including several machines with intervening rolls and shaking trays in a low-roof mill. Usual sample is approx 20%, though 5% may be taken with a special elliptical drive.

6. FINAL SAMPLE

When diam of largest particles is 0.125 to 0.5 in, and weight is 25 to 500 lb, the sample is taken to the bucking room for further reduction, drying, and preparation for assay.

Further reduction is made by any hand method (Art 3), by Brunton shovel, or by riffles. BRUNTON SHOVEL rapidly and accurately reduces the sample to the quantity desired. Fig 14 shows the 3-compartment shovel, with 1 sample and 2 reject divisions, preferably used only on large samples of medium-grade ores, concentrates or tailings, since, when shoveling from a cone, the center portion tends to select fines. The 7-compartment shovel, with 3 sample and 4 reject divisions, may be used with higher-grade and smaller samples, and for original and duplicate samples. RIFFLING is preferable on small quantities of high-grade ore, and may be done on the flat, Jones, or Taylor and Brunton forms of riffle. The Jones (Sec 30, Fig 1) is similar to the flat form, set at an angle of 45° to the horiz. Taylor

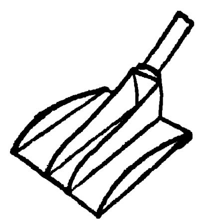

Fig 14. Brunton Shovel

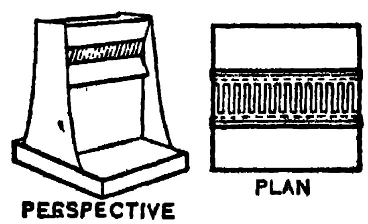

Fig 15. Taylor and Brunton Riffle

and Brunton riffle, Fig 15, resembles a double Jones, with short stiff horiz dividing edges, strongly built to withstand rough usage and to avoid the bending, leaking, and clogging of other forms. Riffling gives good results only if the device is kept in repair, the ore moved across the riffles during feeding, and partitions do not overflow.

Drying. When the sample weighs from 2 to 50 lb, but preferably not less than 20, it is dried by steam or electricity. Steam plates are steel boxes through which steam circulates, having a top drying area of 6 to 20 sq ft, on which the sample is spread. Steam coils are enclosed in a brick or steel closet, the pipes forming shelves for holding pans containing sample. Electric driers consist of resistance coils in a closet containing shelves for holding sample in pans. Temperature is important and should be slightly above the boiling point corresponding to elevation above sea-level. Thermometers are used for steam, and automatic regulating devices for electric driers. Insufficient or excessive drying causes trouble and error in assaying and valuation of an ore (Art 7).

Grinding of the dried sample to 40 to 60 mesh is done by rolls, or grinders of the Englebach cone- or Braun disk-type. The ENGLEBACH TYPE consists of a bell-shaped cone, revolving horizontally within and beneath a stationary iron ring flaring at top and bottom. The cone rests on a vertical driving shaft, and the ring is carried on a hinged frame so that parts are quickly swung open for cleaning; 8 or more channels are cut vertically in the grinding surfaces of both cone and ring. Ore is fed through top of ring and channels. Fineness of grinding is controlled by regulating closeness of contact between cone and ring by an adjusting screw and lever attached to driving shaft. BRAUN DISK-TYPE consists of a circular iron plate, revolving in a vertical plane with its face in contact with the face of a similar stationary plate, hinged at the bottom to permit separating and cleaning grinding surfaces; 6 or more feeding channels are cut in faces of both plates, beginning about 1 in from circumference and deepening at center. Ore is fed into a hopper passing through center of the stationary plate. An adjusting screw on shaft carrying the revolving plate regulates pressure between the plates and consequent fineness of grinding.

Quality of iron used in grinders is important. If hard it soon polishes and loses efficiency; if soft it may lose enough iron to the sample to lower the value appreciably, or may even take up particles of valuable metals from one sample and drop them into a succeeding sample. Imperfect parts must be promptly discarded; filling cavities with babbitt is not permissible, as metals are removed from the sample by the soft filling. The ground sample may be further reduced, if desired, by methods described above.

Screening is done through sieves varying from 80 mesh for low-grade to 200 mesh for highest-grade gold ores, average being 100 and 120 mesh (Sec 30).

Sieves should be free from missed wires and holes, and so constructed that all soldering is on the outside. Sieves with broken or misplaced wires should be promptly discarded, and not repaired with a drop of soft solder which may gather metals from the sample. While it is not desirable, it is accepted custom to use loose iron washers in the sieve to prevent balling of dried sample and to hasten screening. Some plants even use in addition a stiff paint brush. If hastening is overdone, especially near end of process, long wires of copper, gold, or silver may pass through and cause puzzling differences in assaying. Single wires of gold have been found heavy enough to cause 0.5 oz gold difference in check assays (7). With such ores, washers should be discarded and more time taken to grind the pieces of metal. Oversize from the sieve is either reground or reduced on the bucking board (Sec 30, Art 1). Quality of iron in bucking board and hammer is important (see above).

Metallic particles resisting grinding, and consisting of metals from the ore (or copper caps or iron from the machinery), are separately weighed and assayed (Sec 30, Art 3).

Mixing the ground sample, now called PULP, is done by coning, by pouring into a rapidly revolving gold pan, by turning over with a spatula, by passing through an Anaconda mixer, or by rolling (not sliding) on a sheet of heavy paper or oil cloth (Sec 25, Art 4). Dividing and sacking the pulp is done by coning and quartering, by the spatula, by a mechanical mixer and divider, or preferably by riffling (Sec 30, Art 1, 3). Paper sacks prepared for mailing are used for holding this assay pulp.

7. MOISTURE SAMPLES

Moisture samples. Ordinarily 2 to 4 samples, of 2 to 5 lb each, are taken from each carload, while high-grade lots may require 10 or more samples. As ore may gain or lose water rapidly, moisture samples are taken as near as possible to the time of weighing the lot. In case of grab samples, care is necessary to obtain proper proportions of all sizes, as fines usually contain much more water than coarse pieces.

As individual grab moisture samples may vary 25%, many must be taken to assure an average. To avoid this difficulty samples may be taken by grabbing, or with a mechanical device, during or after the sampling and when the ore is reduced to 0.25 in or smaller. As ore becomes drier during sampling, it is customary to add arbitrarily about 10% to the moisture as determined from the crushed sample, regardless of varying atmospheric humidity. While all modes of determining moisture are only rough approximations, the sample taken after crushing is preferable and is commonly used.

Weighing the wet sample requires care and judgment, and the exclusive use of either the finest or the coarsest material for final balancing while weighing should be avoided. Special scales, for weighing wet and dry samples, show percentage loss without calculation. Sample should be dried on same drier and at same temperature used for assay sample. Otherwise, because of differences in moisture or in roasting of oxidizable material, the value of the lot can not be accurately computed.

8. MULTI-SAMPLES

Check sampling. Custom plants usually retain each lot of ore intact until settlement is agreed upon. Owing to limited storage room, mills and smelters bed or store the bulk of a lot, retaining intact rarely more than 0.5 to 0.2 of it, and usually only a few hundred pounds. Local custom or contracts usually determine the amount so held, though the State of Montana provides by statute for retention of 2.5%. It is the practice in many plants to make MULTI-SAMPLES, called ORIGINAL and DUPLICATE, or even TRIPLICATE and QUADRUPLET, the division being made when sample has been reduced to 200 to 500 lb. This exposes gross errors in later work, detects salting, is a guide as to necessity for resampling, and averages errors of faulty methods.

At some plants anything less than a specified percentage difference between assays of multi-samples makes settlement on the average compulsory, while a greater difference automatically calls for resample of the retained portion. This difference varies from 5 to 20%, usually 10%. Close checking of multi-samples indicates uniformity of work in the portions so handled, but does not prove correctness of sampling of the entire lot. On the other hand, large or constant differences indicate general carelessness, or improper methods, and make possible undesirable "jockeying" in reaching a final settlement (Art 11). Many plants are so constructed and operated that the average variation in resampling of any sized lot may be less than 2%, with only an occasional 5% or greater.

9. SYNCHRONISM

Definition. When two or more mechanically-operated sampling machines are arranged in series, there is a constantly recurring cycle in their relative positions. If one horizontally-revolving machine is directly beneath another with same rotative speed, the spouts will have a constant angular difference, and with no intervention the second sample spout may

be arranged to receive all, a part or none of the first sample. At different speeds, one spout will pass the other at regular intervals and, if not obstructed, the sample from the first machine will regularly strike certain points on the second machine in any cycle desired. Table 2, containing data from a large plant, illustrates this. Upper row figures *S* show number of consecutive samples from first machine passing partly or entirely into second sample spout. Lower row figures *R* show number of consecutive samples passing entirely into the reject of second machine. These should be read, *S* 5, *R* 5, *S* 10, *R* 1, *S* 1, *R* 5, etc.

Table 2. Example of Synchronism (record representing 0.2 of complete record)

S..............	5	10	1	6	1	4	1	1	4	3	6	1
R..............	5	1	5	1	5	1	1	7	1	5	1	5
S..............	8	1	4	1	6	1	7	1	4	1	8	1
R..............	1	5	1	3	1	6	1	7	1	5	1	5

The value of any sample portion depends on at least part of it reaching the ultimate sample, its complete loss being equivalent to omitting from the shipment the portion of ore which it represents. Intervening rolls alone do not correct synchronism, but elevators, the continuous delivery of the Chas. Snyder sampler, closed hoppers, barrel-mixers, and shaking trays, lessen or prevent it. The BARREL-MIXER has the disadvantage of segregating coarse material and corrugating the following rolls. The SHAKING TRAY causes ideal delivery, besides being a generally useful device. It delays the ore sufficiently to prevent synchronism, gives uniform feed, can be made to correct uneven wear on rolls and to stop pieces of steel or hammer heads that might injure the machinery.

10. GENERAL CONSIDERATIONS

Weighing. Small lots, or high-grade ores, are weighed on special bullion scales. Carload lots are weighed on railroad scales, preferably housed and with space between platform and coping covered by old belting to prevent jambing by pieces of ore. Railroad scales should be tested monthly by special test cars of approx weight of the empty and loaded car, and daily or weekly by 40 test weights totaling 2 000 lb. Great care is necessary in checking with small test weights, as the 20-lb minimum error of the scale is equivalent to 2 000-lb error on a load of 100 000 lb.

Cars should be uncoupled and stationary when weighed, and time allowed for scale rider to swing both up and down. Rapid balancing with rider slightly over and underweight for gross and tare will cause 100 lb or more error in net weight. Balancing scales by placing fine ore or shot on rider may cause an error of several thousand lb. Wagon scales, too short for both team and wagon, must have roadway at each end level with platform, and brakes and tugs must be loose during weighing.

Incomplete lots. Portions of a lot may be received at widely different dates, necessitating the questionable practice of taking several preliminary samples to be combined later for the final sample. With mechanical methods liability to error is not serious, but with hand methods different sets of workmen taking slightly different proportions may cause errors never discoverable, owing to bedding of the bulk of the lot. A combination may be made of SAMPLING WITH ROASTER-CRUSHING PLANT (see Flow sheet No 3), though this of doubtful desirability. There is danger of loss and salting through excessive dust, and general lack of care when sampling is merely incidental to fine crushing.

Cleaning. Plants should be reasonably tight to avoid strong air currents, and ore chutes tightly enclosed to prevent the too common winnowing-out of fines. In hand methods, cleaning with brush and broom proceeds with the sampling. In mechanical mills, cleaning immediately follows the last of the ore, and should proceed from first to last crushing and sampling process, causing cleanings to pass through all following machinery to insure their proper proportion in the sample. Many mills supplement brush and broom cleaning with a blast of compressed air piped to convenient points. After the regular cleaning, rolls, and fine-grinders especially, are fed with barren rock or slag, and again cleaned before receiving the following lot. It is good and economical practice to discard cones, rings, or disks of fine grinders immediately after grinding a very high-grade ore.

Salting. Deliberate salting by addition of rich ore or barren sand is similar to salting at the mine (Sec 25, Art 9). Devices for salting at sampling works have been quite elaborate, including high-grade samples of the exact weight necessary to cause the desired salting, and provided in duplicate for emergencies or for following a lot from sampler to smelter. This practice, undetected for nearly a year, was largely responsible for the financial failure of a well-known smelting company. Of greater importance is salting by incorrect machinery, producing either a high or low sample. As a precaution the miner may employ trained men, called MOOCHERS, to watch the sampling; and the sampling company may lock sam-

pile-hoppers and erect wire screens around important machines. The most effective preventive is a correctly built mechanical mill, operated according to scientific and unvarying rules.

Confusion of samples. This is a worrying possibility in plants handling many large and small lots, of unknown and varying values, especially when they are begun and finished by different workmen.

Accompanying is a record made at the Taylor and Brunton Ore Sampling Co's plant, Murray, Utah, on a form designed primarily to prevent this confusion. It is of strong cardboard, punched for loose-leaf practice, and in 3 sections to permit prompt reports from each department. Upper margins were cut and cards filed for permanent reference. MILL CARD, signed by foreman Quist, shows that 73.28 tons passed through the mill in 2.5 hr, at cost per ton (wages at 25¢ per hr) of 5.1¢ for unloading and 0.8¢ for reloading into 2 other cars. Had the ore arrived in dump cars, costs might have been halved. Cleaning took 0.5 hr, increas-

ing cost 20%. (At present-day rates of wages, these costs would be from 40 to 50% higher). 4 cutters (sampling machines) delivered a theoretical wt of 183.2 lb for the preliminary sample. CUTTING CARD shows that Davies (ass't sampler) began cutting (using Brunton half-shovel) 5 min after last of ore was unloaded, and finished 5 min after clean-up. 8 shovel-cuts produced a partially-dried sample of 22 lb, instead of the theoretical 22.9 lb. 2 moisture samples, taken from the reject at this point, averaged 4.2%. SAMPLE CARD shows delivery to sample man, Spoonley, and prompt placing in steam drier, where it remained 4 hr and 40 min. It was then ground in No 1 grinder, riffled 3 times, bucked, and sacked at 4:40 P.M. Finished pulp weighed 42 oz instead of the theoretical 43.8 oz. Grinder was cleaned with barrens both before and after this lot, eliminating danger of salting from lot 6262 or from Wyoming lot 195. Cost of sampling an ore received in different classes of cars, and in varied physical conditions, is instantly available from the card; it also gives a check on efficiency of foremen and workmen. Its use generally settles disputes.

Manner of sale of ore. Local custom or private agreement determines the procedure. In outlying camps a lot may be sold on samples and prices made at the mine by buyer's agent. But ore is generally sent direct to mill or smelter, is transit-sampled on its way to smelter, or is sold to a custom plant. Valuation may be based on sample and assays made by custom plant, on assays made by buyer and seller on the custom sample, or on buyer's sample only. In last case, seller may use the custom sample as a check and a guide as to the wisdom of calling for a resample by the smelter. As this gives the seller an advantage, some buyers request or demand a report of all such checks before even considering seller's objections.

Resamples may be demanded by either buyer or seller. In custom plants, resamples of entire lots are freely granted, usually on basis of an extra sampling charge if the 2 samples check within an agreed limit varying from 0.05 oz gold on low-grade to 2% on high-grade ores. Other mills, especially hand-sampling plants, have various rules depending on exigencies of the occasion and the confidence existing in methods employed. A commoner practice is to resample freely on unchecked ore, but only in case of 10 to 20% difference, if ore has been check-sampled. Several resamples may be demanded if the earlier ones vary by a specified difference. To be of value resamples should be made of the whole lot, rather than of the small portion usually retained.

Most custom plants and some smelters make payment on the average of assays by buyer and seller on same sample. Others pay on basis of buyers' assay only, with or without knowledge of sellers figures, permitting the seller to demand a repeat, an umpire assay, or a resample, with correction in payment if the assay variation so found is sufficiently large. As the seller is unlikely to make demands should his assay be the lower, the buyer, under this arbitrary system, takes a certain risk which he may lessen by having duplicate assays made by the same or a different assayer, reporting either one or an average, as his judgment and conscience may direct. Custom varies concerning settlement assay in cases of repeats, umpires, and resamples. The last result or the "middle" assay may be selected, or the whole series averaged.

11. COMPARISON OF ASSAYS

Comparison of assays of large shipments and over long periods of time are of value, where special assays or selected resamplings are indecisive. Tables 3, 4, and 5 contain assays representative of the entire shipments from 1 mine to 3 sampling plants for approx 1 year, in lots of 30 to 150 tons. The following uniform rules for settlement existed, but were not rigidly enforced. Pulps were assayed by both seller and buyer, and in some cases by an umpire. Settlement was made on buyer's assays, when results were within limits

Table 3. Comparison of Gold Assays on Buyer's Sample

varying from 0.1 oz gold to 10% of buyer's assay. For greater differences, even after a reassay or umpire assay, a resample was made of the retained portions (Art 8). Original and duplicates were made in all plants. The tables show that seller's assays are generally higher than buyer's (Art 9).

Table 6 shows assays of shipments from 1 seller to 1 buyer for 15 months, and illustrates good sampling and assaying. In Tables 3, 4, 6, resamples were made only on the retained portion of 200 to 500 lb, and were not a check on the whole lot (Art 8). Many of the sampling machines figured in preceding pages are from plants represented in the tables. Table 7 shows assays of shipments from a custom sampler to a smelter using hand methods. Averages in Tables 3, 4, 5, are of much longer series, shown here only in part.

Jockeying with assays. Assays reported by the seller are usually higher than the buyer's, the relation persisting through reassays and resamples (Tables 3, 4, 5, 6). On high-grade ores larger differences occur (Table 7). Eliminating the deliberate falsifying of the mining camp telephone-system of comparison of figures, there still exists the jockeying with assays frequently found in ore-settling practice. Simplest example is the cupeling at an intentionally, but not criminally, high or low temperature, giving correspondingly low or high assays with no particular strain on assayer's conscience.

The principal and more specious excuse for jockeying is the fact that assaying of ordinary pulp is not an exact science. Due to conditions shown in Art 6 (Screening), the most conscientious and skilful assayer may be unable to weigh from the pulp two or more charges containing exactly the same amount of gold or silver. Hence it is customary to assay from 3 to 12 separate charges from each pulp, to weigh all the buttons together, and report the average assay only. But the large differences occasionally occurring between the buttons furnishes a plausible excuse for weighing them separately and discarding, in the average, such as differ excessively from the majority. This elimination may be done by the assayer, or by the settlement clerk, neither of whom may relish the responsibility. It is natural that judgments of buyer and seller will differ as to what buttons should be rejected; but even a conscientious umpire is at a loss what to report when buttons vary by several oz per ton. Possibilities for jockeying are greatly increased when 2 to 4 multi-samples, with repeats, umpires, and resamples are made, involving consideration of perhaps 160 separate buttons for one settlement.

Another opportunity for jockeying is the relation between assays and treatment charges, or the so-called "splitting" points with assays. As-

suming that an ore contains approx 1 oz gold per ton, and treatment charge is \$4 if below 1 oz, and \$5 if 1 oz or more, with gold at \$20 per oz; the buyer prefers a final average of 1.00 to 1.045, and seller anything from 0.995 to 0.955, each preferring the critical assays of 1.005 or 0.995 oz gold respectively. This is shown as follows:

1.045 oz	= \$20.90	0.995 oz	= \$19.90
Less treatment charge	5.00	Less treatment charge	4.00
	15.90 *A*		15.90 *D*
1.00 oz	= 20.00	0.955 oz	= 19.10
Less treatment	5.00	Less treatment	4.00
	15.00 *B*		\$15.10 *E*
1.005 oz	= 20.10	Seller prefers *D* nd *E*.	
Less treatment	5.00	See Sec 32 for ent charges.	
	\$15.10 *C*	Values of 0.955 and 1.045 oz (0.09 oz difference) are equal commercially.	
Buyer prefers *B*, but can stand *A*.			

The question of the splitting point on RR freight classification arises in a similar manner, especially where the ore is bought f o b at shipping point.

NOTE.—In above statement, the value of gold is taken as \$20 per oz (old standard being \$20.67). Present market price (Jan, 1940) is approx \$35, in terms of U S "money on account," a phrase used by the Treasury Dept in its quarterly circulars on Monetary Units. As this assumed value may at any time be changed by Act of Congress, the \$20 standard is retained here and in Tables 3 to 7. In using the tables, assay values can readily be adjusted to existing market price of gold. (See Table 29, Sec 45.)

12. FLOW SHEETS

Flow sheets 1, 2, and 3 are selected from a series of 55 compiled for the U S Bureau of Mines (7). The form is a modification of that used by D. W. Brunton (3). Each line represents a distinct operation. Single spacing indicates that ore passes from the operation shown in one line to that in the line below. Double spacing indicates that the flow of ore divides at that point, different streams taking courses shown by arrow points. Figures after crushers and rolls are indications of standard sizes and fineness of crushing. Percentages taken for sample are shown. At certain stages approx wt of sample is given, based on original lot weighing 100 000 lb. Discard, unless followed by lines or single spacing, indicates elimination of that portion from further sampling.

Hand-sampling Mill (Flow sheet No 1)

Railroad beside storage bins
Shovel sample

Sample 10%, 10 000 lb, left in car ← → Discard
Shovel sample

Sample 50%, 5 000 lb, left in car ← → Discard
Car taken to coning floor
Spread in ring, and coned over wooden cross inside of ring
Quartered

Sample, 50%, 2 500 lb ← → Discard
Spread in ring
Coning and quartering repeated until

Sample weighs 150 to 300 lb ← → Discard
Taken to roll room, and partly dried if necessary
Rolls, 12 by 20 in; about 20 mesh
Riffle, Jones type

Sample, 10 lb ← → Discard
Dried
Grinder, Englebach type, to 50 mesh
Riffle Jones type

Sample, about 2 lb ← → Discard
Hand sieve, 100 mesh ←

Size ← → Oversize
↓ Bucking board
Roll on glazed paper. Put in 6 sacks with spatula; excess discarded

Mechanical-type Sampling Mill (Flow sheet No 2)

Railroad car over hopper. Unloaded into hopper
Crusher, 13 by 24 in; to 2.75 in
Rolls, 16 by 42 in; to 2 in
Shaking tray to elevator No 1
Sampler No 1, Brunton oscillating
Sample 20%, 20 000 lb ← → Discard
Rolls No 2, 16 by 36 in; to 1 in
Shaking tray
Sampler No 2, Brunton oscillating
Sample 20%, 4 000 lb ← → Discard
Rolls No 3, 14 by 27 in; to 0.375 in
Shaking tray
Sampler No 4, Brunton oscillating
Sample 20%, 800 lb ← → Discard
Rolls No 4, 8 by 20 in; to 0.125 in
Shaking tray
Sampler No 5, Brunton oscillating
Sample 20%, 160 lb ← → Discard
Rolls No 5, 8 by 12 in; to 20 mesh
Locked sample car. Taken to sample room
Half-shovel, Brunton
Sample, 20 to 40 lb ← → Discard
Steam dryer
Englebach grinder, to 50 mesh
Riffle, Taylor & Brunton
Sample, 20 to 24 oz ← → Discard
Bucking board ←
Hand screen
Size ← → Oversize
Rolling cloth. All riffles into 4 sacks

Sampling and Crusher-roasting (Flow-sheet No 3)

Track beside mill. Ore shoveled to pan conveyer
Crusher, gyratory No 5; to 1.5 in
Conveyer belt
Hopper
Oxide ores ← → Sulphide ores
Revolving wire screen, 2 mesh ←
Size ← → Oversize
Trommel, 1 in holes
Size ← → Oversize
Rolls, 14 by 30 in. Trommel, 2 in holes
Size ← → Oversize
Rolls, 16 by 36 in — Crusher
Gyratory No 4
Hopper
Sampler, Vezin No 1, 2 arms
Sample 20%, 20 000 lb ← → Discard
Shaking tray
Sampler, Vezin No 2, 2 arms ← → Sampler, Vezin No 5; intermeshing
Sample 20%, 4 000 lb ← → Discard ← → Sample 12.5%, 2 500 lb (Legal reserve)
Shaking tray
Rolls, 12 by 12 in; to 0.125 in
Sampler, Vezin No 3
Sample 20%, 800 lb ← → Discard
Shaking tray
Sampler, Vezin No 4
Sample 20%, 160 lb ← → Discard

Locked sample hopper. Wheeled to bucking room
Partly dried
Coned and quartered
Sample, about 150 lb ← → Discard
Riffled, Jones type
Sample, about 10 lb ← → Discard
Dried
Grinder, Englebach type, to 50 mesh
Riffled, Jones type
Sample, about 2 lb ← → Discard
Hand sieve, 100 mesh ←
Size ← → Oversize
Bucking board
↓
Roll on glazed paper
Sack in 6 pulp samples with spatula, excess discarded

13. COSTS

Table 8 shows operating costs of customs sampling plants in Colorado, Utah, Montana, and Nevada. Costs are affected by price of labor, distance from supply markets, character of ore handled, and service rendered. The probability of receiving even a small percentage of high-grade gold ores necessitates a distinctly better mill and operative care, more time lost in cleanups, more assaying, and generally greater expense than sampling of lower-grade gold, silver, lead, and copper ores. Plants exclusively for transit sampling may or may not furnish assays to customers, and need small clerical force; whereas, if ores are also bought and sold, assaying, clerical force, administration, demurrage, and interest are large items, increasing with value and quantity of ore so interchanged, and distance from smelting points. (See also Sec 32.)

Table 8. Costs of Sampling (1938)

Plant	Period, months	Tons in period	Hr per day	Common labor, wages, dollars	Costs, cents per ton									Footnotes

w = ore transferred by wheelbarrow
t = ore transferred by tram
m = ore transferred mechanically
g = gold ores exclusively
s = silver ores exclusively
h = large proportion of high-grade ore
o = general ores, mostly low grade
c = custom sampling
p = some of ore purchased
* This company had 2 plants

Table 9 shows one month's mill-labor costs, taken from plant *H* in Table 8, and for a day-shift run only. This form was designed for the Taylor and Brunton mills, copies being exchanged monthly between managers of 6 plants for comparison and suggestion. Platting the cost figures for a year's run develops interesting and valuable facts, and tends to efficiency of management.

Hand methods at smelters are usually combined with mechanical methods, and the preliminary fractional shoveling may be charged to sampiing, bedding, crushing, or some other department. Therefore comparative sampling costs are difficult and of doubtful value. Different smelters show costs of \$0.45 to \$2.25 per ton. Assuming a 100-ton lot, crushed to 0.5 in, and labor at \$0.40 per hr, the cost of fifth shoveling this to 20 tons, half-

shoveling to 10 tons, and coning and quartering to 250 lb, will be about $2 per ton, including cost of wheeling or tramming the reject a reasonable distance to bedding floor. This does not include mill supplies and machinery, making the sample, taking moisture, assaying, nor any supervision or administration. At 40¢ per hr, the single operation of half-shoveling 10 tons costs about 8¢ per ton. Were it feasible to handle so large a lot as 100 tons by coning and quartering only, labor cost would be 45 to 75¢ per ton, depending on care required for the grade of ore. In general, the cost of coning and quartering varies from 5 to 10 times the cost of mechanical sampling.

SECTION 30

ASSAYING

BY

E. J. HALL

LATE PROFESSOR OF ASSAYING, COLUMBIA SCHOOL OF MINES, NEW YORK

REVISED BY

EDWARD F. KERN

PROFESSOR OF METALLURGY, COLUMBIA SCHOOL OF MINES

Note.—Numbers in parentheses in text refer to Bibliography at end of this section.

ASSAYING

Introduction. This subject is treated from the standpoint of field work, as to both equipment and methods, with particular reference to local conditions in the more remote districts. Rare minerals, and some others of low unit value, are omitted, because their assay or analysis requires special laboratory facilities. For fuller discussion of assay methods, see textbooks listed in the Bibliography.

In a remote region, the question whether to take in an assay equipment, or to send out the samples, will generally be decided by the number of samples, availability of satisfactory fuel for fire assay, and distance from an established assay office. But, in either case, to secure reliable results, adequate equipment must be provided on the ground for reduction of samples if transport of large samples to place of assay is to be avoided; and, unless individual samples are reduced to small size, their total weight may exceed that of assay equipment.

It is often important, in making mine examinations, to be able to obtain immediate results on certain samples, in order to resample in case of doubt; also, the cost of extensive sampling may be curtailed by advance information. Therefore, when the number of samples is large, or the mine is in a remote district, an assay equipment is almost imperative, notwithstanding that it is rather bulky and liable to damage in transport, and that assay work in the field is often beset with difficulties. In the absence of adequate equipment, simpler and more convenient methods of making determinations are sometimes sought, but there is no satisfactory substitute for the standard methods.

Blowpipe may be used for identification and qualitative tests (Sec 1); quantitative results require much practice and skill, and the results are unreliable. Further, fewer assays can be made per day by blowpipe than by standard methods, and the work is more tedious. An example will indicate the inherent shortcomings of the blowpipe method. Employing the usual charge of 100 mg for a 1-oz gold ore, 0.0034 mg of gold will be present. Combining results of 10 fusions gives only 0.034 mg, a quantity too small to be accurately measured without a microscope, and requiring a delicate balance for weighing. The total wt of ore used, 1 gm, is insufficient for a representative sample, and each assay would require 2 to 3 hours. The blowpipe is more applicable to high-grade silver ores and base metals. The so-called "pocket smelter" gives no more accurate results than the blowpipe.

Pan is useful for testing gold-bearing gravel, or pulverized gold ores, particularly those in which the base metals are oxidized. In experienced hands, it will give better results on spotty ores containing coarse gold than the ordinary assay on 0.5 A T (1 A T, or assay ton = 29.166 gm) charges. (See Art 8; also, Sec 25, Art 7, Sec 31, Art 5.) The pan is useless where the gold is combined as telluride or is enclosed in sulphides, unless the sample is first roasted.

1. EQUIPMENT

Crushing and grinding devices. If power is available, and samples are large and numerous, mechanical devices for reduction of sample should be used. They save time and energy, and diminish tendency to excessively large cuts on coarse ore, which vitiate accuracy of sample. In selecting a JAW CRUSHER, capacity, strength, weight, and convenience in cleaning are important; for ores likely to pack (due to moisture or talcy nature), a crusher with forced discharge is desirable. For fine grinding, the DISK PULVERIZERS are efficient. There are several makes; those having a stationary and a revolving disk give excellent results on hard and granular ores, though for talcy or heavy sulphide ores, they are less satisfactory. Ores of this class are better handled by a PLANETARY GRINDER, in which a revolving disk travels in an orbit, and discharge is positive.

For reduction of coarse ore by manual labor the JAW CRUSHER is most efficient. Relatively small jaws and heavy flywheels of large diameter are necessary. There is a knack in operating these machines, slow feeding and high rotative speed being essential. A simpler device is a STEEL PLATE AND HAMMER (cast iron plate, unless heavy, is apt to break), and a 3 or 4-in section of 10 or 12-in pipe, to prevent the pieces from flying; or, instead of the hammer, a "tamper" with a taller piece of pipe will be found more efficient.

For added convenience, the tamper may have a long handle, projecting through a hole in a board overhead, and the pipe section screwed to a flange for stability. For fine grinding, nothing is better than BUCKBOARD AND MULLER, which, to minimize salting of samples (Art 10) must have a finished surface and be free from pits. Buckboards with rim or flange on 3 sides have an unfinished surface. Some assayers substitute a piece of I-beam or channel iron for the buckboard, using a muller to fit the groove. Mullers should not be over 4 in wide, their greater bearing surface diminishing the unit crushing pressure. The Guanajuato Development Co has long used stone buckboards and cobble-stone mullers, with which thousands of samples have been ground. They are of silicified rhyolite, and it is stated that the pulp is diluted less than 0.5%. (See also Sec 25, Art 4.)

Sampling devices. A convenient and satisfactory sampler is the Jones riffle (as made by Denver Fire Clay Co, Fig 1). It has short spouts, facilitating cleaning. If it is set on the work bench so that its center line coincides with the edge of a rectangular opening in the bench, the rejected portion is delivered directly into a receptacle underneath. The opening is readily closed with a cover plate when both portions of sample are to be saved. The old trough and space-riffle is not recommended for general use; when carelessly used, results are unreliable. (See Sec 25, Art 4, 5, 6, 7.)

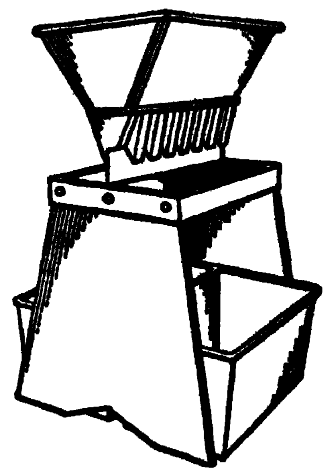

Fig 1. Jones Riffle Sampler

Furnace depends on method of assay, availability and cost of fuel, transportation, and amount of work to be done. MUFFLE FURNACE is equally adapted for all work; gives a more uniform and constant temperature; and is free from effects of furnace gases. It usually gives the best fusions, and crucibles last 2 or 3 times as long as when in direct contact with burning fuel. Soft coal and wood require this type. Disadvantages: Fuel economy is less, size of crucible limited, and destruction of muffles comparatively large. Though the increased cost of muffles is generally offset by saving in crucibles, their size and uncertain life may be the deciding factor when working in remote regions. Advantages of separate crucible fusion and muffle cupellation furnaces are practically the reverse of above. COMBINATION FURNACE attempts to combine the separate furnaces into one compact unit, using one burner for both fusion and cupellation, but it is difficult to maintain both compartments at proper temperature. It is recommended, however, for small amounts of work, or where transport is costly. A stock furnace, obtainable for practically all fuels, is generally preferable. Carborundum muffles are 10 to 1 better than clay.

Furnace built in field, for solid fuel, is rectangular in section, of fire brick laid in a mixture of $^2/_3$ burnt and $^1/_3$ raw clay. Ordinary brick does not stand well and stone is useless. Furnace is bound with angle irons at corners and braced with tie rods, or built in a sheet-iron case. Transverse iron bars at front and back support grate bars, which should project into the draft opening, for convenient dumping of ashes. At 8 to 12 in above grate bars is an opening, through which the muffle is inserted and supported by a block at the rear. Muffle opening is closed by a plug when used for crucible work. Space between muffle and furnace walls must be sufficient to allow fuel to pass.

If old crucibles are available, they may be ground to pass an 8-mesh screen, mixed with water and 10 to 20% of clay, and rammed into a sheet-iron case, containing a core of the shape desired for interior of furnace. Slag adhering to crucibles so used acts as a bond.

Fuel is coal, coke, or charcoal, but the above furnace works best with coke. Charcoal burns rapidly, requires constant attention, and gives fluctuating temperature. Soft coal is apt to coke and form a solid mass, which must be broken up, and the fuel-bed temperature is low until most of volatile products have been expelled. Soft coal gives best results in muffle furnace, thickness of bed being 5 to 8 in, on a grate 15 to 18 in below muffle. Anthracite makes a comparatively slow fire, in which it is difficult to obtain fusions without strong draft.

Oil-burning furnaces are best for field work. When power is available for a blower, heavy oils may be used, at a low fuel cost. In absence of power, gasolene furnace largely compensates for added fuel cost by saving of labor, rapid attainment of any desired temperature, and ready control. Gasolene furnace requires considerably more fuel while heating to required temp than subsequently; hence, short runs should be avoided. Two of the largest manufacturers are: Denver Fire Clay Co, Denver, Colo, and Braun Corp, Los Angeles, Cal. Fig 2 shows a light and satisfactory type, gasolene consumption for which is stated as 0.5, 0.75, and 1 gal per hr, for furnaces taking 6, 8, and 10 20-gm crucibles respectively. The $^1/_8$ or $^1/_4$-in pipe and elbows usually furnished with these

furnaces can be replaced with advantage by small-bore copper tubing, known as hollow wire; it is easier to install and eliminates numerous joints, with their liability to leakage.

Balances. A cheap spring-balance, costing 15¢ to 25¢, with a pan suspended by 3 strings, answers for weighing stock charges. PULP BALANCE should have pans holding at least 1 A T (assay ton = 29.166 gm), and should be capable of being dismounted and packed in the case drawer. They have either all-steel bearings, or steel knives and grooved agate bearing plates, the latter being preferable. For FINE BALANCE, following points should be considered. Since silver beads do not require extreme accuracy in weighing, a very sensitive balance, which is always slow and liable to derangement, should not be chosen for this work alone. Gold determinations are most exacting, and for a large number of weighings, the balance should be of the best. The most sensitive balances are very delicate, and will not stand rough handling. The inverted or "no column" type is recommended. Several makers have special portable balances, which are good, but less satisfactory than the standard types, and should not be used for permanent equipment.

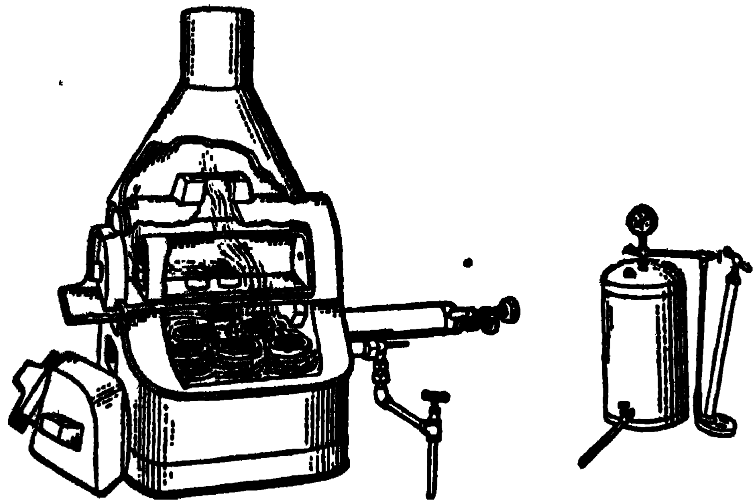

Fig 2. Gasolene Assay Furnace

Weights. For GOLD AND SILVER ASSAY, combination set of 0.01 to 100-gm and 0.1 to 4-A T "second grade" weights is advisable. The ASSAY TON (A T) contains as many milligrams as the avoirdupois ton contains troy ounces; therefore, 1 mg of gold or silver obtained from 1 A T represents 1 troy oz in 1 avoirdupois ton. The short (2 000 lb) and long ton (2 240 lb) will be represented by an A T containing respectively 29 166 + mg (29.166 gm) and 32 666 + mg (32.666 gm). BEAD WEIGHTS comprise 1 mg to 1 gm, and should be of the highest grade. These weights, as furnished by supply houses, are usually inaccurate and should be tested. Slight discrepancies can be disregarded for silver weighings, but a difference of 0.01 mg causes an error respectively of 20¢ on 1 A T, and 40¢ on 0.5 A T charges of gold ore. ANALYTICAL WEIGHTS for base metal and miscellaneous determinations should include 5-mg to 100-gm first grade weights. If both classes of work are to be done, the 5-mg to 1-gm weights may be omitted from the analytical set. It would be possible also to eliminate the gram weights in assay set, but this is inadvisable.

Where ore is weighed in METRIC TONS, gold and silver are reported in grams and kilos. As there are 1 000 kg in a metric ton and 1 000 mg in 1 gm, 1 mg of gold or silver obtained from 1 gm of ore will represent 1 kg per ton. Example: if 10 gm of ore gave 15.5 mg of silver and 0.35 mg of gold, the ore contains 1.55 kg silver and 0.035 kg, or 35 gm, of gold per metric ton. Where metric system is employed the A T weights are useless.

2. REAGENTS

Litharge (PbO) is employed in crucible assay to furnish lead for a button; also, in many charges, as a basic flux, oxidizer, and desulphurizer. It should be tested for silver by fusing 10 A T with silica, borax glass and soda, and enough reducing agent to give a 35-gm lead button. If appreciable bismuth is present, it will be indicated in cupellation by a brown stain at the point where last of the lead is oxidized. Bismuth causes inaccurate results, for which correction can not be made, as in case of silver.

Sodium carbonate (Na_2CO_3). Commercial carbonate or soda ash (Na_2CO_3) is sufficiently pure for assaying and should be employed. Bicarbonate is unnecessary, costs more, and is more bulky per unit of Na_2O. Na_2CO_3 acts as a basic flux and in certain cases is a desulphurizer.

Test lead is a solvent for gold and silver. In scorification assay it is oxidized to litharge, which is the principal flux. It may contain Ag and Bi, and should be tested by

scorifying four 80-gm portions, which are combined and rescorified until sufficiently reduced for cupellation.

Potassium carbonate (K_2CO_3) performs same function as Na_2CO_3; when used with the latter it gives a mixture of lower melting point. It is much more expensive, not essential, and, being hydroscopic, is an unsatisfactory reagent in moist climates.

Borax ($Na_2B_4O_7 + 10\,H_2O$) is a fusible acid flux, useful in assisting to dissolve many basic oxides. It should always be employed in form of borax glass, prepared by fusing commercial borax and pulverizing the resulting glass.

Silica (SiO_2) should be considered as an acid reagent and not a flux, because its melting points, in combination with the constituents of an ore, are higher than those generally used in assaying. When added to a charge an increase of the fusible fluxes is necessary.

Potassium cyanide (KCN) acts as a reducing and desulphurizing flux. It is useful in base metal determinations, but not for gold and silver assays. It should be of good quality. Cyanide containing any considerable amount of cyanate is absolutely worthless for some determinations.

Flour is the most convenient reducing agent; 1 gm will reduce about 10 gm of lead.

Niter (KNO_3) is used to counteract excess reducing action of some ores; it has an oxidizing power of about 4.25 gm lead per gm. Since the power varies, a determination may be necessary, preferably done against the reducing agent occurring in the ore, usually pyrite. Make up two charges, using 2 gm of pyrite, or enough ore to reduce 15 to 20 gm lead, 5 gm silica, 7 gm soda, and 60 gm litharge. In one of these charges introduce 2 gm niter, and fuse both at strong red heat. Reaction should be completed in 15 min. Weigh resulting buttons and divide difference in weight by 2, giving oxidizing power of niter. Niter also acts as a basic flux.

Stock fluxes are advisable when many assays are to be made on one class of ores, using the proportions given below under individual charges. It is often desirable to omit niter or reducing agent, adding these separately to individual assays as required.

Reagents for wet analysis and parting should be chemically pure (c p), unless otherwise stated.

Water. If distilled water can not be obtained, rain water may be used, collected after a portion of the precipitation of a shower has run off. Lacking this, chemically treated water should be used, especially for parting in gold and silver assays, where chlorine, generally present in ground waters, interferes seriously. To prepare water for parting it should be treated with a slight excess of silver nitrate, heated, and allowed to stand for at least 24 hr, then filtered or decanted. This water is used for diluting HNO_3, and for first washing. Another portion of water not treated with silver nitrate should be made slightly ammoniacal and used for second washing.

3. SAMPLING (See also Sec 25 and 29)

General procedure. Working down an original sample to the final stage is often more difficult than making a satisfactory assay, and because of the labor and care involved this operation is frequently slighted. A mine or prospect sample, as usually taken, is apt to be much less accurate than the results of assaying. (For grinding and sampling devices see Art 1.) The original sample should be reduced to small size at place of taking, unless suitable mechanical devices are available elsewhere. Table 1 assumes that the assay office will not have to deal with samples of over 20 lb (preferably 5 lb or under).

Table 1. Minimum Permissible Weight of Sample for Given Size of Ore (1)

Wt of sample		Low-grade and uniform ores		Medium ores		Rich and spotty ores	
Gm	Lb	Mm	Approx mesh	Mm	Approx mesh	Mm	Approx mesh
....	20	3.6	6	2.4	8	1.00	17
....	10	2.5	8	1.7	10	0.71	24
....	5	1.8	10	1.2	14	0.50	32
....	2	1.1	16	0.76	22	0.32	45
....	1	0.8	20	0.54	30	0.22	65
....	0.5	0.57	28	0.38	38	0.16	88
90	0.2	0.36	40	0.24	58	0.10	150
45	0.1	0.25	55	0.17	82	......	....
22.5	0.05	0.18	76	0.12	125	......	....
9	0.02	0.11	150	......	....	......	....

Best method of working down a sample can be ascertained only by experiment, and for a number of similar samples it should be determined. The size of ore particle indicated in Table 1, for a given weight of sample, is much finer than necessary in many cases. The screens used are generally multiples of 10. To save labor, the number of cuts when grinding by hand will be greater than for machine work (Table 2).

Table 2. Working down Samples by Hand and by Machine

Hand work				Machine work			
Original wt of sample	Mesh	Number of cuts	Final wt of sample	Original wt of sample	Mesh	Number of cuts	Final wt of sample
20 lb	4	....	20 lb	20 lb	4	0	20 lb
20 "	8	2	5 "	20 "	10	2	5 "
5 "	20	2	1.25 "	5 "	40	4	5 oz
1.25 "	40	2	5 oz	5 oz	120	assay	....
5 oz	100–120	assay	....	....	....	....	....
1.25 lb	40	3	2.5 oz	....	....	....	....
2.5 oz	120	assay	....	....	....	....	....

To check accuracy of sampling (see Art 9), mix rejected portions thoroughly and repeat operation. If sampling procedure is correct, results will check within limits of assay accuracy. Thorough mixing and mode of dividing sample are as important as size of ore particle. The coning and quartering method, while capable of giving good results, is liable to serious error and the use of riffles (Art 1) is much preferred. Riffles should have an even number of spaces and the sides should be kept in perfect alinement. Ore coarse enough to cause bridging must never be fed on a riffle, and a flat-bottom scoop, over which the ore is uniformly distributed, should always be used. After splitting, the two portions of a sample should differ but slightly in weight.

Metallics in an ore necessitate following procedure. A sample sufficiently large to insure an average value must be taken. This will depend on character of ore, and can be determined only by trying several samples and comparing results.

Assume an ore containing coarse gold to be ground to 20 mesh; weigh 20 A T; grind to 150 mesh and screen. Wt of metallics and coarse ore on screen, 3 gm. Scorify this with 40 gm of lead and cupel; wt of gold = 800 mg. Of siftings, weigh 0.5 A T (in gm) $-\frac{3}{40}$ gm = 14.508 gm = proportionate amount of fines in 0.5 A T of ore. Assay siftings; wt of gold = 200 mg.

$$
\begin{array}{lcl}
\text{Weight of gold in metallics from 1 A T of ore} & = \dfrac{800}{20} & = 40 \text{ mg} \\
\text{" " " " siftings " " "} & = 200 \times 2 & = \underline{400} \\
\text{Weight of total gold in 1 A T of ore} & = & 440 \text{ mg}
\end{array}
$$

or 440 oz per ton.

If metallics on screen will give a bead of more than 2 gm, scorify and sample the product, as indicated below. Ores containing nuggets are extremely difficult, and in some cases impossible, to sample by usual methods. A large sample must be taken.

Assuming it is necessary to take 50 lb of a 6-mesh rich silver ore to obtain an accurate sample: Weigh out 64.3 lb = 1 000 A T (1 lb = 15.5521 A T) and grind to 30 mesh. Metallics on screen weigh 500 gm. Flux with soda, borax, and niter if metallics contain oxidizable constituents such as sulphur, arsenic, or antimony. Weight of bar = 400 gm. Sample the bar and cupel 500 mg. At same time cupel an amount of pure silver and copper, equal in wt to the silver and base metal in 500 mg of bar. Add loss of pure silver in cupellation of latter to bead from bar sample. Say fineness equals 950. Then coarse metallics contain 380 gm silver. Of the 30-mesh product, weigh 10 A T $-\frac{500}{100}$ gm (291.66 − 5) = 286.66 gm, the proportionate amount of fines in 10 A T of original ore, and grind to 120 mesh. Metallics on screen = 8 gm. Scorify with 80 to 100 gm lead to a button of at least 60 gm, since rich gold- and silver-lead alloys are brittle. Roll button and cut sample from different portions of sheet. Cupel 6 gm wrapped in 5 to 10 gm of lead foil. Weight of bead = 450 mg; whence, 450 × 10 = 4 500 mg total silver in metallics.

Of the 120-mesh siftings, weigh 0.5 A T $-\left(\frac{500}{2\,000}\text{ gm} + \frac{8}{20}\text{ gm}\right)$ = 14.583 gm −

(0.25 + 0.4) = 13.933 gm, or 0.5 A T minus the proportional amounts of over 30-mesh and 120-mesh metallics. Resulting bead = 350 mg.

Weight of silver in coarse metallics from 1 A T	= $\frac{380\,000}{1\,000}$	=	380 mg
" " " " fine " " "	= $\frac{4\,500}{10}$	=	450 "
" " " " siftings (120-mesh) "	= 350 × 2	=	700 "
Weight of total silver in 1 A T of ore	=		1 530 mg

or 1 530 oz silver per ton.

Low-grade, spotty gold ores (2), illustrated by some from California, and Black Hills, S D, have their values so segregated that the ordinary 0.5 A T charge of 100-mesh product is unreliable. A sphere of gold 0.147 mm diam (opening in a 100-mesh screen) weighs 0.032 mg. If we conceive a $4 ore in which the particles of gold are of that diam, there would be 3 particles of gold in 0.5 A T, whence the absurdity of expecting to obtain an accurate assay portion of this material is apparent. It is necessary to take 20 to 40 A T of such ore, and as this amount is large to flux, the coarse gold is amalgamated by adding 5 gm mercury, with enough water to make a sludge sufficiently thick to hold fine globules of mercury in suspension. This is ground for 5 to 10 min in a mortar, preferably of porcelain, or a small jar mill, then thinned with water, and panned to recover the amalgam. If the mercury does not collect well, add a small quantity of sodium amalgam (Art 8; see also Sec 31). Place the amalgam in a parting flask or cup, dissolve the mercury in HNO_3, anneal and weigh the gold. The gold may contain some silver and should be inquarted and parted. The tailing is dried, mixed, and assayed, using 1 or 2-A T portions. The two results are combined in proper proportions.

Sample composition tests. Approximate composition of an ore must be known, to make up a proper charge. When ore is in lump form, this may generally be determined by inspection. If pulverized, take 5 to 10 gm in a pan or clock glass, add water and agitate; pour off fine slime and repeat if necessary. Add more water and stratify remaining coarse minerals by panning motion, then determine minerals and their approximate percentage by inspection. Do not attempt to effect a concentration; instead, remove the indistinguishable fine minerals, leaving the coarse particles so segregated that they may be identified and estimated. Treat about 1 gm of ore with HCl; rapid evolution of gas indicates CARBONATES. Allow complete action, noting percentage dissolved, which will be classed as base. Odor of H_2S may give the impression that the action is due to SULPHIDES. Mineral sulphides, however, react slowly with HCl and do not give a rapid evolution of gas. HNO_3 will not answer for this test, as it attacks sulphides vigorously and it is not possible to distinguish between the action of carbonates and sulphides. Evolution of chlorine denotes MANGANESE dioxide, and the amount of this mineral present must be judged by color of sample, remembering that pyrolusite is black. Add strong HNO_3 to about 0.25 gm ore, boil, dilute, make ammoniacal, filter or allow to settle. Blue solution indicates COPPER, and the percentage may be approximated by the depth of color. To test for ARSENIC and ANTIMONY, separate the concentrated metallic minerals from panning test, and heat with blowpipe, or in porcelain capsule, mixed with a little charcoal. Characteristic fumes of arsenic and antimony will denote their presence.

4. CRUCIBLE METHODS FOR PURE ORES

Size of lead button. Crucible method is recommended for field work, as it is applicable to all ores, permits use of large, representative samples, and reduces multiplication factor. While the charges vary for different ores the principle is the same for all. The ore is mixed and fused with such fluxes as will effect complete decomposition and solution at a reasonable temperature, thus liberating the gold and silver. The oxidizing and reducing agents are proportioned to produce 20 to 25 gm of lead, which collects the gold and silver in one button. A lead button of 25 gm is sufficient to collect the values in 1 A T of ore; a larger button is not in itself detrimental, but it must be realized that when a charge is made to yield a button of definite size, all lead reduced in excess of that amount diminishes the quantity of litharge available as a flux, and excessive reduction may thus seriously affect results. Lead buttons of less than 15 gm may or may not collect all the values, and, if adopted, this point should be proved. It is essential that the gold and silver shall be completely liberated before all the lead has settled.

Fusion. Manner of fusion is important and varies with different ores. Close attention should be given to instructions on this point, which accompany the different charges.

As a rule, a fusion should be complete in 25 to 35 min. Fusions at too low a temperature will affect recovery of both gold and silver; too high a temperature usually affects only the silver. Do not place crucibles in the furnace until it is up to working heat.

Slags. A glassy or vitreous slag, which can be drawn into threads when viscous, is generally desirable, since a slag of opposite characteristics may indicate incomplete decomposition, and may also cause poor collection of lead. Glassy slags are produced by having sufficient silica and borax present to form a solid solution with the bases. Character of slag is controlled by these reagents.

Charges for pure ores. Pure ores are composed chiefly of the ordinary rock-forming elements, with small amounts of the elements classed as impurities, viz, S, As, Sb, Cu, Zn, etc. The problem is mainly to proportion the fluxes so that the ore will go completely into solution. The principal fusible fluxes, Na_2CO_3 and PbO, are capable of readily dissolving SiO_2, but their action on the bases is rather limited. To decompose basic ores, enough SiO_2 must be added to combine with the bases in the ore and fluxes used. Different bases require varying amounts of SiO_2 to produce a slag having desirable characteristics. This is indicated in Table 3. In first column is a charge for 100% SiO_2 (acid); in third column, the charge is for 100% of the base; in second column is a charge for what may be called the neutral ores, which have just enough acid to satisfy the base and give a good slag. It is not supposed that ores will have the exact compositions indicated in these charges; but, having 3 points defined for a single base, it is easy to vary the charge according to the ore constituents. If more than one base is present the charges can be combined in proportion to the constituents. There is considerable latitude in composing a charge. With a basic ore, if enough SiO_2, or even a moderate excess, be added to affect complete combination, and then enough flux to give a slag with medium fusing point, good results will be obtained. Flour is the usual reducing agent, yielding approx 10 gm lead per gm. Amount required for a charge is not given, because, since the ore often contains reducing or oxidizing agents, it is possible to state only the total reducing action, in terms of lead; not necessarily the net reducing action, or amount of lead desired. (Remarks following the table should be studied before making use of the charges.)

Table 3. Typical Assay Charges

CALCIUM OR MAGNESIUM CARBONATE

	Acid: SiO_2, 100% (*a*)	Neutral: $CaCO_3$ or $MgCO_3$, 50%; SiO_2, 50% (*b*)	Basic: $CaCO_3$, or $MgCO_3$ 100% (*c*)
Ore	0.5 A T	0.5 A T	0.5 A T
Silica	0 gm	0 gm	15 gm
Sodium carbonate	20 "	15 "	30 "
Litharge	45 "	45 "	75 "
Borax glass	5 "	5 "	10 "
Reducing agent =	20 gm lead	20 gm lead	25 gm lead

IRON OXIDE

	SiO_2, 100% (*a*)	Fe_2O_3, 80% SiO_2, 20% (*d*)	Fe_2O_3, 100% (*e*)
Ore	0.5 A T	0.5 A T	0.5 A T
Silica	0 gm	0 gm	3 gm
Sodium carbonate	20 "	15 "	18 "
Litharge	45 "	45 "	55 "
Borax glass	5 "	5 "	6 "
Reducing agent =	20 gm lead	28 gm lead	30 gm lead

MANGANESE DIOXIDE

	SiO_2, 100% (*a*)	MnO_2, 60% SiO_2, 40% (*f*)	MnO_2, 100% (*g*)
Ore	0.5 A T	0.5 A T	0.5 A T
Silica	0 gm	0 gm	10 gm
Sodium carbonate	20 "	5 "	7 "
Litharge	45 "	40 "	70 "
Borax glass	5 "	15 "	25 "
Reducing agent =	20 gm lead	40 gm lead	55 gm lead

ALUMINUM OXIDE

	SiO_2, 100% (a)	Al_2O_3, 60% SiO_2, 40% (h)	Al_2O_3, 100% (i)
Ore	0.5 A T	0.5 A T	0.5 A T
Silica	0 gm	0 gm	10 gm
Sodium carbonate	20 "	15 "	25 "
Litharge	45 "	45 "	75 "
Borax glass	5 "	5 "	8 "
Calcium fluoride	0 "	5 "	8 "
Reducing agent =	20 gm lead	20 gm lead	25 gm lead

LOW-GRADE ACID ORES AND TAILINGS (k)

Ore	3 A T
Sodium carbonate	120 gm
Litharge	150 "
Borax glass	15 "
Reducing agent =	35 gm lead

Ore plus added SiO_2 is considered as ore for the purpose of composing charge, and fusible fluxes are added accordingly. These charges form silicates and borates with the bases. One-half A T of ore + 15 gm SiO_2 requires same flux as for 1 A T of acid ore. Excess SiO_2 above that required will do no harm, provided sufficient soda and litharge are used. It is therefore apparent that charge (c) may be used for 1 A T of acid ore. Borax glass may be omitted in many charges for siliceous ores, eliminating the more expensive flux. Its use, even when not required, does no harm. In the absence of large amounts of impurity, soda and litharge may be used in these charges to a certain extent interchangeably in ratio of 2 to 3, without objectionable results. Ores frequently contain more or less S, As, Sb, Cu, Zn, which should be oxidized. As this can be done only with litharge, the charges as given will have the greatest general application. There is no special advantage in a charge of the following type, which is in common use: Ore, 0.5 A T; Na_2CO_3, 15 gm; K_2CO_3, 15 gm; borax glass, 15 gm; litharge, 30 gm; flour, 1.75 gm. The use of litharge in above amount makes it impossible to obtain a lead button too large for cupellation, but this is of doubtful advantage. Any saving in cost of litharge is offset by the use of potassium carbonate and increase of borax. The amount of reducing agent required depends on presence or absence of reducing and oxidizing agents in the ore. Pyrite (FeS_2) up to 13% of the ore, or its equivalent, is permissible with these charges; at 13%, it replaces all the reducing agent, giving a 24-gm button. In charges (c), (g), (i), and (k) larger lead buttons are produced because of increase in size of charge. In (d), (e), (f), and (g), a lead button of 20 to 25 gm is desired, but excess reducing agent is necessary to counteract oxidizing effect of Fe_2O_3 and MnO_2. In (f) and (g), manganese as MnO_2 does not go readily into solution; high soda interferes with its reduction; borax glass materially assists dissolution. Charge should be brought rapidly to fusion temperature, the maximum being 1 050° C, or light yellow. Al_2O_3 in combination is a frequent constituent of ores (charges h and i); it slags with difficulty, and interferes with collection of lead. The use of fluorspar (CaF_2) assists in taking Al_2O_3 into solution. If omitted, soda and borax glass must be increased 100%.

5. CRUCIBLE METHODS FOR IMPURE ORES

These include ores containing enough S, As, Sb, Zn, Cu, Ni, Co, and Te, to increase slag and cupel losses, unless their effect is counteracted. For this an oxidizing charge is necessary, and as litharge is the only oxidizing agent which can be used in excess, it is employed freely.

Iron pyrite ores containing less than 13% pyrite have been discussed in Art 4. Those containing over 13% pyrite are treated by either niter or nails method. NITER METHOD gives more reliable results for gold and silver, and admits the presence of other impurities. It usually requires a preliminary assay to determine reducing power of the ore, and this, together with the large flux charge, makes it slow and costly. The NAILS CHARGE is capable of direct application, but only to sulphides comparatively free from other impurities. Gold results by this method are fairly reliable, with possible error of 1%. Silver results, except in the case of small amounts of pyrite (20% or under) are low; the loss increases with percentage of pyrite, reaching 10% with pure pyrite. When in doubt whether an ore is pure or pyritic, the nails charge may be used satisfactorily, even though the pyrite present is less than that requiring this charge.

Niter method. In this the KNO_3 oxidizes all the FeS_2 in excess of that required to reduce the desired amount of Pb, the remaining FeS_2 being oxidized by litharge. To obtain the required definite state of oxidation, a relatively large amount of base is necessary, in which case the S is completely oxidized to SO_3.

Preliminary charge. The reducing power of an ore must be known, to determine the amount of niter required. A knowledge of the ore may furnish the information, or, with sufficient experience, it may be determined by panning. Preliminary fusion is generally necessary, using following charge and calculation:

Ore....................	0.1 A T
Sodium carbonate.......	7 gm
Litharge...............	50 "
Wt of lead reduced.... =	W

$$\frac{(W \times 5) - 20}{4.5} = X \text{ gm } KNO_3$$

or

$$\frac{W - 4}{0.9} = X \text{ gm } KNO_3$$

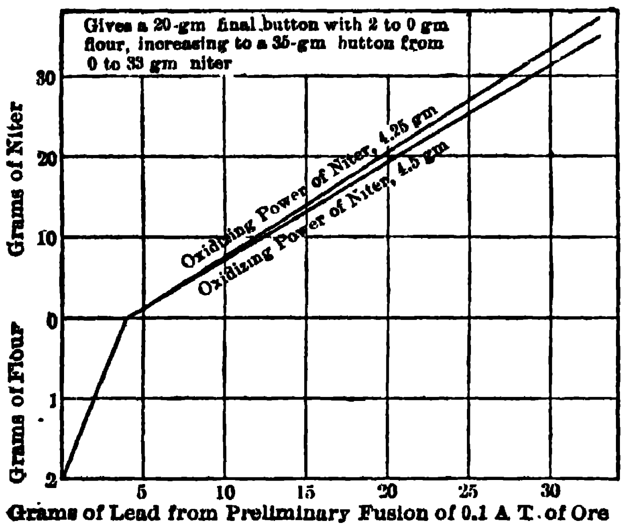

Fig 3. Reduction Diagram for Impure Ores

Charge should be fused in 10 to 12 min, at a light yellow (1 050° C). Slow fusion, or too long a time in the furnace, gives low results. The chart (Fig 3) will eliminate calculations, or HAWLEY'S METHOD may be employed. Weigh out 3.24 gm ore (instead of 0.1 A T) and fuse with the above charge. Place lead button obtained in left-hand scale pan, and suspend a 5.55-gm weight from hook on opposite end of beam (The 3.24 and 5.55-gm wts are based on niter having oxidizing power per gm of 4.5 gm lead.) Balance with niter, thus obtaining the amount required for final charge. The special weights are readily cut from lead; the larger one is suspended by wire from the pan hook. If the lead button from preliminary charge weighs less than 5 gm, or fails to counterbalance the 5.55-gm weight, reducing agent and not niter is required.

Table 4. Final Charges

Over 50% SiO_2 in ore		Under 50% SiO_2 in ore	
Ore..........................	0.5 A T	Ore..........................	0.5 A T
Sodium carbonate..................	10 gm	Silica..........................	6 gm
Litharge..........................	75 "	Sodium carbonate................	15 "
Potassium nitrate..................	X "	Litharge........................	100 "
		Borax glass	6 "
		Potassium nitrate............	X "

Final fusion. Lead button of 20 to 25 gm is desirable for ores containing less than 50% pyrite; for more than 50%, the button should weigh 25 to 35 gm, the size increasing with proportion of pyrite. Success of this charge is largely dependent on manner of fusion, especially in high-pyrite ores. For low to medium amounts of pyrite, a temp of 1 000° to 1 050° C (yellow heat) is satisfactory. For larger percentages, a high initial temp is essential, say 1 050° to 1 100° C (light yellow) maintained for 10 min, or until charge is thoroughly liquid. Temp of furnace is then lowered, and fusion continued for 15 to 20 min. Charge should not be allowed to reach original high furnace temp, or silver losses will increase. This fusion should be made in a high-grade crucible, like the Battersea soft clay pot (not to be confused with the hard clay crucible). There is but little boiling in these fusions, and the dry charge may fill 3/4 of the crucible. From 75 to 100 gm litharge is used to insure complete oxidation of S to SO_3, which combines with Na_2O, forming Na_2SO_4. This floats on slag as a thin liquid, forming a white crust on cooling.

Nails method is essentially reducing, with no attempt at oxidation. Sulphur is absorbed in slag, size of lead button is regulated by adding only sufficient litharge, and

button is desulphurized by nails. It is therefore apparent that impurities can not be oxidised, and have a tendency to concentrate with the lead. Charge is:

Ore	0.5 A T	Borax glass	10 gm
Sodium carbonate	30 gm	Nails (10 d)	4 "
Litharge	25 "	or 1 R R spike	

If ore is high in pyrite, or contains a large amount of base, borax glass should be increased by 5 to 10 gm. Fusion should be at temp of 950° to 1 000° C (yellow), and requires 25 to 40 min. Avoid a strongly oxidizing furnace atmosphere, which produces an unsatisfactory fusion. In withdrawing nails, shake well while their points are immersed in slag, and not simply knock against side of crucible.

Copper ores. Presence of copper up to 5% does not interfere in charges which contain litharge in excess of that which is required for a lead button (Art 4). Copper does not interfere in the fusion of an ore, but has a strong tendency to contaminate the lead button. If the button contains about 8% Cu, or more, it will freeze if cupeled at 700° to 750° C ("feather temperature"). If button contains 5% or less of copper, it will cupel at a lower temperature than pure lead. Even though copper is present in amounts insufficient to cause a freeze, it is detrimental, increasing the loss. While some copper remains in bead, the amount is less than the induced loss, giving low results (especially for silver). Both this loss, and the amount of copper retained, increase with proportion of copper in the lead button. Therefore, copper in excess of 2% of the lead is not advisable. Copper is eliminated from the lead button by large quantities of litharge, either added in the charge or formed by scorification. Amounts of ore and the charges indicated below are intended to give final lead buttons containing less than 2% copper; 2 to 3% copper will stain cupels gray green, shading to a lighter color at center. A blackish-green indicates presence of too much copper. While 175 gm of litharge is given for all charges, it should be reduced when copper is lower than stated. If a scorification is not feasible and ore is rich in copper, the ore charges must be smaller, without diminishing quantity of flux; thus,

Copper 20%, use 0.5 A T		
" 45%, " 0.5 "		and scorify lead buttons + test lead.
" 60%, " 0.25 "		run 4 charges, combine buttons 2 by 2, and scorify.

Note.—In SCORIFYING BUTTONS, add sufficient test lead to make total lead 50 to 70 gm, depending upon amount of copper; 70 gm lead scorified to 15 gm will slag about 75% of the copper. Add about 2 gm SiO_2 to prevent cutting of the scorifier. This does not increase copper in the lead button, for, if not introduced, its equivalent will be taken from the scorifier. Temperature should be low, as there is no mineral to decompose. When lead buttons are not too large for cupellation, and amount of copper not excessive, time is saved by melting the buttons with a cover of 50 to 60 gm litharge for 10 to 15 min in a scorifier, and pouring. About 75% as much copper is removed by this method as by scorification.

Oxidized ores include those which do not contain reducing agents in excess of that required to produce suitable lead buttons.

Acid Gangue		Basic Gangue	
Ore	0.25 or 0.5 A T	Ore	0.25 or 0.5 A T
Sodium carbonate	15 gm	Silica	X gm
Litharge	175 "	Sodium carbonate	15 "
Borax glass	5.0 "	Litharge	175+ "
Reducing agent	= 25 gm lead	Borax glass	5.0 "
		Reducing agent	= 25 gm lead

Note.—It is a disadvantage to produce lead buttons much in excess of required size, especially when scorification follows, because while copper content decreases in percentage it increases in total amount.

For copper ores with basic gangue, see Art 4 to determine amount of SiO_2 to add; then increase soda and litharge in proportion. The minimum of SiO_2 which gives a good fusion should be used, as it directly affects the advantages of large amounts of litharge.

Sulphide ores, or those which have an excess reducing action.

Ore	0.25 or 0.5 A T	
Sodium carbonate	15 gm	
Litharge	175 "	
Potassium nitrate (see above note)	X "	to produce 25-gm Pb button

PRELIMINARY CHARGE:

Ore	0.1 A T	For 0.25 A T charge $\frac{(W \times 2.5) - 25}{4.5} = X$ gm KNO_3
Sodium carbonate	7.0 gm	
Litharge	50.0 "	For 0.5 A T charge $\frac{(W \times 5.0) - 25}{4.5} = X$ gm KNO_3
Lead reduced = W gm		

(See iron pyrite, niter method, for principles and method of fusion.)

SiO_2 or borax glass should not be added to these charges without greatly increasing the litharge. Fusions are made, if possible, in Battersea 20-gm soft clay crucibles, as they withstand the action of charges better and furnish less silica.

Arsenic and antimony ores, being similar in behavior, are considered together. When present in an ore to any great extent these elements occur as stibnite (Sb_2S_3) and mispickel (FeAsS). The quantity of arsenic or antimony in silver minerals is generally insufficient to require special treatment, but should the amounts present require attention the same principles apply as for Sb_2S_3 and FeAsS. The tendency to high slag and volatilization losses, particularly of silver, and the resistance of oxides of As and Sb to moderate amounts of flux, are the principal difficulties in assaying these ores. A strongly oxidizing charge is generally required to decompose the minerals completely. This is not always necessary, but the use of nails is not permissible, because a speiss, carrying values, will be produced when arsenic is present. For ores containing 5 to 10% As or Sb, the charge may be composed as dictated by the principal mineral constituents, possibly increasing the litharge, and varying the amount of reducing agent. Above 10%, a large proportion of litharge should be used.

	(a) FeAsS to 75% Sb_2S_3 to 50% Acid gangue	(b) FeAsS to 100% Sb_2S_3 to 75% Acid gangue	(c) Sb_2S_3 100%
Ore	0.5 A T	0.5 A T	0.25 A T
Silica	....	6 gm	6 gm
Sodium carbonate	15 gm	15 "	15 "
Litharge	75 "	90 "	75 "
Potassium nitrate	X "	X "	X "

Quantity of KNO_3 is determined by preliminary fusion. For principles, and formula for charges (*a*) and (*b*) see pyrite charge (Art 5). For charge (*c*) use,

$$\text{Weight of lead reduced} = W; \quad \frac{(W \times 2.5) - 2.5}{4.5} = X$$

Zinc ores containing no more than 5 to 10% Zn do not affect method of assay. The difficulty in assaying ores high in zinc is to slag the zinc completely after it is oxidized, so as to prevent loss of gold and silver by volatilization with the zinc, and by slag and cupel absorption. To accomplish this, the proportion of flux to ore is usually large. An oxidizing method is necessary where zinc is present as sulphide in gold and silver ores. If the zinc is in an oxidized state, a charge is used similar to those for pure ores (Art 4), the exact composition depending upon proportion of acid and base, but increasing the relative amounts of fusible fluxes. For sphalerite ores containing up to 35% ZnS, having excessive reducing power, use niter charge as for iron pyrite (Art 5). With zinc above that amount, increase soda and litharge, adding SiO_2 and borax glass if ore is of low acidity. MAXIMUM QUANTITIES, for 100% ZnS, are as follows:

Ore	0.5 A T	Silica	5.0 gm
Sodium carbonate	15 gm	Borax glass	10 "
Litharge	120 "	Potassium nitrate	X (see above)

Telluride ores. Tellurium, when present, is nearly always combined or alloyed with gold or silver. The smallest amounts therefore require attention. With only 0.1 or 0.2%, its interference is confined to slag losses; but as it increases there is a tendency to concentration in the lead button, resulting in increased cupellation losses, with a possible spitting of the bead. In extreme cases it may cause complete absorption of gold and silver by the cupel.

	(a)	(b)	(c)
Ore	0.5 A T	0.25 A T	0.1 A T
Sodium carbonate	0.33 "	0.33 "	0.33 "
Litharge	3.5 "	3.5 "	3.5 "
Silica	0 gm	2.5 gm	5.0 gm
Borax glass	10 "	10 "	10 "
Reducing agent	= 25 " lead	= 25 " lead	= 25 " lead

For ores up to 300 oz of gold and silver use charge (*a*); above that amount use (*b*), except for specimens composed largely of telluride, in which case (*c*) is preferable. Charges should be fused at moderate temperature, though it is possible to have too low a temperature, giving low results, probably due to incomplete decomposition of the tellurides. Charge of litharge is high, to give a low melting, highly oxidizing slag, which oxidizes the tellurium, liberating gold and silver. Gangue of telluride ores is generally acid, but if basic, the borax glass must be increased or SiO_2 added. SiO_2, however, should not be added in excess of requirements, as it diminishes the oxidizing effect of litharge and will defeat the desired object. SiO_2 is added in (*b*) and (*c*) to assist in forming a clean slag.

Lead ores are the simplest to assay for gold and silver, because the lead present acts as a reagent. Oxidized ores should be run as acid or basic (Art 4), depending upon the gangue. As the lead increases the required amount of flux decreases. If the ore has excess reducing power, the niter method gives best results, though the nails method may be used (Art 5). With proper equipment, the scorification method is the simplest for lead ores.

Nickel and cobalt ores, carrying appreciable amounts of gold and silver, are uncommon except at Cobalt, Canada, and neighborhood, and in this case the gold is negligible. Ores of this district are often very complex, containing large amounts of As, Sb, and Bi, besides the Ni and Co. Metallic silver in pieces of considerable size is an important feature of these ores. Nickel and cobalt are readily reduced with lead in fusions, and, depending upon amount, interfere with or prevent cupellation, by formation of infusible oxides coating the lead. Experience with these ores indicates a choice of several different methods. If metallic scales are present they must be removed and assayed separately (Art 3). For ores up to 100 oz silver, crucible method seems preferable. The crucible and scorification methods give equally good results on 100 to 500-oz ores, above 500 oz, scorification is more reliable. For ores containing large amounts of impurities, particularly bismuth, it may be desirable to use a combination method (3), treating with HNO_3 either the ore before fusion, or the lead button obtained from fusion of the ore. These statements are general and considerable latitude should be allowed in their application.

	Crucible (*a*)	Crucible (*b*)	Scorification	
Ore	0.5 A T	0.25 or 0.5 A T	Ore	0.1 A T
Sodium carbonate	0.66 "	0.75 "	Silica	0.1 "
Litharge	2.5 "	3.5 "	Test lead	75.0 gm
* Silica	0.3 "	0.33 "	Borax glass	2.5 "
† Borax glass	0.33 "	0.66 "	Note.—SiO_2 not required in very acid ores.	
Reducing agent	= 20 gm Pb	= 25 gm Pb		

* Charge of SiO_2 depends on quantity in the ore. † Borax glass used as a cover.

For the less impure ores charge (*a*) may be used. Very impure ores require charge (*b*), using $^1/_4$ or $^1/_2$ A T, depending upon value and total impurities. In some cases scorification of the lead buttons is necessary or desirable.

6. SCORIFICATION (3)

Limitations. This method is treated briefly here, because, for field work, it is less convenient and has a smaller range of service than the crucible method. It is not suitable for highly basic ores, nor for gold and low-grade silver ores, unless several portions of the sample are run and the buttons combined, to reduce the multiplication factor and the percentage loss, which is usually high due to the small amount of silver present. Good results are obtained on acid ores, but it is best applied to impure ores in which the oxidizing action decomposes the impurities and throws them into the slag.

Charges are closely similar for all ores. They vary from 0.1 to 0.2 A T of ore, 50 to 75 gm test lead and 1 to 3 gm borax glass, depending upon amount and character of impurity present. Ore is mixed with half the test lead in bottom of scorifier and covered with other half, over which the borax glass is spread. Charge is placed in muffle at light yellow heat (1 000° to 1 100° C), and door closed. When charge is thoroughly melted, the muffle door and damper are opened to give a good draft, and temperature is slightly lowered. Slag should be perfectly fluid at all times; it should appear red hot from the lead almost to its surface contact with scorifier, and not merely where the hot litharge from oxidation of lead runs into slag. If sulphur is present, little grease-like patches of Na_2SO_4 will float on the slag, and the furnace should be hot enough to keep these molten, and, as the assay progresses, to cause the slag to run up side of scorifier by capillary action. With an excessive amount of reducing minerals present, the assay will not show

rapid decomposition and solution of the ore, because principal flux is litharge, which can not form to any extent until the reducing agents are oxidized. Oxidation proceeds until the lead is from two-thirds to completely covered by slag; charge is then poured.

7. CUPELLATION

Characteristics of cupels. Separation of lead from gold and silver by cupellation depends upon the high surface tension of the latter metals, which prevents them from sinking into the pores of the cupel, while the fluid PbO is readily absorbed. Any material with a high melting point, not attacked by litharge, and in granular form, may be used for making a cupel. Magnesia, Portland cement, and other substances are used to a limited extent, but bone ash is the most common. Several brands of manufactured cupels are on the market, but there is no special advantage in using them. Bone ash in bulk will stand all conditions of transportation, even to a thorough wetting; and, as cupels can be made with a hand mold at the rate of 100 per hr, the final product is cheaper. A cupel should have a smooth surface, and readily absorb its own weight of litharge without cracking. Cracking is usually due to the cupel being too dense; excessively fine bone ash, too much water or pressure, favor this condition. In making cupels there is no better bonding substance than water, the amount used being so proportioned to the pressure that the cupel will be firm enough to handle, but will break when dropped 8 or 10 in; they become much harder on standing. The cavity of a cupel should approximate the surface of a sphere, with a radius equal to half the diam of cupel and a depth two-fifths of radius; the rim may be angular or preferably rounded (Fig 4). This will give a capacity for lead of 20 to 25 gm, 30 to 35 gm, and 40 to 45 gm, for a 1-in, 1.25-in, and 1.5-in cupel respectively. Weight of the cupel should be greater than its capacity for lead.

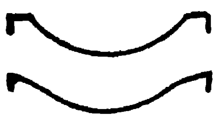

Fig 4. Shape of Cavity in Cupels

Operation. Ordinary bone ash, air-dried cupels should be placed in the muffle close together in transverse rows, sufficiently far back for uniform temperature. Broken rows should always be in the rear, and an empty row, or a fire-clay bar should protect the front row from drafts. After heating 5 to 10 min with furnace at 850° to 900° C (light cherry), insert the buttons. As soon as buttons "uncover," open muffle draft and lower temp to 700° C (below full cherry red), as the burning lead produces considerable heat. When near the end, raise temp to about 800° C. This finishing temp is extremely important; if excessive, large losses will occur and small beads may entirely disappear. A carefully made cupellation will always show a ring of litharge crystals surrounding the bead at a distance of $^1/_8$ to $^1/_4$ in. In case of gold ores, silver should be added before cupellation (Art 8), saving subsequent inquarting and practically eliminating gold losses.

Sprouting is caused by vigorous expulsion of oxygen on rapid solidification of precious-metal button. It is often difficult to prevent, but is minimized by a high finishing temperature and slow cooling. Sprouting does no harm unless particles of the bead are completely ejected or are broken off in cleaning.

Freezing is caused by too low a temp, or presence of impurities. In a low-temp freeze, if remaining lead is less than 5 gm, add test lead to make at least this amount and raise temperature. A piece of wood inserted in muffle will assist "reopening." When cupellation has started, lower the temperature rapidly; best done by placing in the muffle a piece of fire brick or its equivalent. If properly reopened, the results, though questionable, may be satisfactory. Freezes due to impurities may sometimes be recovered by adding considerable test lead and raising temp. Results are unreliable.

Beads are cleaned by squeezing in stout pliers until the base is distorted, and then brushing. Beads need not be weighed closer than 0.02 mg of the exact weight, except when the multiplication factor is large.

8. PARTING AND INQUARTING

Parting of the gold and silver is done preferably in Royal Meissen capsules (Fig 5), 45 mm diam, using first 1 to 12 HNO_3 and heating just below boiling until action ceases, decanting with cup turned well over; then treating with 1 to 1 HNO_3, heating just below boiling for 10 min, decanting and washing once or twice with distilled or treated water (Art 2). Always decant closely. Dry the residue and ignite in muffle or over flame. Take utmost care to prevent gold from breaking up; hence, at first use weak acid and avoid boiling. Flattening the bead to $^1/_3$ its original diameter is helpful, by increasing surface of attack. Parting cup should be free from stains, and the gold should have yellow color after ignition.

If a bead contains less than 4 of Ag to 1 of Au, complete separation may not be affected by parting as described. But, as little as 2 of Ag to 1 of Au may be completely separated by boiling in 1 to 1 HNO_3, if bead is less than $^1/_{64}$ in thick. Beads containing more than 25% Au may be treated directly with strong acid and boiled without breaking up. It is impossible always to tell by appearance whether a bead will part; 60% Au produces very slight color, and, when a bead is near the parting ratio limit, the acid action and color change are practically the same whether the bead parts or not. Pure gold color of the treated bead is no criterion of complete parting. A properly treated bead must have parted if it has lost at least 80% of its wt, without boiling, or at least 66%, with boiling; this is best indication of complete parting.

Fig 5. Parting Dish

Inquartation, or the addition of silver to a bead, is performed by wrapping the bead with silver, in ratio of 1 gold to 4 to 10 silver, in 2 to 5 gm of lead foil, and cupeling.

Temperature must be quickly dropped after starting, else the buttons, being small, will finish at the high initial temp. Silver foil may be added directly to the ore charge, or if silver is to be determined, a measured amount of standard $AgNO_3$ solution may be used, 5 c c being permissible. Since all the silver is not recovered, the value of this solution must be determined by assay of a blank charge.

Weighing gold. Since 0.01 mg Au from 0.5 AT = 40¢ per ton, Au weights must be checked; best by weighing singly and together.

Gold in pannings may be separated from other minerals by blowing, if the sample is perfectly dry. This method is not recommended, and is permissible only in absence of very fine gold. It is better to add a globule of mercury to the gold, either in pan or small mortar, and rub them together. If the gold fails to amalgamate, add 50–200 mg of sodium amalgam. (SODIUM AMALGAM is prepared by adding metallic sodium in pieces, $^1/_4$-in cube or less, to mercury, pressing the pieces beneath surface of mercury and against bottom of container with pestle or rounded stick. If large pieces of sodium are added, objectionable explosions will occur. Continue adding sodium until the amalgam becomes pasty. Keep the amalgam under gasolene or light oil.) There is no objection to adding enough sodium amalgam to the original mercury to cause a slight adherence to iron. The gold amalgam is placed in a parting cup, treated with dilute (1 to 1) HNO_3, washed, dried, and weighed (see Parting). Residue is not pure gold; its fineness is determined by taking 500 mg and inquarting, as above, with silver approximately equal to 2.5 times the actual gold content. Hammer or roll the bead to less than $^1/_{32}$ in, and part in a flask with dilute (1 to 1) HNO_3, giving two separate treatments, boiling each for 10 min. Wash, anneal, etc. If gold is of varying composition, the total product from pannings must be melted together and sampled. The fineness obtained represents the acid-treated product and not the fineness of original gold. A fineness determination made on original gold should not be used in calculations based on the weights obtained from acid-treated amalgam.

9. CHECK ASSAYS AND SALTING

Concordant results on duplicate assays are not conclusive evidence of accuracy, especially when samples are run under the same conditions. Greater weight can be given to checks when varying weights of ore are taken and run at different times. Checks obtained by DIFFERENT METHODS are the best indication of accurate results. When it is undesirable to run duplicates on many samples, the work as a whole may be checked by weighing out extra and equal portions from each ore when the original charge is made up, and carefully mixing and assaying these extra portions. If this work has been carefully done, the composite sample should give results that check to the second decimal the average obtained from the individual samples. (See also Sec 29, Art 8–11.)

Salted assays. To determine whether an assay sample is salted is often difficult. The crude plan of introducing metal filings may easily be detected with a pan and microscope. When fine native metal is employed the problem is more difficult and conclusions less certain. If ore is coarse, the finer material should be screened out and assayed separately from the coarse. The fines will undoubtedly run higher, but if the discrepancy is great there may be reason for suspicion. Where the material used in salting has a different origin than that in the ore, a test of its fineness may bring out this point. Pulverized samples, salted with rich concentrates derived from the same ore, will pass as genuine and can not be detected. If the sample is not ground, the fines should be screened out and the coarse product crushed to produce another portion of fines about equal to the first, which is then separated from the remaining coarse portion. In a normal sample, assay results of the two fine portions should not, as a rule, vary greatly. When salting is

done with solutions, some of the rock components will frequently decompose the original salting, rendering the metal insoluble and frustrating efforts at detection by solution of the metallic compound. The ore may be tested for the acid radical originally associated with the metal. Gold and silver are the only metals likely to be introduced by this method, with a chloride radical for the former, and a nitrate for the latter. Rocks are apt to contain chlorides, and the nitrate may be decomposed. But, a sample which assays high in gold or silver and, even under the microscope, shows no free gold, nor silver minerals, nor minerals which usually contain or are associated with these metals, may be strongly suspected of having received their values from unnatural solutions. See Sec 25, Art 9.

Accidental salting is more frequent; in fact, it occurs to an extent unappreciated by the average engineer. This is particularly true where miscellaneous samples are being treated. The most common source of contamination is in the grinding apparatus, and is at its maximum when small samples are being successively ground, some of which contain metallics. It is almost impossible thoroughly to clean grinding appliances without grinding therein a prohibitive amount of barren material. Pores in the grinding surfaces become filled with ore; particularly when metal is present, which is gradually fed out as the iron surfaces are abraded. Separate apparatus should be used for low- and high-grade samples. Where this is not practicable, barren material is ground after high-grade samples, and in case of gold and silver this material is assayed if the samples which follow are important. Another source of salting is in using old crucibles. This practice is unobjectionable if high- and low-grade pots are kept separate. All reagents, bone ash, and cupels should be protected from dust, especially when rich materials are being handled. Blank assays should be made occasionally on these products to test their purity.

10. PLATINUM METALS (11)

Qualitative tests, To differentiate and determine the metals of this group require considerable equipment and a skilled analyst. Many published methods will not give accurate results, and others only under certain conditions. Platinum, iridium, and palladium are the three most important. The first two come mainly from placer deposits, the last occurring more frequently, though in small quantities, with gold and silver in rock formations. As compared with gold and silver, their important assaying properties are as follows: Melting point: silver, 961°; gold, 1 063°; palladium, 1 550°; platinum, 1 755°; iridium, 2 300° C. If cupellations are finished close to the minimum permissible temperature for gold and silver, 5% of palladium and less of platinum and iridium, will produce a frosted bead. Frosting may also be produced on an ordinary bead by sudden chilling just before the finish, but solid litharge is then generally present on the cupel surface. Larger quantities of the platinum metals produce a rough bead, of leady appearance. HNO_3 dissolves silver and palladium, giving, with the latter, a yellow to reddish brown solution, depending on concentration; 10 c c of dilute HNO_3 solution, containing 0.15 mg of palladium, in a parting cup, has sufficient color to be detected when matched against distilled water. When alloyed with silver, platinum is also soluble in HNO_3, though not completely. The solution is only slightly colored, but may appear dark, due to colloidal platinum. Gold and iridium are not attacked. Hot concentrated H_2SO_4 dissolves silver and slowly attacks paladium; the other metals are unaffected. Aqua regia converts silver to chloride and dissolves palladium, gold, and platinum, but not iridium, except with vigorous treatment or when alloyed with platinum. All these elements, except silver, give colored solutions, which range from yellow through orange to dark red, depending on the combination and concentration of the metals. Oxalic acid precipitates gold from slightly acid solutions, but not the others. Potassium or ammonium chloride in concentrated solutions will precipitate platinum and iridium, but not gold or palladium in its usual condition. Potassium iodide, even in dilute solutions, with gold, gives free iodine; with platinum, brownish red color of potassium platinic iodide; with palladium, a black precipitate soluble in excess. This last reaction is extremely delicate. Dimethylglyoxime precipitates palladium completely, platinum less readily. Silver precipitated as chloride in presence of palladium and platinum is contaminated by these metals. Platinum metals concentrate in lead buttons with gold and silver in the usual method of assay, but unless present in sufficient amounts to affect cupellation or parting are apt to be overlooked. If parting acid is evaporated to small bulk a few hundredths of a mg of palladium will produce a color. When platinum is present the parted residue is likely to be finely divided. Iridium may show as dark spots on the gold.

Methods of assay. For ores and black sands, large samples, 10 to 20 A T, are frequently necessary to yield sufficient metal. Samples are fused in several portions (Art 4 and 5), and lead buttons are combined by scorification. Platinum concentrates are fused

with lead, producing a 1 to 6, brittle, non-homogeneous alloy, which is pulverized for sampling and assay. An approximate knowledge of the metal content is necessary for good results, and the first assay may serve only as preliminary. Alloy for cupellation should contain at least 7 times as much gold as platinum metals, and silver 2.5 times the gold, these being added if necessary. Wrap alloy in sheet lead, cupel, finish rather hot, and allow to remain in muffle 10 min after bead has set. Weigh, flatten to 0.5 mm, and if palladium is absent, part with boiling concentrated H_2SO_4 for 15 min in a flask, inserting a glass rod. (A glass tube 3 mm diam, sealed with a blowpipe flame 2 mm from the end, leaving a small cavity, prevents violent bumping.) (**Note.**—A yellow or orange solution indicates palladium, in which case this procedure is not applicable.) Decant and repeat. Wash twice, transfer to annealing cup, heat, and weigh. If silver ratio has been very high the parted residue will be so finely divided that some may decant with solution; hence, solution must be diluted, filtered on ashless paper, and ignited with main residue. Loss in weight is silver. Inquart with silver 2.5 times the weight of gold, flatten bead and part in dilute (1 to 1) HNO_3, giving two treatments, boiling for 15 min in parting flask, washing twice. Repeat inquartation and parting. Anneal and weigh gold, plus iridium, if present. Loss in weight is platinum. When only small quantity of platinum is present, one inquartation and parting with HNO_3 suffices. To test for iridium dissolve the gold in cold dilute aqua regia (HNO_3 1, HCl 3, water 5, parts); residue is iridium. Results obtained as above are fairly accurate, and if a check of pure metals, duplicating the assay, is run at same time, errors are largely eliminated. When palladium is present, the H_2SO_4 parting is omitted, and the bead treated with HNO_3 as described. In absence of platinum the HNO_3 is nearly neutralized, and palladium is precipitated with dimethylglyoxime, heating for an hour and allowing to stand over night. Filter, ignite, and weigh palladium. When platinum is present, repeat inquartation and parting if necessary, dilute the solution considerably, precipitate silver with HCl, filter, evaporate solution nearly to dryness, add HCl, evaporate again, and repeat. Add a saturated solution of ammonium chloride and allow to stand over night. Filter on ashless paper, wash with 75% alcohol, ignite, weigh Pt. Palladium may be precipitated as described above. Unless errors have compensated, results will be only approximate.

11. COPPER AND LEAD

The following methods for copper presuppose that the metal is soluble in acids. Ores which are not decomposed as described require use of hydrofluoric acid (H F) or a fusion.

"Slop cyanide method" is not suitable for all ores, but where interfering elements such as Ag, Zn, Ni, Co, and certain other elements to a lesser extent, are absent or present in small amounts, the results are remarkably satisfactory. It is most useful when a large number of determinations are to be made on fairly uniform ore, and a high degree of accuracy is not required. Success with this method depends upon a strict uniformity of conditions, as to quantity of chemicals used, volume and temperature of solution, and rate of adding cyanide. Cyanide solution, containing 22 gm c p KCN per liter, or half that amount for low-grade ores, is standardized against an aver sample of the ore to be assayed, a check on the solution being run every few days with the ore samples. Copper content of standard sample is accurately determined by electrolytic or iodide method.

Treat 0.5 to 1 gm of ore with 10 c c HNO_3, of 1 42 sp gr, in a 6-oz copper flask, or 20 c c of dilute (1 to 1) HNO_3 containing 80 gm $KClO_3$ per liter. Boil until all the lower oxides of nitrogen are expelled, add 25 c c of water and enough ammonia to give an excess of 5 to 10 c c, usually 20 c c. Cool, titrate to a faint blue, filter, drain (washing unnecessary), and finish titration of filtrate. The end point is not particularly sharp, and a definite end tint must be selected. For large amounts of work, a dozen burettes will be found convenient, titrating this number of assays at one time, as it is necessary to allow the ferric hydrate to settle when the end point is approached, in order to observe color of solution. Dispensing burettes for reagents are a convenience.

Iodide method, for accuracy, is not surpassed even by the electrolytic method as usually carried out, and, as it requires less expensive and elaborate equipment, is given the preference here. A solution of sodium thiosulphate containing 19 gm per liter, or one-half that strength for low-grade ores, is necessary. STANDARDIZE by dissolving 200 mg of copper, or 100 mg for the weak solution, with 5 c c of (1 to 1) HNO_3, in a 6-oz flask. Boil until lower oxides of nitrogen are expelled, add 5 c c of bromine water and continue boiling until the bromine is eliminated. Add ammonia until the solution just turns deep blue and boil vigorously for a few minutes, or until the ammonia is nearly expelled. Acetic acid is then added, 2 or 3 c c in excess, and if any precipitate fails to dissolve, the solution is boiled. Cool, dilute to 50 c c, add 3 gm potassium iodide and

titrate with hypo until the brown color fades to a light straw. Add starch solution until the solution becomes a decided blue, and finish titration slowly towards the end. (STARCH SOLUTION is made by dissolving 2 or 3 gm soluble starch in 100 c c of boiling water and allowing to cool. Lacking soluble starch, pour an emulsion of ordinary starch into boiling water, boil for a few minutes, and allow to cool. Starch solutions do not keep well, but Low states that a few drops of oil of cassia will preserve them perfectly.)

Decompose 0.5 to 1 gm of ore with 10 to 15 c c of strong nitric acid and 3 to 5 c c of hydrochloric acid in a 6-oz wide-mouthed Erlenmeyer flask, boiling until red fumes disappear. Add 6 to 10 c c of concentrated H_2SO_4 and continue heating until SO_3 fumes appear, then give the flask a circular motion over a free flame until SO_3 vapors are visible only at the mouth of flask. Allow to cool, add 20 c c of water, boil, filter, and wash. The copper may be precipitated from this solution, after diluting to 50 or 75 c c, by boiling with 2 pieces of aluminum foil, 1.5 in square (bend corners 90°, having adjacent corners bent in opposite directions). After complete precipitation, the copper is filtered out, care being taken to prevent oxidation and re-solution. Dissolve copper in beaker, treating aluminum foil with dilute (1 to 1) HNO_3, and titrate as in standardizing.

If a MUFFLE FURNACE is available, the following method is preferred. The filtered sulphate solution is diluted to 50 c c, brought to boil, and a hot 50% solution of thiosulphate is poured in slowly until the precipitate which forms turns black; boil 3 to 5 min, until the supernatant liquid is clear, filter, and wash with hot water. Allow to drain, fold filter, and place in scorifier or clay annealing cup and ignite in muffle at barely red heat until completely oxidised. Transfer to flask, dissolve in (1 to 1) HNO_3, and proceed as in standardizing. The thiocyanate or permanganate (4) method for copper has become deservedly popular and is extensively used on the so-called porphyry ores.

Lead; fire assay. Weigh 10 gm of ore and mix with 25 to 30 gm of the following flux in 10 or 15-gm crucible: Na_2CO_3, 38 parts; K_2CO_3, 38; borax glass, 15; flour, 9 parts. Insert 4 10-d nails, points down, place in furnace at 750° C (cherry red), and hold for 1/2 hour, or until reaction nearly subsides. Then raise temp to 1 050° C (yellow to light yellow), leaving pots in furnace until reaction, which has become more vigorous, ceases, except possibly for slight bubbling around nails. This usually requires about 15 min. The degree and control of heat, varying somewhat for different ores, are of utmost importance. Therefore the temperatures and times given above are more indicative than exact. Results by this method are in the average 1 to 2% low, but in the presence of other reducible metals they may be very high.

12. TIN

Vanning test is unreliable as an assay, on account of the loss of fine tin and the retention of foreign minerals. Shipments supposedly of black tin, from Nigeria, as determined by this method, were found to contain 4% and less of that metal. The test may be of use in ascertaining possible recovery, but this requires a knowledge of the percentage of tin in concentrate produced. SPECIFIC GRAVITY of a tin concentrate is a fair index of the metal content, and when the relation is ascertained for a given product a close approximation may be obtained (5).

Fire assay (6) is applicable only to a high-grade product free from other reducible metals. For ores, this involves a preliminary concentration, with its attendant loss which may reach 30% of the tin. Results on a properly cleaned concentrate are, however, fairly accurate. To assay an ore, crush to 40 or 60 mesh, to liberate the tin minerals, taking care to produce a minimum of slime. Weigh a portion to yield about 10 gm of concentrate, and pan. If the concentrate contains oxidizable material, it is roasted and soluble constituents removed by boiling in strong nitric acid. After drying, mix the concentrate, or a 10-gm portion of it, with 30 gm of pure potassium or sodium cyanide, and place in a crucible having 5 gm of cyanide in the bottom; cover with another 5 gm. Charge is fused for 20 to 30 min at a good red heat (750° C), cooled, and crucible broken. Prills of uncollected tin are recovered by crushing slag and panning.

Volumetric assay. Best wet methods are those of Beringer (7) and Pearce-Low (8).

Pearce-Low method. Ore must be crushed to at least 100 mesh, and portions of 0.2 to 2.5 gm are weighed. Add to 5 times its weight of sodium peroxide, and fuse in a nickel crucible. Should the ore contain readily oxidized material, melted peroxide is allowed to solidify and the ore gradually added to the hot mass. The crucible is then given a circular motion over a burner till a clear melt results. Hold the outer surface of crucible in contact with 50 c c of water in a beaker, till cool; then immerse, and when melt has dissolved remove crucible, and wash. Transfer beaker contents to a 600-c c flask. Add 125 c c HCl, using a portion of this to clean the crucible further, and enough water to

make a total volume of 400 c c. Strips of nickel having a surface of at least 10 sq in are added, the flask closed with a stopper fitted with a small funnel or Bunsen valve, and heated to boiling until tin is completely reduced; 25 min is sufficient for 40 mg and 1.5 hr for 400 mg of tin. Add a crystal of calcite (4 or 5 gm), cool in water. Remove stopper and nickel strips after calcite is completely dissolved, and titrate with iodine solution containing 11 gm iodine and 20 gm potassium iodide per liter for a rich product, or one-half that strength for poor material.

To standardize iodine solution, weigh 0.2 gm pure arsenious acid (As_2O_3), and dissolve in 5 c c of a 20% NaOH solution, dilute, acidify with HCl, neutralise with sodium carbonate, using litmus paper as an indicator; then add 20 c c cold saturated $NaHCO_3$ solution and titrate to a blue color, using starch as indicator. The arsenic standard multiplied by 0.1202 gives value in tin. Iodine solution should be standardised at least once a week.

Interfering elements are bismuth, titanium, and tungsten. BISMUTH is precipitated as metal during reduction and should be filtered out, the reduction being completed with clean nickel. To eliminate effects of TITANIUM, add the weighed ore, small portions at a time, to 5 gm of $KHSO_4$ melted in a platinum or quartz crucible, and fuse for 5 min. Dissolve in 60 c c water plus 7 c c H_2SO_4. Filter, dry, ignite, and fuse residue with sodium peroxide as described. TUNGSTEN, if present, gives a blue precipitate during the reduction with nickel. This is filtered off, and solution again reduced before titration. When tungsten and titanium occur together, acid sulphate fusion is made as described above, and washed residue treated with ammonium carbonate solution, filtered, and washed. This residue is ignited, fused with sodium peroxide, and so on.

13. MERCURY

Whitton's apparatus affords results less accurate than those obtained by wet methods, but is better adapted for the technical assayer. Fig 6 shows apparatus as made by Braun Corp, Los Angeles. Take an amount of ore containing not over 50 mg of Hg (0.15 to 2 gm), mix with 6 gm of iron filings sized between 50 and 80 mesh, freed from grease and dried at a high temp; add 3 gm more as a cover. Clamp in place silver foil and cooling dish filled with water. Heat retort with a low flame for 15 min and allow to cool. Remove silver foil, and weigh it; gain in wt is Hg. The deposit should be white, and, after weighing, may be removed by volatilizing, when the foil is again ready for use.

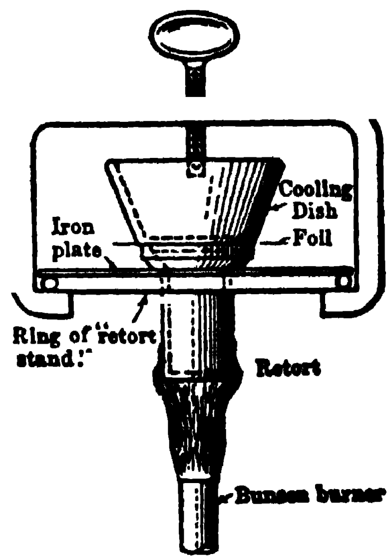

Fig 6. Whitton's Apparatus for Mercury Assay

14. ANTIMONY

Fire method, fusing 10 gm ore mixed with 40 gm KCN and KCN cover, may give approx results by compensation of errors, but is unreliable.

Permanganate method (4). DECOMPOSITION. Treat 0.5 gm ore with 10 to 15 c c HCl, followed by small additions (0.2 gm) of $KClO_3$, heating until all soluble matter is decomposed. Better results are sometimes obtained by following method: Treat ore with 15 c c HNO_3, evaporate to 4 c c, add 20 c c HCl, and evaporate again to 5 c c. If ore contains oxides, insoluble antimony (Sb) is likely to remain in residue. In this case, fuse residue or ore with 15 times its weight of Na_2O_2 in a 2-in iron or nickel crucible, preferably nickel, to complete decomposition (5 to 10 min). Give crucible a rapid circular motion while cooling, thereby causing melt to solidify in thin layer on bottom and sides. Place crucible in beaker of water and heat until melt is dissolved. Remove crucible, wash well, using dil HCl, if necessary, and acidify with HCl. If fusion is made on insoluble residue, add resulting solution to that from original acid treatment of ore.

SEPARATION. Add 3 gm tartaric, dilute to 50 c c, if necessary, filter dilute filtrate to 400 c c, pass H_2S until sulphides are completely precipitated. Filter and wash with H_2S water. Test filtrate by passing more H_2S. Unless precipitate is nearly pure antimony sulphide, wash from filter into beaker without removing paper from funnel and treat twice with hot alkaline sulphide solution, approx 10%, prepared by dissolving the salt in water or passing H_2S through a NaOH or KOH solution. Filter through original

paper, and wash with dilute alkaline sulphide solution. This treatment dissolves As, Sb, and Sn from other sulphides. Acidify filtrate with HCl; filter and wash with H_2S water. If As is absent, treat antimony sulphide as described later. When As is present, wash precipitate from paper into beaker, using a little dilute caustic solution and a minimum of wash water. Dissolve sulphides in HCl and a little $KClO_3$; boil out chlorine and transfer to pressure bottle. (Clamp-top beer bottles are satisfactory.) Add twice the volume of conc HCl (sp gr 1.2), saturate cold with H_2S, cork bottle, place in cold water, bring water to boiling, and allow to stand at least 1 hr. Lacking pressure bottles, ordinary flasks may be used; after saturating liquid with H_2S, close with stoppers and allow to stand cold over night. Filter out arsenic sulphide on double papers (S and S 597). Wash with HCl diluted 2 to 1, and saturated with H_2S. Dilute the filtrate 6 to 8 volumes, and complete precipitation of Sb with H_2S. Filter and wash precipitate with H_2S water. Test filtrate by passing more H_2S. Transfer antimony sulphide to 350-c c flask, removing traces of precipitate from paper with a little dilute caustic solution. Add 5 c c of conc H_2SO_4 and 3 gm $KHSO_4$. Heat over free flame, giving flask a circular motion until water is expelled and precipitate completely dissolved. Cool. Add 25 c c HCl and slowly add 125 c c H_2O, and cool.

TITRATE with $KMnO_4$ solution. The end-point color is not permanent. For ores containing less than 30% Sb, use a solution of approx 2.6 gm $KMnO_4$ per liter; for ores over 30%, use double that strength. To STANDARDIZE SOLUTION, weigh 0.2 gm sodium oxalate for the weak solution, or 0.4 gm for the strong; dissolve in 150 c c water, and 10 c c strong H_2SO_4. Heat to 70° to 80° C, and titrate. Start titration slowly, as the first additions are not decolorized readily and manganese oxide may separate out. Once the reaction has started the permanganate solution may be added as rapidly as desired. Sodium oxalate value multiplied by 0.8963 gives Sb standard. It is more satisfactory to standardize with pure Sb when this can be obtained. Dissolve the metallic Sb in H_2SO_4 and $KHSO_4$, as described for antimony sulphide, and titrate.

Iodide method (10). Final titration is more commonly, and possibly more accurately, done with KI and hypo. Dissolve the antimony sulphide in strong HCl, with small additions of $KClO_3$. Boil off 25 to 50% of solution to remove Cl, and bring acid to a constant boiling strength. Now add enough (1 to 1) HCl to make a total volume of 90 c c and dilute to 600 c c with cold water from which air has been boiled. (The foregoing steps are important.) Add 3 gm KI. Allow to stand a few min, and titrate with hypo solution, adding starch indicator near finish (see Art 11). Reaction between KI and Sb proceeds slowly to completion, and if hypo is added rapidly toward the end the color may be completely discharged only to reappear. Hypo should be added at such rate that the blue color gradually fades to colorless, which condition should hold for several min. Hypo solution is preferably standardized against pure Sb, following the procedure described for antimony sulphide. The solution may be standardized with Cu (Art 11), multiplying results by 0.9549, not by the theoretical factor 0.9454, to obtain Sb standard.

15. COAL (12)

Proximate analysis of coal (9) requires certain standard conditions, as the method is arbitrary and results vary with procedure. Crush sample to 0.25-in size, and if moisture content is likely to change, place a sample in stoppered bottle for a separate moisture determination. The remainder should be air-dried, heating moist sample, if desired, to 70° C, and allowing to cool in the air. Grind a portion to 80 or 100 mesh and place in stoppered bottle.

Moisture. Place 1 gm in crucible and heat to 104° to 107° C for 1 hr. Cool in desiccator, and weigh covered.

Volatile and combustible matter. Heat 1 gm for 7 min in a 20 to 30-gm covered platinum crucible, supported by a triangle 6 to 8 cm above top of a Bunsen burner having a flame 25 cm high.

This test may be made in a muffle at moderate red heat (950° C), using clay or porcelain annealing cup, though results will not be identical. Moisture must be deducted from loss in weight thus ascertained. Fixed carbon = 100 − (moisture + ash + volatile matter).

Ash. Burn off the carbon completely from sample used for moisture determination, using a low heat at the beginning. This operation may be conducted in a platinum crucible over a Bunsen burner, or in a clay or porcelain cup in a muffle.

If, on air-drying, the sample loses an appreciable amount of water, a determination should be made on the original moisture sample, and results corrected. Where this is necessary, and percentage of moisture is not over 10%, correction may be simplified, though not in accordance with the standard method, by weighing out 1 gm minus the

percentage loss of weight in air-drying. Results may then be pointed off in % directly. EXAMPLE: Loss of wt in air-drying, 2.5%. Wt of sample for determination, 0.975 gm. Ash.—Wt of ash, 0.0975-gm; percentage of ash, 9.75%. Moisture.—Loss in wt, 0.0275 gm; moisture in air-dried sample, 2.75%.

16. LABORATORY EQUIPMENT FOR GOLD AND SILVER ASSAYS

Following list includes equipment and reagents for 500 crucible assays. Quantity of fluxes will vary with character of ore assayed and charge used; they are estimated mainly for acid ores on 0.5 A T samples, with excess PbO charge.

- 1 gasolene furnace, with 2-in burner, capac six 20-gm crucibles and 24 1.25-in cupels
- 1 tank outfit
- 4 tongs: for crucible, scorifier, parting cups and cupels
- 1 muffle scraper
- 3 6-hole assay molds
- 1 anvil
- 1 hammer, 2-lb, for Pb buttons
- 1 cupel tray
- 2 bead trays, 24-hole
- 1 button pliers
- 1 button brush
- 1 kerosene or gasolene stove for parting
- 4 asbestos stove mats
- 1 sheet of asbestos, 3/16-in, 40 by 40 in
- 50 porcelain parting cups, 1.5-in
- 2 hand cupel molds, 1.25 and 1.5-in or Iler's cupel machine, dies 1.25 and 1.5-in
- 200 Battersea or other soft-clay 20-gm crucibles
- 50 scorifiers, 2.5-in and 10 3-in, Bartlett shape
- 3 Battersea annealing cups, A
- 3 Erlenmeyer parting flasks, 50-c c
- 1 blowpipe
- 1 alcohol lamp
- 6 5-in roasting dishes
- 1 still and condenser
- 1 demijohn for distilled water
- 3 ft 5/8-in glass tubing, 1.5-mm wall
- 2 ft 3/16-in glass tubing, 1.25-mm wall
- 3 ft 3/8-in rubber tubing
- 2 pinch cocks
- 3 32-oz wash bottles
- 2 6-in and 2 2-in watch glasses
- 24 test tubes, 6 by 3/4-in
- 1 test-tube brush, 9 by 3/4-in
- 1 500-c c graduated cylinder
- 1 nest beakers, 100 to 600-c c
- 2 funnels, 1.5 and 6-in
- 2 5-pint acid bottles, empty
- 1 pkg filter paper, 8 in
- 1 oz c p Ag foil
- 40 lb soda ash
- 50 lb litharge, silver-free
- 10 lb borax glass
- 3 lb niter
- 2 lb silica
- 3 lb test lead; 1 lb lead foil, silver-free
- 40 lb bone ash
- 14 lb nitric acid c p
- 1 lb hydrochloric acid c p
- 1 lb sulphuric acid c p
- 1 lb ammonia
- 1/4 lb charcoal, powdered
- 6 charcoal sticks for blowpipe
- 1/2 lb reddle, for marking
- 1 small ore crusher
- 1 buckboard and muller
- 1 Jones sampler, 8-in, or 9-in riffle sampler
- 1 nest 8-in tin sieves, 20-40-60-100-mesh
- 1 sieve, 10-mesh, 12-in, wood frame
- 2 brushes, 4-in for buckboard
- 2 doz tin sample pans, 6-in
- 500 paper sample bags, 4 by 7-in
- 1 scoop, 4.5 by 5-in, flat
- 2 7-in steel spatulas
- 1 horn or aluminum spoon
- 1 camel's hair brush, flat, 1.5-in, and pencil brush
- 1 yd rubber mixing cloth
- 1 piece of surfaced mixing cloth, 50 by 50-in
- 1 spring balance for weighing stock flux
- 1 button balance
- 1 pulp balance
- 1 set assay and gram weights
- 1 set button weights and riders, 1 mg to 1 gm

SECTION 31

TESTING OF ORES

BY

ARTHUR F. TAGGART

PROFESSOR OF MINERAL DRESSING, SCHOOL OF MINES, COLUMBIA UNIVERSITY

(**Note.**—The text herein on Amalgamation and Cyanidation is retained from original Sec 31, of first edition, by J. E. Clennell and Edward K. Judd.)

Note.—Numbers in parentheses in text refer to Bibliography at end of this section.

TESTING OF ORES

Testing involves the determination of: (*a*) best method for treating a given ore; (*b*) practicability and best method of operating a given process. In general, testing for a process requires the application of several processes to the same ore, while testing of processes involves subjection of different ores to the same process. The work requires painstaking attention to detail, close and accurate observation and record of performance, and incessant inquiry into causes. Correct interpretation of results requires wide experience in testing and mill operation, and a healthy balance between pessimism and optimism. Though the best laboratory results can often be bettered in mill operation, it may be impracticable in the mill to expend the care lavished on laboratory tests; mill operation is seldom economically subject to as close control of quantities treated, and purity and uniformity of substances used, as is the laboratory. This is especially true of hydro-metallurgical processes and flotation.

Time is usually an element in testing work. On the one hand is the demand for quick results; on the other, necessity for thorough investigation before announcing conclusions. Clear recognition of this situation should be a sufficient guide.

Principal tools for testing are: assay, testing sieve and microscope. Others are: the specific-gravity flask, heavy solutions, and small-scale replicas of or substitutes for mill machines, including hammer and anvil for estimating crushing resistance; hand jig, pan, batea and plaque for gravity concentration, and hand magnet.

1. OUTLINE OF PROCEDURE

Steps: (*a*) Obtain a proper sample; (*b*) Determine qualitative mineralogical composition; (*c*) Determine content of valuable mineral (assay); (*d*) Determine distribution of valuable mineral (sizing-assay test); (*e*) Determine aggregation of valuable mineral (microscopic examination and sizing-sorting-assay test); (*f*) Study existing flow-sheets for treatment of similar ores; (*g*) Devise a tentative flow-sheet for laboratory procedure; (*h*) By following (*g*), procure material representing the feed to each machine, and treat these materials in batches on the indicated machines, to determine best possible conditions of treatment and corresponding results; (*i*) Construct a metallurgical balance sheet of results of the batch testing (Art 8, Table 2); (*j*) Make a continuous run to confirm the results of (*i*).

Continuous run. A testing laboratory rarely has sufficient equipment, properly balanced as to size, to make a continuous run on a scale that will give reliable indications of mill performance, except to an experienced interpreter, and the greater his experience the greater his doubt as to his interpretation. Hence, if the size of the mill installation justifies the cost, the continuous run should be made in a pilot mill, built at the mine, fed with freshly-mined ore as nearly as possible representative of what the final mill will get, and run long enough to answer definitely, with minimum interpretation, what will be the performance of each machine and of the whole mill. Cost of a pilot mill is usually a small fraction of that of the main plant, is fully justified as insurance and is quickly saved, if the main mill is thereby put more quickly into regular operation.

When the contemplated mill is too small to justify cost of a pilot mill. the continuous run or runs must be made in the laboratory; in which it is usually impossible to duplicate mill conditions as to middling circulation and water reclamation. But, except for questions of sedimentation and incrustation in the water channels and their effects, reclaimed water has no effect on performance of gravity concentration. Its probable effect in flotation or in hydro-metallurgical processes can be investigated by small-scale tests, supplementing the continuous run. On the other hand, middling must be circulated in the continuous run and eliminated from the final products. If the middling circuit differs, as it does in almost all cases, from that to be expected in the operating mill, its effect must be closely studied, for making allowance in the final design. This is by far the most difficult part of testing and interpretation.

Samples must be correct, and of such wt (50–1 000 lb) as is necessary for all the initial small-scale laboratory tests. The smaller amount usually suffices when enough is already

known concerning the ore to indicate fine grinding and a simple treatment like cyaniding or flotation; the larger amount is necessary when nothing is known or when what is known indicates a complicated flow-sheet.

Mineralogical composition of the ore must be approximately known as the first step in the testing work (1-5). Gold and silver ores usually require an assay; complex base-metal ores demand microscopic examination.

Sizing analysis comprises quantitative separation of a mass of material of various sizes into a number of grades, each having a relatively small size-interval between largest and smallest particles. Means of grading: (*a*) screening; (*b*) differential settling, in water or in air.

2. STANDARD TESTING SIEVES

These are special sets of screens (usually 8-in diam), with pan and cover, or telescopic for field work. Apertures in successive sieves vary according to a regular rule.

The TYLER SERIES (best known) begins at 0.074 mm (0.0029 in), the aperture of each coarser size being obtained from that of the preceding by the multiplier $\sqrt{2}$. Full series in mm is: 0.074, 0.104, 0.147, 0.208, 0.295, 0.417, 0.589, 0.833, 1.168, 1.651, 2.362, 3.327, 4.699, 6.690, 9.423, 13.33, 18.83, 26.67. Proposed ASTM STANDARD series comprises a coarse and a fine sub-series. Coarse screens are the nearest usual fractions to a $\sqrt[4]{2}$ series, progressing from 1 in through the range from 0.25 in to 4 in, thus: 4, 3.5, 3, 2.5, 2, 1.75, 1.5, 1.25, 1.0, 0.875, 0.75, 0.625, 0.5, 0.438, 0.375, 0.312, 0.25. Fine series adopts U S STANDARD SCALE. It progresses on a $\sqrt[4]{2}$ ratio from 1 mm through the range from 5.66 mm to 0.037 mm, thus: 5.66, 4.76, 4.00, 3.36, 2.83, 2.38, 2.00, 1.68, 1.41, 1.19, 1.00, 0.84, 0.71, 0.59, 0.50, 0.42, 0.35, 0.297, 0.250, 0.210, 0.177, 0.149, 0.125, 0.105, 0.088, 0.074, 0.062, 0.053, 0.044, 0.037. Micron designation (1 mm = 1 000 microns) is customary for fine screens. Both of preceding series derive from RITTINGER (base = 1.0 mm, multiplier = $\sqrt{2}$) and RICHARDS (base = 1.0 mm, multiplier = $\sqrt[4]{2}$). INSTN MIN & MET (London) SERIES has no regular basis of variation. The rating is in number of meshes per linear in; the list is 5, 8, 10, 12, 16, 20, 30, 40, 50, 60, 70, 80, 90, 100, 120, 150, and 200-mesh. Aperture, in, is the reciprocal of twice the mesh designation; thus, 100-mesh screen has 1 ÷ 200-in aperture. Other series proposed are: DEKALB, base = 0.003 in, and, for any other size, add $0.001n$ in (n being the number of screen in the series); HOOVER, base = 1.0 in, constant multiplier (or divider) = $\sqrt[3]{2}$. SIEVES FOR COAL TESTING, round hole, base = 1 in, constant multiplier (or divider) = 2 (Sec 35).

3. METHODS OF SCREEN ANALYSIS

Crude analyses, suitable for ordinary work, are made by placing a weighed dry sample on the top or coarsest screen of a nest, shaking the nest (1-2 min), until most of the undersize has passed the coarse screens; then removing 1 screen at a time, beginning at top, shaking each separately over a pan until the amount passing through in 1 min is less than 1% of that remaining on the screen. Undersize is added to top screen of the remaining nest. On coarse screens (0.75-in or larger) pieces near the screen size may be tested and put through, if possible, by hand. Oversizes and final undersize should be weighed and kept separate until all have been weighed and the total checked against original wt. Weighings should be accurate to within 1%, and total wt of the grades should check original wt of sample within 1%. Screens should be so shaken as to cause the material to travel slowly in a thin sheet over whole surface of the sieve, and jarred at the same time to cause the cloth to vibrate gently in a direction perpendicular to its plane.

When fine dry material is caked, it may be broken by rubbing on the sieve with bristle brush or rubber cork. Cut-metal washers are sometimes placed on the finer sieves while shaking, but this wears and distorts fine screen cloth and, with soft material, produces an excessive amount of the finest size.

For testing coarse material, sample must be large, due to impossibility of cutting down accurately. But, except for very accurate work, a carefully riffled sample of −0.12-in material weighing 250 to 300 gm is large enough. Considerable time can be saved by sifting a large sample roughly on the 0.12-in screen, cutting down the undersize to 250 to 300 gm and screening this on the finer screens, while oversize is re-screened, beginning with coarsest screen. On re-screening, the undersize from 3.327-mm may usually be safely considered as oversize on next finer screen and so treated in calculating the redistribution (24).

Standard method for hand sieving. Abstract of method recommended by ASTM: SIEVES should be 8-in diam with well-fitting pan and cover, free of crevices that will hold particles; sieve-scale ratio, not greater than $\sqrt{2}$; finest sieve, 400-mesh (0.037-mm). PREPARATION OF SAMPLE. Dry at 110° C, mix well and riffle out a sample to within 10% of the accompanying figures.

If largest particle is — mm	Sample wt should be — gm	If largest particle is — mm	Sample wt should be — gm
16.00–11.32	40 000	2.00–1.00	500
11.32– 8.00	12 500	1.00–0.50	250
8.00– 5.66	5 000	0.50–0.25	100
5.66– 4.00	2 000	0.25–0.00	50
4.00– 2.00	1 000		

General procedure. Sieve wet through finest sieve, with water containing little or no dissolved solids. If the material is coarse, wash out all slime by vigorous decantation and put only decanted material on screen. Dry undersize and oversize at 110° C. Add loss, if any, to undersize. Sieve dried oversize first on finest screen and the oversize on successively coarser screens.

In this operation a rough end-point is reached when undersize for one-min shaking is less than 0.1% of original wt of charge. At this point remove oversize, and brush both sides of screen cloth to remove dust and lightly-held particles. Return oversize, and sieve further until a one-minute undersize is less than 0.05% of original wt of charge; remove oversize, brush screen as above and re-screen oversize one minute. If undersize of this screening is again less than 0.05% of original charge, return to oversize; otherwise add to undersize and repeat until two successive one-minute sievings as above yield less than 0.05% of original charge as undersize. MANIPULATION: Work over a smooth paper. Hold sieve with pan and cover in place, slightly inclined in one hand; shake with an amplitude of 6–8 in, about 150 strokes per minute, terminating each stroke by a gentle blow against the other hand. Turn sieve about $^1/_6$ rev every 25 strokes. With 6-in diam sieves, use 200 strokes per minute and turn $^1/_8$ rev every 25 strokes.

Wet samples are best handled by jigging on finest screen at the surface of water in a pail, and washing with a fine jet until practically all the slime has passed. Oversize is then dried and re-screened on a nest including the finest screen, and undersize of finest screen on the dry sifting is added to dried undersize from wet screening. This procedure is quicker and more accurate than preliminary drying and dry sifting, due to difficulty in breaking up slime cake formed in drying. But, as sampling wet pulp for the screen sample is difficult, drying, riffling and wetting to break slime cake may be justified.

Mechanical testing-sieve shakers. It requires 1–3 hr to sift a 200-gm sample containing 30 to 50 gm of −200-mesh material by manual shaking. Mechanical shaking will reduce the time to from 30 to 45 min, and, while the sieves are being shaken, the operator is free for other work. If mechanical sieving is used as a substitute for hand sieving in the proposed standard method, end points for each sieve should be tested by hand as therein prescribed.

Ro-tap testing-sieve shaker (W. S. Tyler Co), for 8-in sieves, consists of a movable cage with base and top plate, between which a nest of 13 half-height sieves, or 7 full-height with pan and cover, can be mounted and subjected to rotary sifting motion, while a lever strikes the top plate once per rev and produces vibration of the screen cloth. A time switch on the motor is useful. Duplicate samples, sifted for equal periods of time on the same or different machines, check well within limits of sampling error. If total amount of dust in the sample is important, the sieves (after removal from the shaker) should be brushed around the inside of the rims with a soft brush and shaken individually for a short time as in hand sifting, as a little dust collects around edges of coarser screens during mechanical shaking and does not pass through.

A simpler and cheaper apparatus comprises a vertical motor with eccentrically loaded flywheel on the rotor shaft mounted between two parallel hardwood sticks about 10 in apart and 44 in long, which are joined at their lower ends by a base plate for the screen pan and carry between this and the motor a vertically slidable recessed plate that fits over the cover of the nest of screens. The whole structure is suspended by a $^3/_4$-in rod from a suitable support. The motor revolves 900 rpm and vibrates the frame and contained screens through a small amplitude.

4. ELUTRIATION

This operation may be resorted to for further sizing of finer-than-sieve sizes. It consists in grading finely divided solid matter according to size, by taking advantage of differences in settling rate of different-sized particles in air or water. There are two general

methods: (*a*) allowing solids to settle freely in still water for varying periods; (*b*) subjecting the solids to rising air or water currents of different velocities.

Decantation is the simplest method. Place a 10 to 20-gm sample in a tall beaker of 300–500 cc capacity, fill with water to a predetermined depth, stir thoroughly, then allow the beaker to stand for such a time that the time in seconds, divided by depth of water in mm, equals a predetermined settling rate corresponding to the largest-sized particle desired. Required time may be read from Fig 1. Next, pour off supernatant liquid with the non-settled solids in suspension, re-fill to the mark and again allow settlement for same time; repeat until the appearance of supernatant liquid indicates that all the finest slime has been removed. Combine decanted portions, take a sample, while wet, for microscopic determination of size (Art 5), then dry at 110° C, cool and weigh. Re-fill the beaker to the mark with fresh water, and repeat above operations, allowing a shorter time for settling corresponding to the next coarser grade desired, and repeating with this settling time until the supernatant liquid, at end of period, shows no solids in suspension. Repeat as above until the desired number of grades is obtained. If, in using tap water, there is obvious chemical action (formation of gelatinous precipitates), use distilled water. If this does not remedy the trouble, weak solutions of acid or alkali may be used, but the presence of the added chemicals or their salts in the dried solid must be recognized. Organic liquids, as kerosene, benzene, acetone, may, with some dry pulps, prevent flocculation of fine sizes, but the chart velocities (Fig 1) can not be used. If microscopic sizing of the different grades is omitted, overlapping of sizes in the different grades must be borne in mind, because not all the solids begin settling from the surface of the liquid in the beaker, and some fine particles that begin to settle from a point below the surface will reach bottom while coarser particles starting above them are still in suspension. Repetition lessens this inaccuracy, but does not eliminate it.

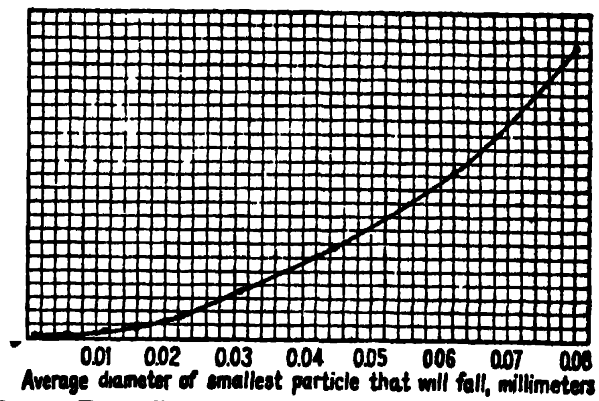

Fig 1. Free-falling Veloes of Quartz (after Richards)

Elutriation by rising currents is done by subjecting the material to be graded to rising currents of different velocities, and collecting the material lifted by each current separately. General form of apparatus is the same, whether the fluid is liquid or gas. It consists of a series of cone-bottomed cylinders of increasing diam, closed at the top and pipe-connected so as to permit continuous fluid flow from the smallest through largest cylinder. Provision must be made to collect solids deposited in successive chambers. When air is the fluid, a ball or the like rests on the bottom inlet in such a way as to give annular entry to the fluid stream. Haultain's infra-sizer, using air for fluid, is the best today; it produces granular grades to 10-micron size that, when magnified, look like screen grades.

Interpretation of elutriation tests. Settling rate of solids in fluids depends upon: sp gr and shape of particles, degree of packing of particles in the sorting column and the uniformity of sorting current. If the sample sorted comprises grains of different sp gr, the grades always contain grains of highly divergent sizes; also, even if all the material is of same sp gr, the coarser grades will contain more or less finer grains carried down mechanically or by eddy currents; the finer grades will contain flat scaly particles that settle much more slowly than their aver "diam" would indicate. Hence, the only sure way to determine aver size of grains in a given grade is by microscopic measurement. If desired, this may be made separately on heavy and light particles and on flat and rounded particles, and the analysis re-cast on basis of these measurements.

5. TESTING WITH THE MICROSCOPE

Microscope is used: (*a*) to aid in mineral and rock identification and classification; (*b*) to aid in study of mineral occurrence and the characteristics upon which the treatment scheme depends; (*c*) in quantitative mineralogical analysis; (*d*) in sizing analysis. The microscope may save much time and money in qualitative determinations, which frequently will demonstrate the uselessness of more elaborate quantitative investigations.

Microscopic mineralogy and petrography are familiar to the geologist and the literature is excellent and large. Principal apparatus required is a petrographic microscope. Samples for examination are prepared either as thin sections or pulverized fragments. For details of methods and interpretation of thin sections, and study of pulverized fragments see Bib 1, 3, 4, 5.

Mineragraphy is the study of opaque minerals, including native metals, most sulphides, certain base-metal oxides and the like, by the metallographic microscope. The methods, including study of polished sections by reflected light, etching and various microchemical tests, hardness tests, etc, are much more effective in identification of opaque minerals than either of the ordinary petrographic methods (6–11). See also Sec 1.

Particle size. Of greater importance in testing than identification and the information concerning ore genesis afforded by mineragraphic work is the knowledge given by the polished section as to particle size and method of occurrence of the valuable mineral. The first fact can be established with coarse-grained ores by a sizing-sorting-assay test (Art 8); for such ores, the second fact is of minor importance, but with finely disseminated and complex ores the polished section quickly gives essential information obtainable in no other way.

Determination of grain size fixes the size to which the ore must be crushed to free the valuable mineral; upon this and the kind of mineral and gangue the chief elements of a tentative flow-sheet can be founded. The appearance of the edges of sulphide-mineral grains and of cracks traversing them will tell whether any alteration likely to affect flotation has occurred. Inclusions of worthless or deleterious substances that would lower the grade of concentrate, as silicates between the laminae of graphite grains, blende in galena and the like, are immediately apparent in a polished section. The degree of admixture of sulphides in complex ores can be readily studied, and one or two properly chosen sections often show the hopelessness of attempts at mechanical separation. Time and money can thus be saved, and ores should never be tested beyond the preliminary assay stage without such microscopic examination.

Quantitative mineralogical analysis is useful primarily in studying the products of concentration. The first step is identification of important minerals and mineral groups. The analytical work is done with low magnification, since identification of valuable mineral, accompanying heavy mineral or minerals, and the gangue minerals as a group, is easy. Failing this, analysis must be preceded by identification, for which Rogers' crushed-fragment method with the petrographic microscope is best (1).

Mill pulps may also be mounted in a matrix of bakelite or similar plastic, by stirring into a viscous mass thereof softened by heat, and, when the mass is resolidified, may be polished for mineragraphic examination. For quantitative applications of this technique, see Bib 16b, 16c.

Microscopic sizing analysis. Sizing by screens below 200-mesh (0.074 mm) is highly inaccurate, because of imperfections in screens and the difficulty of getting material through them. Elutriation alone is similarly undependable, due to differences in settling rates induced by differences in shape and sp gr of particles. Microscopic sizing has of late been highly developed, to supplement or supplant settling methods. With proper equipment and good technique, microscopic sizing can be carried to less than 1 micron (1 micron = 0.001 mm), and the aver size of very fine products stated with a precision of 0.1 or 0.2 micron.

Indirect measurement, described by Green (17), is adapted to very fine materials of greater uniformity than the non-metallic natural fillers measured by Weigel (18). It involves making a slide, photographing one or more fields, projecting the negative on a screen and measuring and counting the grains thereon.

For details of more elaborate methods of screen sizing, elutriation and microscopic analysis, see Taggart, Handbook of Mineral Dressing.

6. AVERAGE SIZE OF PARTICLES

Mineral particles produced by crushing and grinding have an almost infinite variety of shape and size. No accurate numerical expression of the dimensions of a single particle nor of the aver of a group is possible; only an approximation is feasible, ordinarily expressed as a single number, as though the particles were spheres or cubes. This number is called the DIAMETER or SIZE of an individual particle, or the AVER DIAM or AVER SIZE of a group of particles.

Diameter of a particle. The fundamental assumption of particle measurement is that it has three principal axes at right angles and that its dimensions are completely stated when the distances between the intercepts of the surface on the respective axes are given. Starting with this assumption, which is, on its face, only a crude approxima-

tion except in the case of materials with cubical cleavage, averaging of the three principal dimensions into a single figure is attempted by one of several different methods, as follows:

$$d = b, \quad (1); \qquad d = (l + b) \div 2, \quad (2); \qquad d = (l + b + t) \div 3, \quad (3)$$

$$d = \sqrt{lb}, \quad (4); \qquad d = \sqrt[3]{lbt}, \quad (5)$$

$$d = \frac{\sqrt{2lb + 2bt + 2lt}}{6}, \quad (6); \qquad d = \frac{3lbt}{lb + lt + bt}, \quad (7)$$

where d = "diameter," and l, b and t respectively the distances between the intercepts of the surface on the long, intermediate and short axes; in common parlance, length, breadth and thickness of particle. The significance of the first 5 approximations is immediately apparent; the sixth gives the edge of a cube, the total surface of which equals the total surface of a rectangular parallelopiped of dimensions equal to the principal dimensions of the particle. The seventh is the harmonic mean of the dimensions. When screens are used alone, assumption (1) is adopted perforce; for elutriation, without subsequent microscopic measurement of fractions, assumption (5) is necessarily involved; when individual particles are measured, any one of the seven may be adopted, but (2) and (4) are most commonly used.

Aver diam is computed by averaging the mean or equivalent diam of a number of particles. Perrott and Kinney (19) suggest the following:

1. Arithmetical mean $D = \frac{d_1 + d_2}{2}$
2. Geometrical mean $D = \sqrt{d_1 d_2}$
3. Laschinger's mean $D = \frac{d_1 - d_2}{\log_e d_1 - \log_e d_2}$
4. Mellor's mean $D = \frac{\sqrt[3]{(d_1 + d_2)(d_1^2 + d_2^2)}}{4}$
5. Mean of form $D = \frac{4}{5}\frac{d_1^5 - d_2^5}{d}$.
6. Von Reytt's mean $D = 0.435(d_1 + d_2)$
7. Number mean $D = \frac{\Sigma nd}{\Sigma n}$
8. Length mean $D = \frac{\Sigma nd^2}{\Sigma nd}$
9. Surface mean $D = \frac{\Sigma nd^3}{\Sigma nd^2}$
10. Volume mean $D = \frac{\Sigma nd^4}{\Sigma nd^3}$

To these should be added:

11. $D = \sqrt{\frac{\Sigma nd^2}{\Sigma n}}$
12. $D = \sqrt[3]{\frac{\Sigma nd^3}{\Sigma n}}$

where D = mean diam; d_1 and d_2 = max and min mean particle diam; d = successive mean particle diam in a sizing operation, and n = numerical frequency of the corresponding d. For discussion of the above, see Taggart, Handbook of Mineral Dressing.

Table 1. Comparison of Methods of Calculating Average Diam

Microscopic analysis								
Diam, microns (d)...	60	50	40	30	20	10	5	2
No of particles (n)...	87	100	156	660	1 750	6 200	25 600	155 000
Percentages								
Σn ...	0.05	0.05	0.1	0.3	0.9	3 3	13 5	81.8
$\frac{nd}{\Sigma nd}$ ...	0.9	0.9	1.1	3.4	6.1	10.7	23.7	53.2
$\frac{nd^2}{\Sigma nd^2}$ ...	7.8	6.3	6.3	14.9	17.5	15 5	16.1	15.6
$\frac{nd^3}{\Sigma nd^3}$ ...	22.4	14.9	11.9	21.2	16.7	7.4	3.8	1.5

Formulas	Microns
1. $D = (d_1 + d_2) \div 2 = (60 + 2) \div 2$	= 31
2. $D = \sqrt{d_1 d_2} = \sqrt{60 \times 2}$	= 11
3. $D = (d_1 - d_2) \div (\log_e d_1 - \log_e d_2) = (60 - 2) \div (2.303\,[1.7782 - 0.3010])$	= 17.0
4. $D = \sqrt[3]{(d_1 + d_2)(d_1^2 + d_2^2)} \div 4 = \sqrt[3]{(60 + 2)(3\,600 + 4)} \div 4$	= 38.2
5. $D = 4(d_1^5 - d_2^5) \div 5(d_1^4 - d_2^4) = 4(60^5 - 2^5) \div 5(60^4 - 2^4)$	= 48

12.	$D = \sqrt[3]{\Sigma nd^3 \div \Sigma n} = \sqrt{(87 \times 60^3 + \ldots 155\,000 \times 2^3) \div (87 + \ldots 155\,000)}$	$= 7.6$

Comparison of methods. Perrott and Kinney (19) give the microscopic sizing analysis shown in Table 1. Comparison of the aver diam computed by the different formulas shows clearly the uncertain meaning of this term, and necessity for stating the method of calculation when giving a numerical result. The result by formulas 1 to 6 is unaffected by the amounts of any of the grades. Hence, each will give the same result for any mass of mixed size grains, irrespective of the size composition of the mass, provided the largest and smallest particles are in each case of same size.

This fact condemns these formulas for anything but the crudest work. Formulas 9, 10 place too much weight on the coarser sizes, and, with No 8, give results that are meaningless in terms of the diam of ideal particles that could be substituted for the actual particles. But, No 9 is useful when specific surface is important. No 7 gives the easiest calculations and the physical significance is most readily visualized. It weights the finest particles most heavily and therefore gives an aver that leans toward the fine end. No 12 weights the coarsest particles most heavily, and consequently the results lean toward the coarse end. No 11 is intermediate between the other two and would, on that score alone, seem preferable; it is distinctly so when surface is the valuable property of the material.

7. PLOTTING SIZING TESTS

Sizing tests are best compared and their significance understood by graphs. Common methods are: DIRECT PLOT, particle size against percentage weight; CUMULATIVE DIRECT PLOT, particle size against cumulative weights of the entering and the coarser (or finer) sizes; DIRECT LOGARITHMIC PLOT, weights as ordinates against logarithms of particle sizes; CUMULATIVE LOGARITHMIC PLOT, cumulative weights against logarithms of particle sizes; PERCENTAGE APERTURE PLOT, cumulative weights against apertures expressed as percentages of the aperture passing all of the sample; RECIPROCAL PLOT, weights, cumulative or direct, against reciprocals of particle size; FREQUENCY CURVES, number of particles (or a function thereof) against size (17).

8. SIZING-SORTING-ASSAY TEST

This test affords an excellent basis for estimating the recovery possible to make on an ore, and of the flow-sheet needed for treatment.

A sizing test is made of a sample ground to approx the size at which clean mineral or clean tailing results, separating each grade by approx means into concentrate, middling and tailing, and weighing and assaying the products. Hand picking can be used for separation to the oversize on a 1-mm screen, and panning on the finer sizes; or, if the bulk of the finer sizes is large enough, and the ore amenable, they may be combined into a sample for a flotation test.

Table 2 shows results of a test thus run and the method of calculation. Assuming that the concentrate from retreating middling separately would average 65% Pb and the tailing 0.4%, the middling recovery would be 97.8%. This assumption was justified in the test, because microscopic examination of the middling showed that practically all mineral would be free at 100 mesh, that concentrate from 14% feed would be somewhat richer than that from 5% feed, and that assays of tailings from both feeds would be roughly in proportion to the feed assays. Such middling retreatment would add 3.710 ton concentrate containing 2.4095 ton lead, and 13.386 ton tailing containing 0.0535 ton lead. If doubt exists as to behavior of the middling on retreatment, it should be ground and treated.

9. TESTING OF MACHINES

Crushing. Behavior of ore in coarse and intermediate crushing and in grinding should be investigated, because the results of breaking apart mineral aggregates by this crushing may differ entirely from those due to breaking down the individual mineral grains by grinding. The safest method is to make parallel tests on an ore of known crushing characteristics and the unknown ore; these tests being made with machines of the types used in mill treatment of the known ore and to be used for the unknown. Laboratory crushing tests used as a basis of mill installation are, in any case, about 5% manipulation and 95% interpretation based on experience, and an experienced investigator, with a few lumps of the unknown and some known ores and a hammer and anvil, can tell more than an inexperienced man with a complete laboratory equipment.

Accessory apparatus. Testing an ore for performance in hydraulic and mechanical classifiers, thickeners and filters, dryers and the like is usually done in small-size substitutes for the essential parts of the various machines. Experiments require much skill in manipulation, and experience in interpretation. They form part of the general testing campaign for determining a flow-sheet and should not be attempted as part of preliminary field work. For details of methods, see Taggart, Handbook of Mineral Dressing.

10. HAND PICKING

This often affords valuable information, even when not considered a practicable mode of treating a given ore under existing conditions. It may be applied to ore as fine as 0.25 in, and, in investigating screened products, may be carried down to 1.0 or even 0.5 mm with aid of a hand-glass or a low-power microscope. The ore should be clean and sized between rather close limits; washing brings out the distinctive color or luster of the minerals.

Practicability of hand picking on a commercial scale may be tested by attempting to make the following products, or as many of them as practicable: (*a*) pure minerals, fit for market or for metallurgical treatment, as galena, blende and chalcopyrite; also very rich ore, which might be treated better metallurgically than by mechanical means, for example, copper carbonates or silver chloride; (*b*) rich ore, with coarse disseminated mineral; for coarse crushing and jigging; (*c*) fine disseminated ore, usually poor, containing useful mineral in such small particles as to require very fine crushing to liberate it; (*d*) material that does not seem to be mineralized. Several classes may sometimes be made of this, if differences of color, texture, etc. indicate a possible difference in richness. Assays will show which may be thrown away, and which should be included with the ore for mechanical treatment.

Economy of hand picking may be investigated by the formulas in Sec 28, Art 11.

11. HAND JIGGING

This is used for testing ore ranging in size from about 12 to 2 mm. It requires a tub of water and a few 6 to 10-in screens of differing mesh. Before jigging, the ore should be sized fairly closely.

Put about 2 in depth of sized ore into a sieve having a mesh fine enough to retain it, and jig for several minutes under the surface of water, with a long, slow stroke for coarse ore, and a shorter and quicker stroke for fine sizes. A quick down stroke combined with slower up stroke is most effective. Care should be taken to keep the sieve level and to avoid horiz or overturning movements. When tailing appears clean, scrape off upper layer and replace with an equal amount of ore; then resume jigging. Middling and concentrate may be allowed to accumulate on sieve, until the layers become inconveniently thick. Main object of preliminary jigging is to produce a tailing as poor as possible. Concentrate is cleaned by careful jigging, aided by hand picking, if necessary. Skimmings from the concentrate are added to the middling, and this is re-jigged and reduced to the smallest possible bulk, by separating concentrate and tailing. Sometimes two or more grades of middling may be made, their richness being tested separately to determine the effect of combining them in part with concentrate or with tailing. Assays of products, and close scrutiny of middling obtained at different sizes, will indicate the max size at which jigging should be begun. Mill operation will rarely improve hand-jig tailing, but mill concentrate is usually of higher grade.

12. PAN, GOLD PAN, MINER'S PAN

The above are different names for the same device. It is in shape a conical frustum, 10, 12.25, 16 in or more across the top, 2–2.5 in deep, the sides at an angle of 35–75° to the bottom. It should be light, with smooth inner surface, free from grease and rust. Polished steel and granite ware are the usual materials, though the latter is apt to chip. USES: (*a*) to assay gold-bearing gravels in prospecting, and, less frequently, to make a rough assay of crushed vein material for gold; (*b*) to work gold-bearing gravel on a small scale; (*c*) to make gravity-concentration tests on heavy-metal ores.

Procedure. To pan gold gravel, take a panful, and work the material over in water with the hands, rejecting stones free from fines and clay. Continue this until all coarse gravel is removed and the mass thoroughly disintegrated. Then, with the material in the pan submerged, and the pan held nearly horiz, subject it to a rotary motion sufficient to produce suspension of the solids, and settle the heavy particles, leaving the surface metal-free. Next, with pan above water, tilt it slightly forward, and, by rocking it from side to side, cause the water in the pan to wash solid matter to the lower edge; the amount of tilt and speed of rocking being such that only the superficial particles are washed down into a "toe" at the lower rim. The toe is then washed off by alternate lowering and raising through the water surface. These operations are repeated until nothing remains in the pan but heavy minerals and some fine light sand. Further separation can sometimes be made by so moving the pan that a little water therein will course around the trough formed by intersection of side and bottom. This strings out the material with the lightest sand ahead and the heavy material behind, so that more sand can be removed, and particles of gold uncovered. Final separation of gold from the heavy minerals is usually made by amalgamation; or by drying, and separating magnetite with a magnet, or by blowing.

In prospecting, it is important to know the number of pan loads per cu yd of gravel in place. This ranges from 100 to 200, according to size of pan and its load, and should be determined by measurement in each case.

Testing an ore differs from above procedure in that: (*a*) ore must first be ground to a size that will free much of the valuable mineral; (*b*) the wt of the sample should be determined; (*c*) stratification in the pan requires more careful and prolonged manipulation; (*d*) the surface layer removed in each cycle must be thinner. The operation should be conducted over a tub, in which the first tailing is collected for repanning. Concentrate always contains considerable gangue and the tailing some valuable mineral. An experienced operator can make about the same recovery as is possible in mill work, but mill concentrate, especially coarser sizes, will assay higher.

A skilled panner, working steadily, can treat about 100 pans of loose gravel per 10-hr day; proportionately less if cemented matter is present. The same man can not run down more than one-third as many samples of galena-quartz ore; even less of ores in which the difference in sp gr of heavy and light minerals is smaller.

13. VANNING

This resembles panning, but is not applicable to as coarse material and is limited to much smaller quantities, say about 50 gm. Vanning plaque is of enameled iron, in shape of a spherical segment, about 12 in diam by 0.75 in deep at the center. Cornish vanning shovel is essentially a plaque on a 24-in handle. A batea or a large watch glass may be used instead of a plaque.

Procedure. Sample, if dry, is first wet down carefully, avoiding skin flotation. Wet pulp is first swirled vigorously to get slime in suspension, then more slowly to let all granular material settle, after which the slime is decanted. Repeat until all slime is removed. Thereafter, a vanning operation comprises: (*a*) stratification by horiz rotary motion, as in panning; (*b*) throwing the lower heavy concentrate to the edge of plaque, while the upper stratum remains near center; (*c*) washing the upper stratum off the plaque away from the head of concentrate. To throw up the head of concentrate, the plaque, held on opposite edges in the hands, is moved as in swirling with one hand while the other describes, at each rev, a small vertical circle, say 1-in diam, in clockwise direction, moving downward more rapidly than upward. The swirling motion keeps upper stratum in suspension, while the lower hugs the surface; hence, as the plaque moves away from the operator, the heavy material moves with it, and thus moves from under the pulp in suspension. The rapid down stroke drops the plaque from under the heavy mineral, and when the latter again reaches the plaque surface it rests on a point farther away

from operator than *before*. The head of concentrate is thus made to travel up onto the edge of the plaque away from the operator, while the lighter sands remain nearer the center. Horiz separation is continued by imparting a gentle swirl that moves the water only, giving the plaque a smart shake while the swirling water is traveling away from the concentrate. Thus, the sand is washed down toward the operator by a film-sizing action. Some operators manipulate the second phase so as to draw the head toward them, washing tailing off the far side; others throw up the head by simple swirling with one hand and jarring the side of the plaque at each rev against the heel of the other hand. In this case, the mechanics of the horiz separation are different, but result in the same; it is easier to learn than the first, but is tiring, if much vanning is done. With a vanning shovel the head is thrown up by a slight side fillip on the back stroke of the swirl.

Principal uses of the plaque are in examination of finely-ground mill products, and in assaying, as in the Cornish tin-ore assay. Vanning has an advantage over a chemical assay in giving some idea of the amount of middling and the size of the free-mineral grains. It is being superseded in Cornwall tin assaying by chemical methods, but for many years it was the chief, if not the only method there used. It had, of course, the apparent advantage of indicating only recoverable tin (free cassiterite of a size that could be won by gravity concentration), and this was all that most millmen were interested in; but experiment showed that skilful operators reported discrepant results on the same sample, none, of course checking the chemical assay.

Haultain super-panner is a mechanized vanning horn, about 30 in long by 10 in wide, set with a slight longitudinal slope and having a curved bottom of radius increasing toward the lower end. A cam-controlled bump moves settled solids toward the high end, while a side motion of controllably-various magnitude, together with wash water, suspends and moves light material toward and over a transverse baffle at lower end. It may be used on charges as small as 1 gm; making remarkable separations on infra-sized grades.

14. HEAVY SOLUTIONS

Liquids of high sp gr (up to 3.55) may be used to separate minerals more closely than by any other means; but the method is limited to mineralogical testing, except in the use of $ZnCl_2$ solution for coal (Sec 35, Art 11).

15. FLOTATION

Testing flotation processes is more difficult than testing other methods of concentration, because the process operates by means of chemical reactions in solutions so dilute that solutes derived from the ore itself or present in the mill water may exert very great influence.

Fundamentally, in order that bubbles may attach preferentially to a solid surface, that surface must first be water repellent, while all other particle surfaces remain readily wettable by water, as they are in virgin ore (excluding ozokerites and the like). The desired water-repellent surface is always of hydrocarbon nature. In a few special cases, as sulphur, graphite and coal, it can be applied by selective smearing with relatively insoluble oil. This is done by agitating the ore with water and a little oil. In all other cases, coating is effected by chemical reaction between the affected mineral and a collecting agent. This results in an oriented precipitate of a reaction product of mineral and reagent at the mineral surface.

Substantially any mineral may be separated from any other by proper choice of a collector. The prerequisites are: (1) slight solubility of the mineral to be coated (and floated) in the pulp solution; (2) an organic reagent that will form an oriented precipitate of hydrocarbon nature on the desired mineral surface, by reaction therewith, while the other minerals are unaffected thereby. Solubility of the mineral, of the organic collecting reagent and of the reaction product may be controlled by other suitable (CONDITIONING) reagents. In general the silicates, except those containing considerable proportions of heavy or alkaline-earth metals, are non-floatable. Substantially all other minerals are floatable. For more complete discussion of the chemistry involved, see Bib 20—23.

Reagents. Salts of organic thio acids, usually carrying upwards of 4 carbon atoms, are commonly used as collectors for sulphide minerals. Examples: xanthates, thiocarbonates, thiophosphates, mercaptans. Fatty and resin acids and their alkali-metal salts (soaps) are the usual collectors for non-metallic minerals. Added oil is an aid in coating the latter. Pulps are usually kept slightly on the alkaline side (pH 8–10).

Differential reagents are added to modify the surface of certain minerals and thus change their behavior. Copper ion replaces zinc ion on sphalerite surfaces and thus, since zinc does not form insoluble precipitates with many thio-acid ions of low hydrocarbon content while copper does, activates the sphalerite. Alkali cyanides added to a pulp containing copper ion suppress the concentration of this ion. Hence they are added to prevent activation of sphalerite by incidental copper in galena-sphalerite ores. With a high concentration of zinc ion, obtained by addition of zinc sulphate or chloride, cyanide probably forms an insoluble zinc cyanide on sphalerite surfaces and further depresses that mineral. Cyanide probably also forms ferrocyanide coatings on pyrite in alkaline pulps and thus depresses it. These examples constitute a bare outline of possibilities of differential control.

Steam-distilled pine oil and cresol are the most usual frothing agents.

Crude, small-scale tests, by the agitation-froth process, may be made by hand shaking in a test tube or a wide-mouth bottle, or in a milk-shake machine. A motor-driven bar mixer with a small square glass jar is excellent for preliminary tests; froth being removed by overflow by introducing sufficient water through a tube below the pulp level.

Preliminary pneumatic-process tests may be made with a short length (8–12 in) of 1.5 or 2-in tubing, a 1-hole rubber cork and a piece of finely porous cloth, arranged as in Fig 2. Air may be supplied by a bicycle or automobile pump or, at worst, by an atomizer or syringe bulb. It is well to have a receiver made, say, of a 2-liter acid bottle, between the pump and cell, arranged so that the air supply can be regulated by a pinch-cock. Preliminary tests by such apparatus are

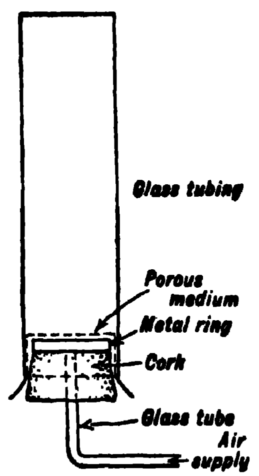

Fig 2. Blowing Tube for Pneumatic Flotation Tests

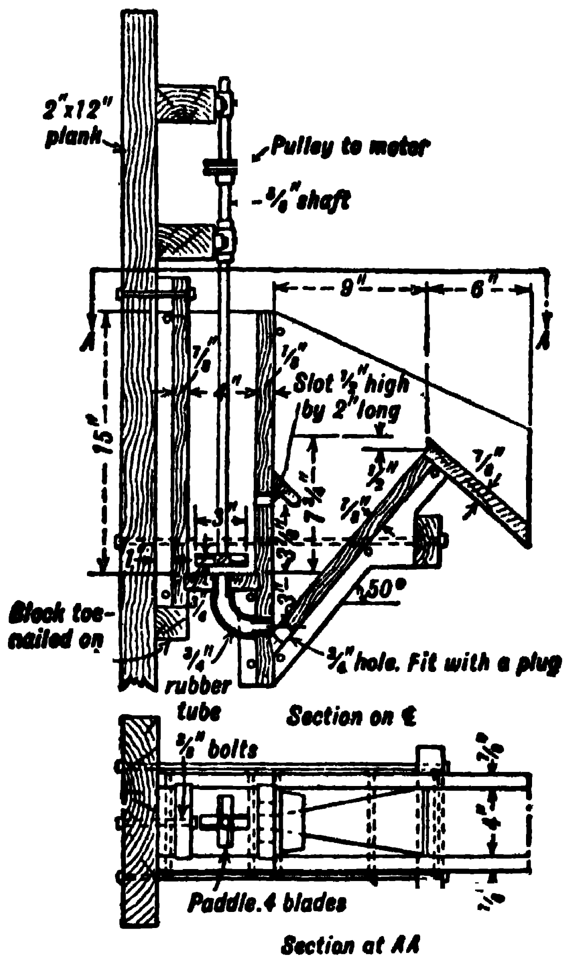

Fig 3. Agitation-froth Laboratory Flotation Machine

valuable chiefly to determine amenability and, perhaps, to give some idea of the grade of concentrate that can be made. They will not yield good recoveries.

The best machines for laboratory work are single-cell models of mill machines, taking charges of 500–1 500 gm, with provision for froth overflow, and arranged for pulp circulation. They will yield results that are usually directly comparable to mill operations. Such models of their commercial machines are made by many mfrs.

Fig 3 shows a satisfactory agitation-froth machine, which is easily made in any mine shop. A 0.25-h p motor, giving the agitator a speed range of 800–2 000 r p m, is desirable. Ore charge, 750 gm. The pneumatic machine in Fig 4 can be built in any good mine shop; arranged for either continuous or batch treatment, according to position of the tailing-discharge slide. Ore charge for a pulp containing 20–25% solids, 1 500 gm. For small-scale batch tests, a machine similarly proportioned, without glass side and arranged for overflow both sides, 2 by 7 in in plan, is easier to handle and can operate on 500 gm

or less. It should be fitted with a small air-lift, of glass tubing, to circulate from the deep end back to the shallow end.

Testing procedure. All apparatus should be clean. Mode of preparing the ore charge depends upon nature of the ore and reagents. Dry grinding in a disk sample-grinder, or a small ball or pebble mill permits preparation of many samples at one time, but the character of the product may not be the same as that of the same ore wet-ground. Wet grinding, simulating mill conditions, is best, unless it is known that dry grinding produces no essential difference in results.

In wet grinding the ore is first reduced to pass 10 or 20-mesh dry. The charge is then weighed into a small batch cylinder mill, water equivalent to 30–50% of the combined wt is added, and the charge ground for the predetermined time required to produce the desired size. Collecting and conditioning agents may be added, so as to be present during grinding. With non-metallic ores it may be preferable to do all fine grinding out of the presence of iron, or to add a precipitant for iron ion, as phosphate or hydroxyl ion. For many ores, preliminary tests of metal content of tailing may be made by vanning, assays being superfluous unless vanning indicates good recovery.

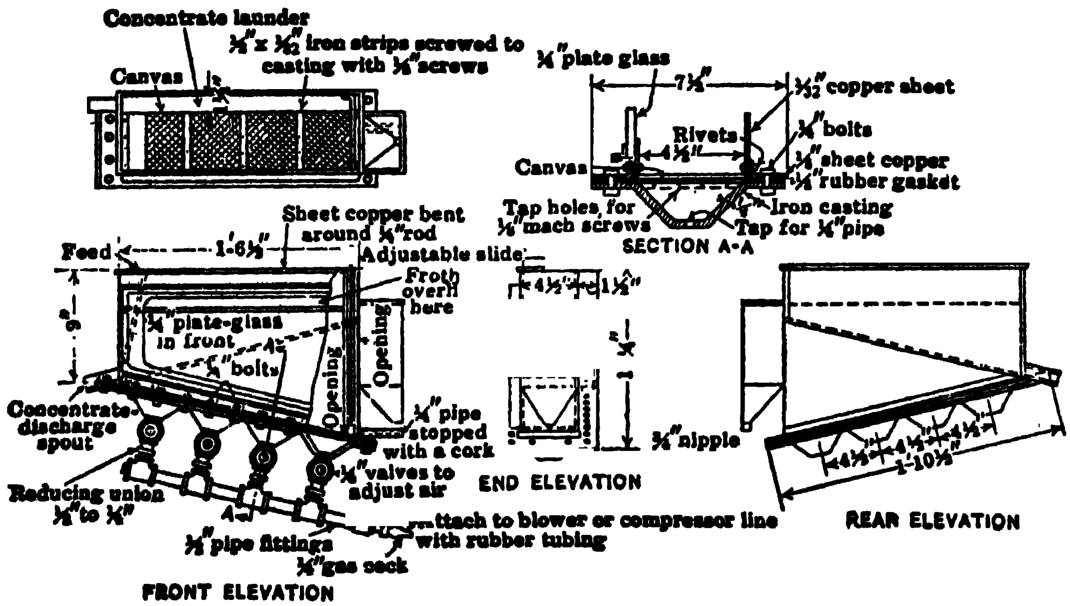

Fig 4. Callow Cell, Laboratory Size

Quantity of reagents. Thio-acid collectors, 0.05–0.15 lb per ton of dry ore; soaps, 0.2–1.0 lb per ton; neutral oils, as petroleums, when needed, 0.25–3 lb per ton; Cu, 0.05–0.25 lb per ton; hydroxyl ion (lime, caustic soda or soda ash) to give desired pH; cyanide, 0.25–0.5 lb per ton (concentration of CN, with a given quantity of cyanide salt present, increases with alkalinity); frothing agents, as pine oil, cresol, sulphonic soaps, 0.05–0.15 lb per ton.

For a bottle test, place the pulp (containing about 25% solids) and reagents in a wide-mouth bottle holding 500–2 000 cc, filling it half to two-thirds full, cork, shake vigorously for 3–10 min, moving the bottle parallel to its axis, so that the mass of pulp acts as a piston or plunger, then allow it to stand for froth to separate. This test requires practice, and an inexperienced operator should not be discouraged by failure.

For a machine test, place the pulp with reagents (as above) in the machine and agitate at 1 000–1 500 ft per min peripheral speed for 10–30 min. If first froth is high-grade, it may be taken as finished concentrate and later overflow as middling; if first overflow is low-grade, take all overflow as rough concentrate and clean in a second operation.

For differential flotation of galena from blende and pyrite, grind the ore with 2–4 lb per ton of sodium bicarbonate, 0.2–0.4 lb coal-tar or wood creosote, 0.5–1.0 lb sodium cyanide and 1–2 lb zinc sulphate; then charge to the machine with 0.1–0.25 lb pine oil and float the lead. Next add about 1 lb copper sulphate and, if necessary, H_2SO_4, sodium carbonate or another inorganic agent, to float blende away from pyrite. Sodium carbonate, bicarbonate, or cyanide alone may serve to separate a blende-pyrite ore or to float chalcopyrite from pyrite. The same procedure as for flotation of galena will frequently float chalcopyrite from blende and pyrite. Sodium sulphide (1–10 lb per ton) may sometimes be used instead of cyanide.

For further details of flotation testing, see Taggart, Handbook of Mineral Dressing.

Interpretation of flotation-test results. Translation of laboratory results into terms of mill-scale operation is generally less difficult in flotation than in gravity concentration, and is always more certain than where there are chemical reactions, as in leaching and precipitation. Any flotation result obtainable in a laboratory machine is obtainable in mill operation, if the essential laboratory conditions are duplicated. The converse of this statement is also true, except that the mill-size machine can handle somewhat coarser feed than the laboratory machine. Considering the essentials of pulp treatment in detail, the translation from laboratory to mill results are as follows:

Average size of feed may be slightly coarser in mill than in laboratory, or, if the mill grinding is carried to the same extent as in the laboratory, a somewhat better result may be expected in the mill, other conditions being equal.

Water may make a considerable difference between laboratory and mill results, and this difference may be either in favor of or against the mill. It will usually be in favor of the mill if part of the water is reused; in which case the flotation agent returned by the mill water may lessen considerably the amount of new flotation agent that must be added, and the froth is more easily obtained with admixture of this reclaimed water. But, if there is much soluble salt in the ore, or if the settling ponds are of considerable area and in an arid region and there is much dissolved salt in the new water, these salts may injure flotation.

Flotation agents in the mill will be the same as in the laboratory, except that in the mill it is generally possible to lessen the proportion of frothing agent in the mixture.

Peripheral speed of agitators is usually somewhat less in mill than in laboratory.

Air consumption per cu ft of pulp treated in pneumatic machines is usually less in mill than in laboratory. Pressure on underside of the blanket must be higher in mill than in laboratory machines, due to the greater head on the pulp side of the blanket.

Time of treatment necessary in the mill will be very nearly the same for a given recovery and grade of concentrate as in the laboratory. Hence, the required volume of mill machines may be calculated therefrom.

Grade of final concentrate obtained in the mill will be close to that in the laboratory.

Recovery will be close to the indicated extraction, computed by the formula (Art 19, Eq 4) from laboratory results, if the figure used for grade of concentrate is that obtained from the cleaner operation; the figure for rougher tailing is that obtained from the rougher operation, and the middling or cleaner tailing obtained in the laboratory is disregarded, provided that the grade of this middling product is not more than twice the grade of the original heads, and that the mineralogical character of the middling is not markedly different from that of the original feed.

Mill tests. It can not be too strongly urged that, before a mill is erected, some testing work be done with mill-size flotation machinery. It should be done in a test mill at the mine, on ore, the prior handling of which corresponds closely with the scheme to be followed in the finished mill; the water also should approximate the character of the water that will be used in the final plant. If such a test merely confirms the laboratory results, it will pay for itself in the information that it gives concerning mill operation on the ore, and the test may reveal conditions which were overlooked in the laboratory. As some of the equipment used in such a test can generally be utilized in the final plant, not all of it needs to be charged to the testing work.

16. AMALGAMATION TESTS

Pan amalgamation. A sample of the ore, previously crushed to 30 or 40-mesh, is ground for a definite length of time in a Wedgwood or an iron mortar, with addition of Hg and such ingredients as would be used in practice; for example, caustic soda, salt, copper sulphate, or H_2SO_4. Following mixture is commonly used: ore, 300 gm; water, 100 cc; caustic soda, 1 gm; Hg, 50 gm. Grind for 1 hr, pan off the Hg, dry and assay the residue, and calculate extraction.

In a small test of this nature, results calculated from DIRECT DETERMINATION of the Au and Ag taken up by the Hg are seldom reliable, owing both to the difficulty of obtaining Hg quite free from these metals, and to the likelihood of loss while driving off the excess Hg by heat, or dissolving it in acid. If the Hg breaks into small globules that will not coalesce readily, the addition of caustic soda, sodium amalgam, or sal ammoniac may assist in causing the Hg to unite in a single globule.

Plate amalgamation. A method often giving good results is to roll a weighed sample backwards and forwards in a large bottle containing Hg and dilute caustic soda solution. Following proportions may be used: ore, 200 gm; solution, 100 cc, containing 1% NaOH; Hg, 10–15 gm. The bottle is kept revolving for 0.5–3 hr, after which the contents are panned to separate the Hg. Extraction is calculated by difference between original and

final assays of pulp. SIZING-ASSAY TEST, made on tailings from this bottle best, tells whether finer crushing would be likely to improve recovery. TESTS ON PLATES may be made by passing small quantities of ore over an amalgamated plate or pan, or by agitating with strips of amalgamated copper in a bottle. Tests simulating plate amalgamation will almost always give lower recoveries than can be obtained in a mill.

17. CYANIDING TESTS (see Sec 33)

Preliminary tests are often desirable to determine whether a given ore is at all suitable for cyanide treatment. The first test may imitate the extreme limits to which such treatment could be carried in practice. No standard test will cover all possible cases, but the following will serve in many instances. Take 100 gm of ore ground to 200-mesh. Add lime or caustic soda until a distinct alkalinity remains permanent on agitation with water. Dilute to 3 parts of liquid to 1 of ore; add cyanide to give strength of 1% KCN, and agitate continuously for 72 hr; wash out on vacuum filter; titrate filtrate for cyanide. Wash residue on the filter thoroughly with water, dry and assay. With certain classes of ore it may be necessary to supplement this treatment by injection of compressed air before or during the agitation, and to wash the final residue repeatedly by decantation, stirring, and settling each time before decanting, with or without vacuum filtration.

Variable conditions in cyanide treatment. If the ore proves generally suitable for cyanide treatment, the next points requiring investigation are: (*a*) fineness to which ore must be crushed; (*b*) alkali necessary for neutralization; (*c*) most suitable dilution of pulp; (*d*) strength of cyanide required; (*e*) time of treatment necessary; (*f*) whether to treat entirely by agitation, or to separate a portion for percolation treatment; (*g*) whether oxidizers or other auxiliary agents are necessary.

Bottle agitation. Most of the above points can be ascertained by simple agitation tests in bottles along the lines of the standard test given above. These are conveniently performed by attaching bottles (glass preserve jars are suitable) to any revolving mechanism, placing the stoppers towards the center of rotation. Bottles may be protected by wrapping in cloth, or may be secured in wooden cases affixed to the wheel, and firmly packed to prevent slipping. Speed should be sufficient to give efficient agitation, but not so rapid that the pulp is held against the bottom of the bottle by centrifugal force; about 20 rev per min are generally suitable. The following scheme may serve as a model, to be varied in detail according to circumstances.

Fineness of crushing. Make 6 bottle tests, using in each case: ore, 100 gm; solution, 300 cc; lime, 1 gm; cyanide, 0.5% KCN. Crush an average sample of the ore to 20-mesh and weigh out one charge of 100 gm for test; then crush remainder to 40-mesh, taking 100 gm for test; and so on successively to 60, 80, 120, and 200-mesh. Agitate in bottles as above for 24 hr, test strength of solution and add enough cyanide to restore solution to its original strength of 0.5%. Continue agitation another 24 hr, make up strength as before, and continue agitation for a total period of 72 hr. Filter, wash, and assay residue.

Alkali strength. On indications of previous series of tests, determine fineness to which the ore should be crushed. Supposing that nearly identical results are given with 120 and 200-mesh ore, crush a sufficient quantity to 120-mesh, and prepare 6 identical tests, using: ore, 100 gm; solution, 300 cc; cyanide, 0.5% KCN. Add respectively the following weights of lime: 0.02 gm, 0.05 gm, 1 gm, 1.5 gm, 2 gm, 3 gm. Agitate simultaneously for 72 hr, and test residue as before; also determine alkalinity and cyanide strength of final solution (see below).

Total acidity of an ore is determined by agitating with an excess of alkali solution of known strength. For example, agitate 100 gm of ore, crushed, say, to 120-mesh, with 200 cc of 1% NaOH solution, without cyanide. After 1 hr, titrate solution (without diluting) with standard acid, and calculate consumption of alkali. Sometimes comparative tests are desirable to determine whether lime or caustic soda is preferable.

Dilution of pulp. Crush a sample of ore to fineness indicated by preceding tests. Add lime or other alkali, also as indicated. Make 6 tests, each on 100 gm ore, with the following volumes of 0.5% KCN solution: 100, 150, 200, 250, 300, 500 cc. Agitate 72 hr, maintaining strength at 0.5%; test final solutions for cyanide and alkali, and assay residues after filtering and washing. Results will indicate the most desirable dilution of pulp, assuming that the ore is to be treated by agitation, on the all-sliming principle (Sec 33, Art 11).

Strength of solution. Supposing that best results are obtained with a dilution of 2 : 1, run a series of 6 identical tests, with 100 gm of ore, 200 cc solution, 1.5 gm lime (or other amount as previously indicated). Agitate continuously for 72 hr, using solutions respectively of 0.05, 0.10, 0.25, 0.5, 0.75 and 1% KCN strength. Test final solutions,

calculate cyanide consumption, and assay residues after washing and drying. In case one or more of these tests show all or nearly all of the cyanide to have been consumed, it is advisable to repeat the series, determining the cyanide strength at intervals of a few hours, and adding sufficient solid cyanide, or strong solution, to bring the strength up to the required standard. This is repeated until successive tests show practically no further consumption of cyanide. Any solution drawn off for such tests should be replaced by an equal volume of water, so as to maintain a constant ratio of solution to ore. Final extraction, when the solution has been maintained at given strength, will often be much higher than that obtained by a test in which most of the cyanide was destroyed early in the treatment.

Example showing method of maintaining strength. Suppose 200 cc of 0.25% KCN solution originally taken; total cyanide contents = 0.50 gm. After period of agitation with ore, 50 cc taken out, after standing to settle clear, shows a strength of 0.19% KCN; remaining solution, 150 cc at 0.19% = 0.285 gm KCN. Cyanide to be added to make up strength = 0.50 − 0.285 = 0.215 gm. Suppose we have a strong solution containing 1.05% KCN; then 20.5 cc of this will contain 0.21525 gm KCN. Measure out 20.5 cc of the strong solution, dilute this to 50 cc with water, and add to the test. This gives 200 cc, containing altogether 0.50025 gm KCN, or practically 0.25%.

Time of treatment. Assuming previous tests to show best result with 0.25% KCN, run tests with (say) 100 gm of ore, 200 cc of 0.25% KCN solution, 1.5 gm lime, stopping treatment successively after 12, 24, 36, 48, 72, or 96 hr. Test solutions and assay residues.

It may sometimes be desirable to vary two or more conditions simultaneously. Thus, if a strength of 0.25% KCN gives the best result with 72 hr agitation, it does not necessarily follow that this strength of solution will be most advantageous with 24 or 96 hr agitation. Where facilities permit, a large number of tests under varying conditions may be made simultaneously, thus shortening time required for investigation.

Percolation tests. Whenever the results show a tolerably good extraction without extremely fine grinding, it becomes a question whether percolation would not be advantageous for at least a portion of the ore, and the following test may be made.

Crush (say) 20 to 100 lb of ore to pass 40-mesh. Separate fine portion by hydraulic classification, or by repeated stirring with water, settling, and decanting. Drain the sandy portion as dry as possible, mix thoroughly, by passing through a coarse screen, and on an average sample determine moisture and value. Add lime to the remainder, in proportion determined by previous acidity tests, and charge into small percolation tank. This may be an inverted glass bottle with bottom cut off, a stoneware jar, or half of a small cask. Filter-bed is required, which may be a perforated wooden disk, or a framework of wooden slats, covered with thin canvas, or a layer of cocoa matting with canvas cover. The edge of the filter-frame must be tightly packed in with rope, waste or similar material. An outlet for the leaching solution is provided below the filter frame, the flow of liquid being regulated by rubber tube and screw-clip or pinchcock. Only a little space must be left between filter-frame and bottom of percolator. Solutions are added at intervals, once or twice a day, in amounts of 0.1 to 0.2 times the wt of ore each time. A good plan is to begin with a weak solution to replace moisture in the ore; follow with strong solution, draining off and adding more until the whole charge is saturated with it; then add enough strong solution to cover the charge, and allow to stand, with outlet closed, for at least 24 hr. After this, a number of washes of successively weaker solution may be given, ending with a water-wash, not exceeding in weight the original moisture of the sand treated. Each solution should be drained off as completely as possible before applying the next, to secure maximum extraction with minimum of liquid. The charge may be sampled at intervals with a sampling tube, taking care to get a correct average from top to bottom, and not to remove too large a proportion of the charge. If all the solutions drawn off are measured, and tested for cyanide and alkali, a very fair estimate may be made of the probable consumption of chemicals on a working scale. Finally, the entire charge should be emptied, thoroughly mixed, sampled, and assayed. A portion may also be tested after extra water-washing on a vacuum filter.

Aeration tests are generally made in small model tanks, imitating the construction of the Pachuca or other form of aeration tank. The regulation of air supply requires careful attention; if insufficient, agitation is ineffective; if too abundant, consumption of chemicals may be excessive. It is instructive to compare results from aeration tests with those from bottle tests made without aeration, but under otherwise similar conditions.

Other tests. A great variety of conditions may occur in different ores, which may necessitate an elaborate research into such questions as the necessity or disadvantage of preliminary water-wash, acid-wash, or alkali-wash, oxidizing agents, roasting, concentration, amalgamation, or other process, and the use of additional reagents during cyanide treatment, such as bromocyanide, lead salts, etc. These tests are not, however, in the general class of field tests. WATER-WASHING is

advisable for partially oxidised ores containing iron or copper sulphides, and ACID WASHING is also frequently beneficial under the same conditions, particularly where basic sulphates insoluble in water are present. ALKALI WASHES may be advisable with arsenical and antimonial ores. OXIDIZING AGENTS improve extraction from certain ores containing easily oxidisable sulphides and certain kinds of organic matter; preliminary treatment with permanganate, with or without dilute sulphuric acid, is sometimes advantageous when these conditions are present. ROASTING is beneficial and sometimes essential with ores containing heavy sulphides, arsenides, sulpharsenides, tellurides, etc, but the cost of the operation, in comparison with the possible increased saving of valuable metals, should always be considered. CONCENTRATION is often advantageous when values are associated with sulphides or other heavy minerals, provided that the latter do not constitute too large a percentage of the ore. AMALGAMATION should always be tried in presence of coarse Au and perhaps, also, of native Ag. BROMOCYANIDE has been commercially successful only with telluride and with mispickel ores.

Precipitation tests following bottle tests or small-scale field tests are not reliable, due to the minute amounts of precious metals to be handled.

Consumption of KCN. In the past, assay of solutions for KCN, after classification, has been depended upon to give an idea of KCN consumption. But methods have been developed for regeneration of KCN, that return important amounts in excess of that obtained by precipitation of the Au and Ag. They involve formation and collection of hydrocyanic acid, and are not amenable to accurate field determination.

Interpretation. Plant recovery will not generally be as high as that obtained in the preliminary test in strong solution, provided the ore is ground to same size in both cases. But mill practice will probably permit use of weaker solutions than the best laboratory work, and KCN consumption will be smaller than is indicated; lime consumption in the mill may also be less.

It is distinctly questionable whether the other tests outlined are justified as field work, because amenability to cyanidation is determined by the preliminary test, and testing on a larger scale than bottle tests is necessary before plant construction is begun. Besides elaborate cyaniding tests, other tests, on grinding, mechanical classification, thickening and filtering, should also be made. For detailed instructions for general cyanide testing, see Bib 24–27.

18. OTHER METHODS

Leaching with different solvents is an important possibility in treating low-grade Cu ores, especially those in which much of the Cu is oxidized.

For certain ores, water alone serves as a solvent; others require chemicals, among which H_2SO_4, H_2SO_3, Fe_2SO_4 and ammonia are most promising. Leached Cu may be precipitated as metal, and floated, all in presence of the original pulp solids. ZnS ores, in form of fine concentrate only, can be leached with H_2SO_4 after roasting. Oxidized Pb ores containing Ag can be leached with strong acidified brines, but leaching has nowhere been commercially successful. Leaching of base-metal ores is not yet sufficiently standardized to permit of specifying methods of field testing.

With copper ores, simple tests may be tried with dilute solutions; and, if these give high extraction, the details of precipitation and plant operation can probably be worked out successfully. For ores containing copper sulphides, aeration is important in the leaching reaction.

Leaching applied to Pb–Ag and Zn ores is not a matter for crude field testing.

Volatilization is a possible method of treating oxidized Pb ores containing Au and Ag. Ores should be free from sulphides. Amenability may be tested by grinding fine and roasting a small charge in a dish in a pot furnace at temperature of incipient fusion. A small amount of a chloride may be added, but it is not generally necessary. Extraction is determined by assay of tailing.

19. FORMULAS FOR MILLING CALCULATIONS

Notation. C = wt of concentrate, expressed in any units, but necessarily the same as F. For use in these formulas, concentrate may be defined as any product of treatment of a given feed that contains more of a given ingredient than the feed.

c = assay of concentrate (see notes to f).

c_a, c_b, c_c. See notes to f_a, substituting "concentrate" for "feed."

E = effic. This term is usually applied to two-product classification, indicating the ratio of wt of classified material in overflow to wt of classifiable material in the feed.

F = wt of feed, expressed in any units. Feed is the material entering for treatment in a plant or individual machine.

f = assay of feed, expressed in any units, as: %, oz per ton, lb per ton, or dollars per ton, when the value is directly proportional to the wt of a given constituent, say Au or Ag, but not when it is the combined value of the Au and Ag, unless the ratio of their weights is the same in all products as in the feed.

f_a, f_b, f_c, etc. When feed contains more than one valuable ingredient, assays are made of each, expressed separately in the formulas, and distinguished by subscripts.

K = ratio of concentration, meaning the ratio of wt of feed in a given operation to wt of concentrate obtained from it; or, the tons of feed required to produce 1 ton concentrate.

M = wt of middling, expressed in any unit, but it must be the same unit as F. Middling, in these calculations, is the product of the treatment of a given feed containing an amount of a given ingredient that lies between those in the tailing and concentrate.

m = assay of middling (see notes to f).

m_a, m_b, m_c. See notes to f_a, substituting "middling" for "feed."

R = recovery, the percentage ratio of the wt of the sought-for ingredient in the finished product of a given operation, to the wt of same ingredient in the feed in this operation. The terms EXTRACTION, INDICATED EXTRACTION, ESTIMATED EXTRACTION and ACTUAL EXTRACTION are sometimes used to indicate recovery. The terminology is so greatly confused that the meaning of none of the terms can be safely assumed without specifying the method of determination. Some writers have attempted to distinguish between extraction and recovery, making extraction mean the value of R computed from assays of feed and products, and recovery, the ratio of the wt of metal in concentrate actually recovered (= actual wt of concentrate × assay of concentrate) to the actual wt of metal in the feed (= actual wt of feed × assay of feed). Others use the term INDICATED or ESTIMATED EXTRACTION to signify R from assays alone, and ACTUAL EXTRACTION to signify the % of total metal fed that is actually recovered.

T = wt of tailing, expressed in any unit, but it must be the same unit as F. Tailing is here defined as that product of treatment of a given feed which is distinctly impoverished in content of a given ingredient as compared to the feed.

t = assay of tailing. (See notes to f.)

t_a, t_b, t_c. See notes to f_a, substituting "tailing" for "feed."

Two-product formulas:

$$C = F(f - t) \div (c - t) = T(f - t) \div (c - f) \quad (1)$$

$$T = F(c - f) \div (c - t) = C(c - f) \div (f - t) \quad (2)$$

$$K = (c - t) \div (f - t) \quad (3) \qquad R = 100c(f - t) \div f(c - t) \quad (4)$$

Three-product formulas, one metal:

$$C = \frac{F(f - t) - M(m - t)}{(c - t)} = \frac{T(m - t) - F(m - f)}{(c - m)} \quad (5)$$

$$M = \frac{F(f - t) - C(c - t)}{(m - t)} = \frac{F(c - f) - T(c - t)}{(c - m)} \quad (6)$$

$$T = \frac{C(c - m) + F(m - f)}{(m - t)} = \frac{F(c - f) - M(c - m)}{(c - t)} \quad (7)$$

$$R = 100\left[\frac{c(f - t)}{f(c - t)} - \frac{Mc(m - t)}{Ff(c - t)}\right] = 100\left[\frac{c(m - f)}{f(c - m)} - \frac{Tc(m - t)}{Ff(c - m)}\right] \quad (8)$$

$$K = \frac{F(c - t)}{F(f - t) - M(m - t)} = \frac{F(c - m)}{T(m - t) - F(m - f)} \quad (9)$$

If F is taken = 1:

$$R = 100\left(1 - \frac{Tt}{f}\right) = 100\left[\frac{Cc(f - t) + Mm(f - t)}{Cf(c - t) + Mf(m - t)}\right] \quad (10)$$

and

$$K = \frac{C(c - t) + M(m - t)}{C(f - t) + M(f - t)} \quad (11)$$

Three-product formulas, two metals, *a* and *b*:

$$C = F\left[\frac{(f_a - m_a)(m_b - t_b) - (f_b - m_b)(m_a - t_a)}{(c_a - m_a)(m_b - t_b) - (c_b - m_b)(m_a - t_a)}\right] \quad (12)$$

$$M = F\left[\frac{(c_a - f_a)(f_b - t_b) - (c_b - f_b)(f_a - t_a)}{(c_a - m_a)(m_b - t_b) - (c_b - m_b)(m_a - t_a)}\right] \quad (13)$$

$$T = F\left[\frac{(c_a - m_a)(m_b - f_b) - (c_b - m_b)(m_a - f_a)}{(c_a - m_a)(m_b - t_b) - (c_b - m_b)(m_a - t_a)}\right] \quad (14)$$

In formulas (12), (13), (14), C = wt of concentrate rich in metal "a," and M = wt of concentrate rich in metal "b."

$$K_a = \frac{(c_a - m_a)\,(m_b - t_b) - (c_b - m_b)\,(m_a - t_a)}{(f_a - m_a)\,(m_b - t_b) - (f_b - m_b)\,(m_a - t_a)} \tag{15}$$

$$K_b = \frac{(c_a - m_a)\,(m_b - t_b) - (c_b - m_b)\,(m_a - t_a)}{(c_a - f_a)\,(f_b - t_b) - (c_b - f_b)\,(f_a - t_a)} \tag{16}$$

$$R_a = \frac{100c_a[(f_a - m_a)\,(m_b - t_b) - (f_b - m_b)\,(m_a - t_a)]}{f_a[(c_a - m_a)\,(m_b - t_b) - (c_b - m_b)\,(m_a - t_a)]} \tag{17}$$

$$R_b = \frac{100m_b[(c_a - f_a)\,(f_b - t_b) - (c_b - f_b)\,(f_a - t_a)]}{f_b[(c_a - m_a)\,(m_b - t_b) - (c_b - m_b)\,(m_a - t_a)]} \tag{18}$$

Four-product formula. Let G, S, M, T be the products, their assays in 3 metals, a, b and c being: c_a, c_b, c_c; s_a, s_b, s_c; m_a, m_b, m_c; t_a, t_b, t_c. If F be the feed, assaying f_a, f_b, and f_c:

$$G = F\left[\frac{(s_c-t_c)(m_a-f_a)(t_b-m_b)-(t_a-m_a)(s_c-t_c)(m_b-f_b)+(m_b-f_b)(t_c-m_c)(s_a-t_a)}{(s_c-t_c)(m_a-c_a)(t_b-m_b)-(t_a-m_a)(s_c-t_c)(m_b-c_b)+(m_b-c_b)(t_c-m_c)(s_a-t_a)} \right.$$
$$\left. \frac{-(m_a-f_a)(t_c-m_c)(s_b-t_b)+(t_a-m_a)(s_b-t_b)(m_c-f_c)-(t_b-m_b)(s_a-t_a)(m_c-f_c)}{-(m_a-c_a)(t_c-m_c)(s_b-t_b)+(t_a-m_a)(s_b-t_b)(m_c-c_c)-(t_b-m_b)(s_a-t_a)(m_c-c_c)}\right] \tag{19}$$

Formulas for S, M and T may be written from Eq (19) by symmetry: $S = F(X \div Y)$, in which X is obtained from the numerator of Eq (19) by substituting f for s, wherever

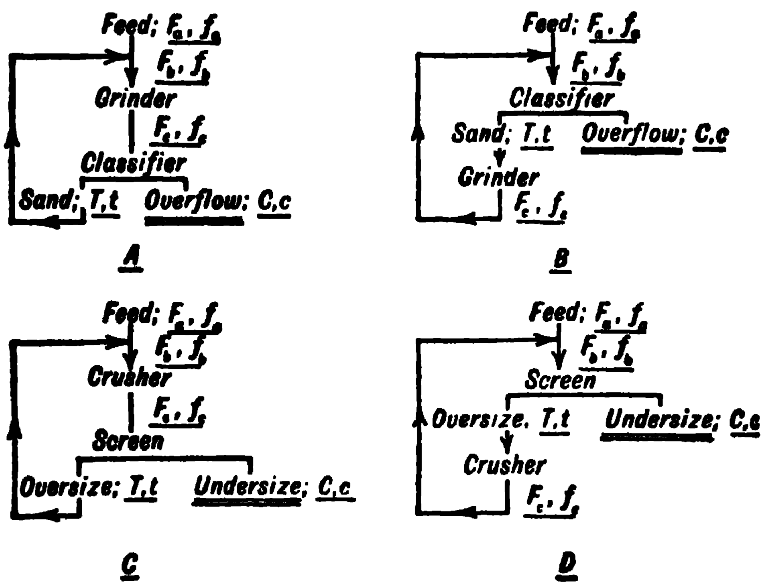

Fig 5. Typical Closed Crushing Circuits

the latter appears, and c for f. Thus the first term of the numerator becomes $(f_c - t_c)\,(m_a - c_a)\,(t_b - m_b)$. By similar substitution, the first term in formula for M is $(s_c - t_c)\,(f_a - c_a)\,(t_b - f_b)$; for T it is $(s_c - f_c)\,(m_a - c_a)\,(f_b - m_b)$. In all cases, Y is the same as the denominator of Eq (19).

Warning. Results from these equations may be seriously in error due to small inaccuracies in sampling and assaying, or even to the inaccuracies inherent in slide-rule calculation. For discussion, see Taggart, Handbook of Mineral Dressing.

Classifier efficiency, $$E = \frac{100(c - f)\,(f - t)}{f(100 - f)\,(c - t)} \tag{20}$$

Tonnages in milling circuits may often be determined by applying the two-product formulas. Fig 5 shows 4 typical closed-crushing circuits.

In Fig 5 (A), $$F_c = \frac{F_a(c - t)}{f_c - t} = F_b \tag{21}$$

$$T = F_c - C = \frac{F_a(c - t)}{f_c - t} - F_a = \frac{F_a(c - f_c)}{f_c - t} \tag{22}$$

$$f_b = \frac{F_a f_a + Tt}{F_a + T} \tag{23}$$

In Fig 5 (B). $$F_b = \frac{F_a(c-t)}{f_b - t} = F_a\left(\frac{c - f_a}{f_c - t} + 1\right) \tag{24}$$

$$T = F_c = F_b - C = F_b - \frac{F_b(f_b - t)}{c - t} = \frac{F_b(c - f_b)}{c - t} \tag{25}$$

$$f_b = \frac{F_a f_a + F_c f_c}{F_a + F_c} = \frac{cf_c - tf_a}{(c - f_a) + (f_c - t)} \tag{26}$$

$$F_c = \frac{F_a(f_a - f_b)}{f_b - f_c} \tag{27}$$

$$T = \frac{F_a(c - f_a)}{f_c - t} \tag{28}$$

$$f_c = \frac{F_a(c - f_a - t) + F_b t}{F_b - F_a} \tag{29}$$

$$f_a = \frac{f_c(f_b - c) + f_b(c - t)}{f_b - t} = c + (f_c - t)\left(1 - \frac{F_b}{F_a}\right) \tag{30}$$

$$R = \frac{c(f_c - t)}{cf_c - tf_a} \tag{31}$$

Specific gravity assay. When an ore is a mixture of two minerals only, or of one useful mineral and a mixture of gangue minerals the relative proportions of which are substantially constant, rapid approx assays may be made of a mixture of useful mineral and gangue by determining the sp gr of the mixture, provided the individual sp gr of useful mineral and gangue are already known.

The usual method is by use of a sp-gr flask. Weigh the flask empty and when full of water. Dry it, introduce the ore sample, weigh, fill with water (taking care to remove all air bubbles) and again weigh. In centimeter-gram units, if S_o = sp gr of ore, S_m of mineral and S_g of gangue; F = wt of dry flask, W = wt of water to fill the flask, O = wt of dry ore, and T = total wt of flask + ore + water; then the wt of water required to fill flask with ore in it = $T - (O + F)$ = volume of water in the flask, and volume of ore in flask = $W - [T - (O + F)]$.

$$S_o = \frac{O}{F + W + O - T} \tag{32}$$

If m = % of mineral in ore = wt of mineral per unit wt of ore, then

$$m = \frac{S_m(S_o - S_g)}{S_o(S_m - S_g)} \tag{33}$$

Cyanidation. Let F, wt of feed = 1; C = wt of concentrate (if made), T = wt of tailing from concentrating (= F, if no concentrate is made), A = wt of sand feed, B = wt slime feed, X = wt sand tailing and Y = wt slime tailing, all expressed as decimal parts of F; and f, c, t, a, b, x and y = respective assays of above products, then,

$F = C + T$ (34). $T = A + B$ (35). $f = cC + tT$ (36). $Tt = aA + bB$ (37)

$C = \dfrac{f - t}{c - t}$ (38). $T = \dfrac{c - f}{c - t}$ (39). $\dfrac{A}{T} = \dfrac{t - b}{a - b}$ (40)

Substituting: $A = \dfrac{(c - f)(t - b)}{(c - t)(a - b)}$ (41). $B = \dfrac{(c - f)(t - a)}{(c - t)(b - a)}$ (42)

$$R = \frac{c(f - t) + \dfrac{c - f}{a - b}[(t - b)(a - x) - (t - a)(b - y)]}{f(c - t)} \tag{43}$$

Pulp consistency. Let p = % solids = wt of solids in unit wt of pulp; D = dilution = water-solid ratio = parts water, by wt, per part of solid, usually written like 6:1; S = sp gr of dry ore; d = sp gr of pulp; then,

$\dfrac{p}{S} + 1 - p = \dfrac{1}{d}$ (44). $d = \dfrac{S}{S - p(S - 1)}$ (45). $p = \dfrac{S(d - 1)}{d(S - 1)}$ (46)

$S = \dfrac{dp}{1 - d(1 - p)}$ (47). $D = \dfrac{1 - p}{p} = \dfrac{S - d}{S(d - 1)} = \dfrac{1}{p} - 1$ (48).

$d = \dfrac{D + 1}{D + \frac{1}{S}}$ (49). $p = \dfrac{1}{D + 1}$ (50). $S = \dfrac{d}{1 - D(d - 1)}$ (51)

If Z = SOLID FACTOR = ton solid per FLUID TON (= 32 cu ft) pulp; G = fluid ton pulp per ton dry solids; and q = % solids by volume; then,

$$Z = pd = \frac{d}{D+1} = \frac{pS}{S - p(S-1)} = \frac{S}{DS+1} = \frac{S(d-1)}{S-1} \quad (52)$$

$$G = \frac{1}{Z} = \frac{1}{pd} = \frac{D+1}{d} \quad (53) \qquad q = \frac{Z}{S} = \frac{d-1}{S-1} = \frac{p}{S - p(S-1)}. \quad (54)$$

Counting assay. If all particles are practically of same shape (that they are of substantially the same intermediate dimension has been assured by sizing), the volume percentages are equal to the number percentages. If there is a distinct difference in aver shape of particles, the number percentages must be adjusted by factors expressing relative volumes of the mean shapes, in order to get volume percentages. If v = % by volume of mineral in sample = volume per unit volume, and S_m and S_g = sp gr of mineral and gangue respectively, the % of mineral by wt is

$$m = \frac{vS_m}{v(S_m - S_g) + S_g} \quad (55) \qquad v = \frac{mS_g}{mS_g + S_m(1-m)} \quad (56)$$

Note that these formulas are applicable to the case of mixtures of solid and water, in which case, if m and v are taken as percentages of solid, S_m is sp gr of solid and S_g = 1.

SECTION 32

SELLING, PURCHASING, AND TREATMENT OF ORES

BY

ARTHUR L. WALKER

FORMERLY PROFESSOR OF METALLURGY, COLUMBIA SCHOOL OF MINES

Note.—Numbers in parentheses in text refer to Bibliography at end of this section.

SELLING, PURCHASING, AND TREATMENT OF ORES

Introduction. This section deals briefly with some of the metallurgical problems relating to the disposal of ores after they have been mined, and which are of interest to mining engineers. An understanding of the terms used in buying ores, and reasons for same, are of prime importance; often making it possible for miners to sort and classify ores so as to obtain max return on a fixed or given schedule (17–23). To cover the subject thoroughly would require citation and discussion of numerous schedules, which would be out of place here. The schedules and forms given will clarify the text.

When an ore is of constant character and value, as is common, for example, in case of iron and zinc, fixed and definite terms can be formulated for sale or purchase. But, for variable or complex ores, special terms and quotations are necessary, which are sometimes difficult to comprehend. Most non-ferrous reduction works receive heterogeneous ores, involving more or less complicated schedules and terms of settlement. Moreover, as local conditions in different ore-producing centers often vary widely, schedules applicable to one district may require radical modification in another. Rates are seldom intentionally made complex, but in certain cases it must be admitted that they could be simplified, for readier comprehension by small shippers. NOTE.—Due to varying local conditions, and governmental regulations of monetary values, exact prices and rates of general application can not be given. Figures on following pages are a fair average over a long period of years (except where dates are given), and will serve as a guide for the seller.

1. TREATMENT OF LEAD AND COPPER ORES

Smelting operations: (*a*) roasting the ore, if necessary; (*b*) furnace treatment; (*c*) refining the metallic product from furnace, and treatment of by-products.

Products of smelting Pb-Ag ores: LEAD BULLION (shipped to refinery) and SLAG (waste). By-products: MATTE, artificial sulphide of a metal or metals; SPEISS, artificial arsenide of Fe, FLUE DUST, COTTRELL, and BAG-HOUSE FUME; these are retreated to recover metals. Products of smelting copper sulphide ore: COPPER-IRON MATTE, converted to BLISTER COPPER, which goes to refinery; SLAG. By-products: SPEISS (seldom produced), FLUE DUST and FUME.

Cost of each treatment step must be considered in fixing the terms for purchasing an ore, and these costs vary with local conditions at the smelting plants.

Mine managers should realize in a general way, the complicated processes necessary to extract metals from ores, and prepare them for market (see Fig 1 and 2). Low-grade ore is often concentrated before being smelted, to eliminate worthless, and/or undesirable, gangue, thus reducing cost of subsequent treatment. High-grade lead and copper ores can be smelted direct.

The sale of small lots of ore while a mine is being developed is of advantage in providing funds for the work. As it is impracticable for the smelter to treat small lots of ore separately and pay for the actual metal recovered, the only alternate for the custom smelter is to purchase the ore outright and settle for it on basis of the analysis as determined by sampling and assaying (23). (See Sections 29 and 30.) This is especially true of ores carrying Au, Ag, Cu and Pb.

Gold ore and silver ore containing little or no Cu or Pb are often treated by the cyanide process (Sec 33). Zinc is recovered from high-grade ore or concentrate by distillation in a retort, or by dissolution and electrolysis.

Many plants now roast ore so perfectly that no matte is produced in lead blast furnaces. The small amount of Cu in the charge passes into the base bullion, and then into the drossing kettle. Dross is treated in a reverberatory, the products being: lead bullion, sent to refinery; copper matte, to the copper smelter; speiss, back to the blast furnace; slag, to waste. This practice often eliminates the copper-matte blast furnace from the scheme and increases direct production of lead bullion.

General basic costs at large plants, per ton of charge, are. for lead smelting, exclusive of roasting and sampling, \$3–\$5; for copper smelting under the same conditions, \$2–\$3. Corresponding costs per ton of lead- or copper-bearing material alone are almost always higher, due to inclusion of barren flux in the charge. For refining lead bullion, \$8–\$12

per ton; for converting copper matte, about $10 per ton of blister copper produced; for refining copper bullion, $15–$23 per ton of copper cathodes produced. Costs at small plants are much higher than for large. Interest and amortization should always be included.

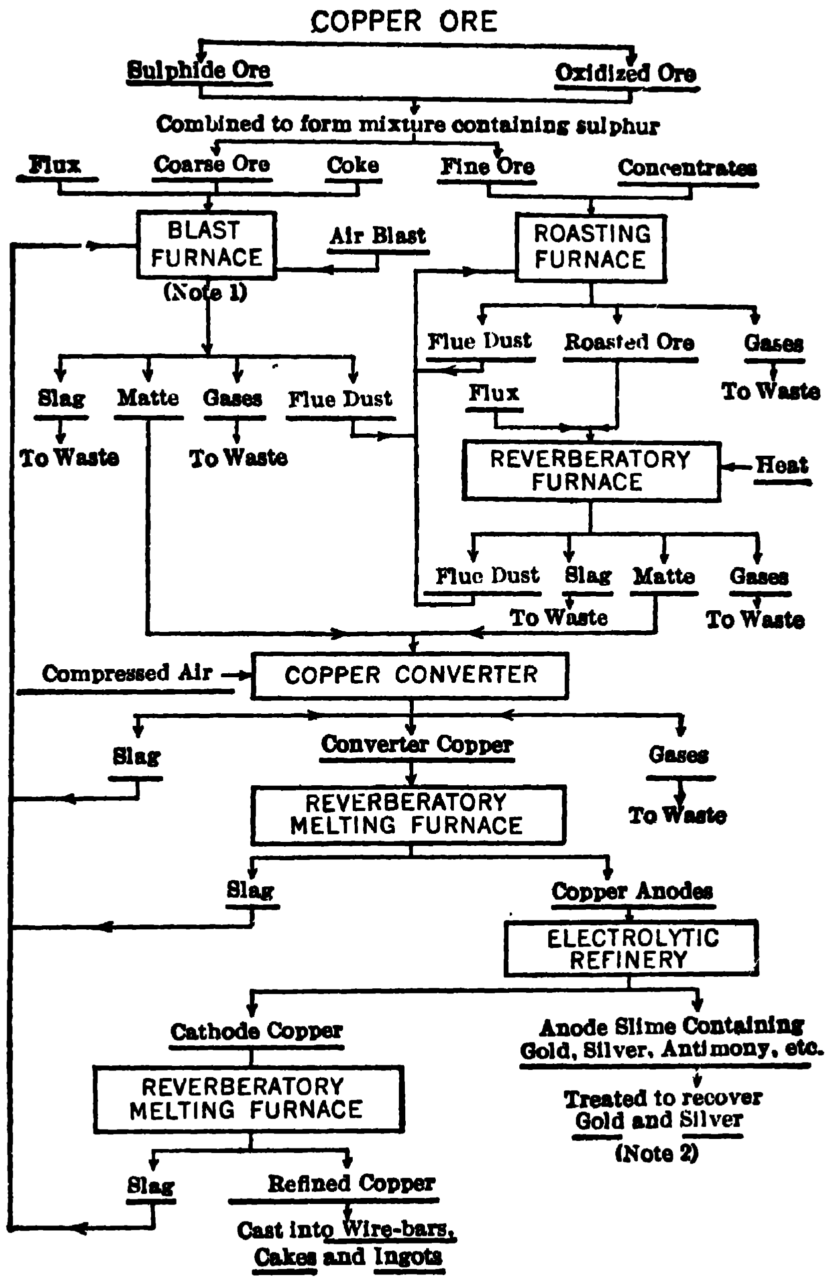

Fig 1. Scheme for Treating Copper Ores.

Note 1. Formerly in the U S copper ore was almost always smelted in blast furnaces; later, both blast and reverberatory furnaces were used. Now (1938) copper ore and concentrate with few exceptions are smelted in reverberatories; a practice due largely to increase in amount of fine concentrate produced and to more economical handling.

Note 2. Metals of the platinum group contained in the gold are recovered by electrolysis.

Metal losses in smelting and refining. In LEAD ORE, loss of Pb varies from 4 to 15%, depending upon percentage of Pb, and upon whether refractory or not. The lower limit is for a charge carrying about 40% Pb; the higher, for a charge carrying about 10–12% Pb. COPPER loss in lead smelting sometimes reaches 30%, as the amount of Cu permissible in a lead-smelting mixture is limited. In smelting COPPER ORE, the loss varies with the

percentage of Cu, but the recovery is always much higher than with lead. Loss in SILVER is small, only about 2%, unless conditions are abnormal. Loss in GOLD is small, and is not usually considered.

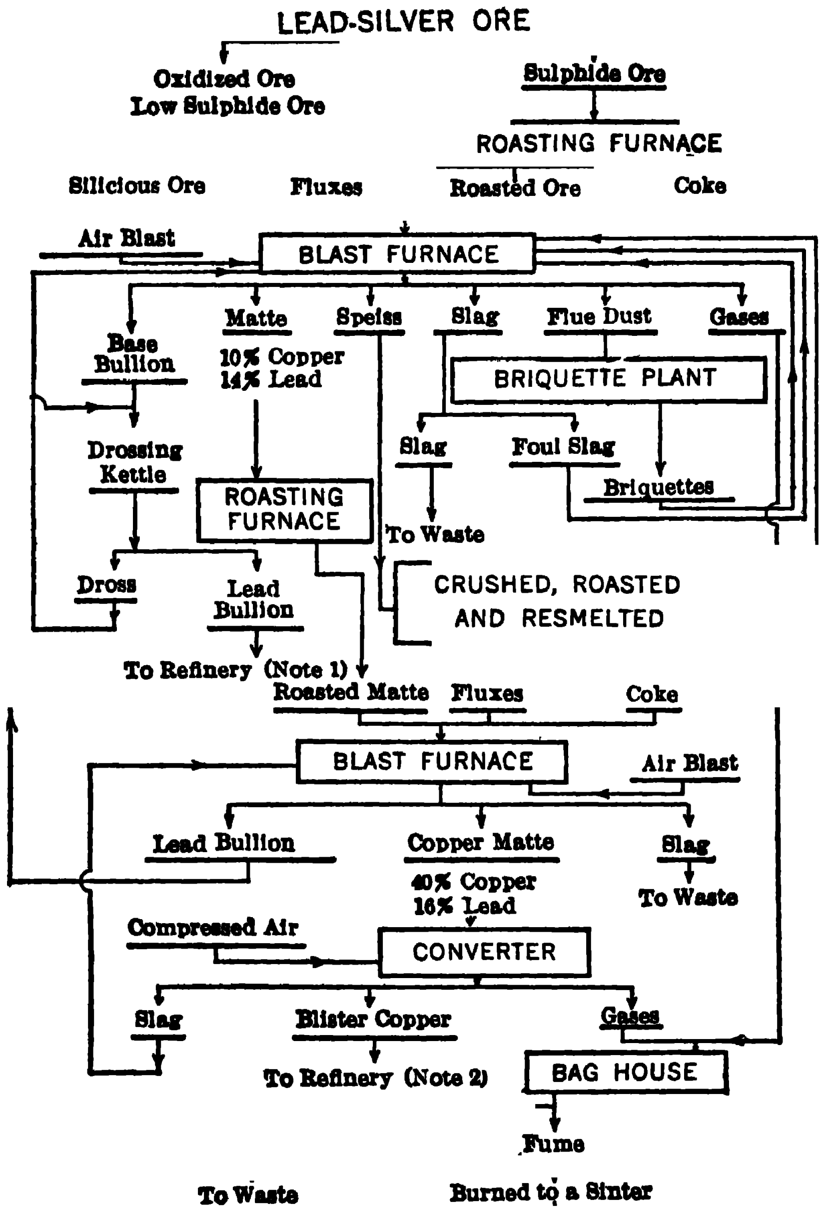

Fig 2. Scheme for Smelting Lead-silver Ores.

Note 1. At the refinery the lead bullion is desilverized, the products being refined lead, silver, gold and antimonial lead, if, as is usual, the ore charge contains antimony. If bismuth is present in refined lead, it can be recovered by an electrolytic process.

Note 2. Blister copper, if any is produced, goes to the copper refinery, for treatment in the reverberatory anode-casting furnace (Fig 1).

2. SALE AND PURCHASE OF LEAD AND COPPER ORES

Principal questions relating to sale and purchase are: (*a*) freight rates; (*b*) method of sampling; (*c*) composition of the ore; (*d*) fluxing requirements to produce a satisfactory slag, and available fluxes at the smelter, either in form of barren material or other classes of ore; (*e*) value of recoverable metals; (*f*) influence of impurities contained in the ore; (*g*) cost of treatment and refining; (*h*) metal losses occurring in treatment; (*i*) interest on value of metals tied up during treatment, and commission for selling metals; (*j*) terms of payment; (*k*) base charge; (*l*) interest and amortization on plant.

Freight charges from mine to reduction works vary with: (*a*) distance; (*b*) value of ore; (*c*) tonnage handled. Custom plants usually pay the freight from the mine to their works, the amount being included under FREIGHT AND TREATMENT. Freight rate on high-grade ore always exceeds that for low-grade, because of the extra responsibility assumed in transporting more valuable material, and to stimulate production of low-grade ore, thereby increasing the railroad's business. Shipping ore should be as dry as possible; smelting returns are on dry ore, and shipper pays freight on moisture present.

Ores and concentrates are usually transported from western mining districts to the smelters by RR or trucks. When the quantities are large and distances long, RR transport is the cheaper. For small lots and short distances, trucking may be more economical. Also less-than-carload lots can usually be shipped cheaper by truck than by rail.

Gardner (26) summarizes the cost of trucking regular tonnages over good dirt roads, when trucks can be steadily employed, and with no shoveling in or out, in conditions existing in gold-mining districts in N W Ariz and Calif in 1935, as follows:

Distance, miles	Aver cost per ton-mile	Distance, miles	Aver cost per ton-mile
up to 1	\$0.35	5 to 10	\$0.09
1 to 2	.22	10 to 20	.06
2 to 5	.12	20 to 100	.05

When shipments are made by rail, a base rate for low-grade ore is quoted, an increase being made for regular increments in the ore values. Aver base rate on western RRs is about 1¢ per ton-mile (1937). Rates for large tonnages of low-grade ore are as low as ½¢; rates on branch RRs may be 2¢ or more per ton-mile (27).

Sampling. For methods, see Sec 29. The moisture sample must be carefully taken, especially in wet or snowy weather, and, as nearly as possible, at time of weighing the ore. It should be dried at not over 212° F, otherwise water of crystallization may be driven off, which is not moisture within the scope of the present definition and the shipper thereby loses weight in settlements for ore. Final fine-pulp sample is usually divided into 4 parts, each placed in a sealed envelope and marked for identification. One sample is used by seller and one by purchaser, to determine the value of the ore. If these determinations agree within certain SPLITTING LIMITS, provided by agreement, the average is taken (Sec 29, Art 11); otherwise, the third sample is sent to an umpire, the fourth being held for emergency use of seller, purchaser, or umpire. The seller or shipper should always have a representative at the smeltery, to watch the sampling, and receive duplicate samples.

Chemical composition. Determinations should be made for: Au, Ag, Cu, Pb, Zn, SiO_2, Fe, Al_2O_3, CaO, S; sometimes for MgO, Ba, As, Sb, and other substances. The analysis reveals the gangue constituents, and indicates whether the ore is self-fluxing, silicious, or basic. A typical analytical smelter report is shown in Form 1.

Form 1. Tacoma Smelter, A S & R Co

Tacoma, Washington 193

Bought of

Material

Smelter lot Mine lot Date received

Car or vessel Entry No Dated

Gold quotation	Silver quotation	Foreign / Copper quotation / Domestic	
Date	Date	Date	Date
\$ per oz	Less	Less	Less

Pb	Zn	As	Sb	Ni	Bi	Sn	Fe	SiO_2	CaO	S	Cl

Lot No	No sacks	Wet weight	H_2O	Dry weight	Assays: Au	Ag	Cu	Contents: Gold, oz	Silver, oz	Copper, lb

(Space of 14 lines)

Notice: If not advised to the contrary within.........days from date we will assume the returns are satisfactory. All prices on ore, not under contract for a specified time, are subject to change without notice. An additional charge of \$10 per lot. for sampling and assaying, will be made on all lots of less than 5 tons, and a reasonable size sample will be held for a period of 30 days.

Few ores are self-fluxing; they are usually either silicious or basic. If silicious, basic material is added to the furnace charge; if basic, silicious material is added. As most of the ore mined in many regions is silicious, basic ore commands a premium, and silicious ore is penalised. The aim is to make a self-fluxing mixture. Allowances for Fe and CaO, and the penalty for SiO_2, are such that they offset each other when the ore mixture is calculated to produce proper slag. The smelter is supposed to obtain no advantage from this system of premiums and penalties; in practice the results may be slightly in his favor.

Fluxes. For proper fluidity of slag, certain percentages of the silicates of FeO and CaO must be present. In copper smelting, slag formerly contained more silica in proportion to bases than in lead smelting. Now (1938) the difference is slight; in some cases lead slag is even more silicious than copper slag. In making up a smelting mixture, CaO usually costs 5–10¢ per unit, and Fe, 8–14¢ (a unit is 1% of a ton, or 20 lb for a short ton); but prices must be accurately known for any given region. The charge for SiO_2 is sufficient to offset payments for Fe and CaO. Penalty for silicious ore may be returned as bonus for Fe and (or) CaO in basic ore.

Example. If smelter pays 5¢ per unit for CaO and 10¢ per unit for Fe, the charge for SiO_2 is determined as follows: Composition of slag desired, 36% SiO_2, 36% FeO(=28% Fe) and 19% CaO. Cost for 28 units of Fe at 10¢ = \$2.80, 19 units CaO at 5¢ = \$0.95; total \$3.75, which is the cost of fluxing 36 units of SiO_2; whence, the penalty per unit of SiO_2 = 10.4¢, say 11¢. Under these conditions, CaO is paid for at 5¢ a unit, Fe at 10¢, and SiO_2 is charged for at 11¢ per unit.

Fe is usually obtained from special ores containing a large Fe excess. But CaO occurs to such a limited extent in most ores that it must be secured by smelting barren limestone, quarried as near the smelter as possible.

3. VALUE OF PRODUCTS; INFLUENCE OF IMPURITIES

Value of recoverable metals is determined by analysis and assay of the samples (Art 2). The principal metals in smelting ores are Pb, Cu, Au and Ag.

Pb and Cu are reported in percentages. The value of Cu is determined by the standard quotation per lb; of Pb by the quotation per lb or unit. Au and Ag are reported in Troy oz per ton of 2 000 lb; their values are now (1938) regulated by the Govt; terms are given in Art 4. In determining the value of Cu, Pb, and Ag, it is specified that the quotation used shall be that of a certain date. The buyer usually pays for the ore at once, making allowance for the time he has to carry the values in the ore. Sometimes it is specified that the quotation used shall be that of a certain number of days after settlement of assay (30, 60, or even 90 days); during which period the metals may be recovered by the smelter and sold at approximately the price that is paid for them.

Influence of impurities has an important bearing on the value of an ore and upon the price paid for it. If the impurities are small in amount, they receive no attention. But, if there is possibility that the ore contains impurities to an extent that will interfere with reduction and recovery of metals, penalties are imposed.

Principal impurities. SULPHUR in copper ores is not detrimental and is not penalized. But sulphur in lead ores, if above a certain limit, makes roasting necessary. As this increases treatment cost, an ore containing more than say 3% S is penalized on the basis of 15 to 25¢ per unit in excess of that amount, up to a maximum of \$2.50 per ton. ZINC, especially as blende, creates irregularities in smelting; part goes into the matte, part into the slag, making it pasty, and part is volatilized, causing trouble in the furnace, and increasing silver losses by volatilization. The usual limit is 8% Zn; at some smelters, all in excess of 5% is penalized. The charge for excess Zn is 15 to 50¢ per unit. ARSENIC is usually penalized in lead, and frequently in copper ore. With lead, it forms SPEISS (Art 2), a troublesome by-product difficult to retreat; with copper, some of the As is reduced in the bullion, increasing refining cost. ANTIMONY is also troublesome, but less so than As. In refining lead bullion from smelting Pb-Ag ore, part of the Sb is recovered as antimonial lead. BISMUTH is objectionable, not being removable in ordinary refining and is found in the refined lead. It can be removed only by electrolysis. PENALTIES for impurities vary greatly, and exact figures are impossible. In lead smelting, As + Sb + Sn in excess of 0.5 to 2 units are often penalized at 50¢ to \$1 per unit. Bi is usually penalized at 50¢ per lb or fraction thereof in excess of 0.1% of the lead content of ore.

4. TERMS OF PAYMENT FOR METALS

In purchasing any class of ore, all the points stated in paragraph 1 of Art 2 must be considered. From (*e*) is found the value of recoverable metals, and from (*j*) the amount paid for them, the difference being the MARGIN ON METALS. From (*c*) and (*d*) result the premium or penalty for basic or silicious ores, and from (*f*) the penalty for impurities. Cost of treatment (*g*) and losses of metals (*h*) are determined from records and experience

in the smelting plant. A base charge (k) is then fixed by considering all the costs and the margin on metals, adding to the margin a charge that will give a total equal to all the costs, plus profit desired. Thus the greater the margin on metals the less the base charge needs to be, to secure a given profit. The base charge, therefore, is an arbitrary figure, acting as a balance wheel.

Gross value of an ore to the smelter is the total metal content, at prices for each constituent arrived at by taking market quotations and deducting from them the cost of freight, smelting, refining and metal losses. The term GROSS MARGIN means the difference between total value of the metals present and the amount paid for the ore; it covers all operating costs, losses of metals, and profit (1).

Gold (typical terms): none paid for if less than 0.03 oz per dry ton. If 0.03 oz or over, entire content paid for at "contract price" as follows: on old standard price for gold, if less than 1 oz per dry ton, \$19 per oz; if 1 oz or over but less than 5 oz, \$19.50; if 5 oz or over, \$20; provided that under the conditions stated in the "Gold Schedule" USAU-A7 (obtainable from the Govt or any large smelter), whenever in any calendar month the "realized price" as defined therein exceeds \$20.67 per oz, payment is made at contract price plus 90% of such excess; and, whenever in such month the "realized price" is less than \$20.67 per oz, then the realized price is paid, less 8%. At present Govt price (June, 1939) these terms are equivalent, for 0.03 oz or over but less than 1 oz per ton, to \$31.818 per oz; for 1 oz or over but less than 5 oz, to \$32.318 per oz; and for 5 oz or over, to \$32.818 per oz. As there is little or no loss of Au in ordinary smelting operations, the difference between value of the Au and amount paid for it more than covers the carrying interest and losses, and therefore adds to the margin on metals in the ore.

Silver (typical terms): none paid for if less than 1 oz per dry ton. If 1 oz or over, entire content less 5% or 0.5 oz per ton (whichever deduction is greater) is paid for at the aver of Handy & Harman N Y silver quotations for the week of delivery at smelter. But if the silver is qualified for delivery to U S coinage mints, as provided in the "Silver Schedule" (USAG, obtainable from the Govt or any large smelter), then, subject to conditions stated therein, the seller shall receive the aver Handy & Harman N Y silver quotation or the "Mint price," whichever is higher on quotation dates. Handy & Harman price (Apl, 1938) was 42.75¢ per oz and the Govt price for U S Silver, 64.64¢. Usually more Ag is recovered in smelting than is paid for, the difference adding to the margin on metals, as for gold (10).

The "Gold" and the "Silver Schedule" (USAU-A7 and USAG) are complicated, but the above summaries give a clear idea of what may be expected.

Lead. Many different payment schedules are in use, the most common deducting 1.5 units from the wet lead assay and paying for 90% of the remainder at some current published price, less freight to refinery and refining and selling charges. A Pb content of less than 5% is rarely paid for. The assay deduction is supposed to cover smelting loss and in making it the variation in Pb content does not affect subsequent terms and conditions. Charge for freight, refining and selling may be about \$30 per ton or 1.5¢ per lb of lead bullion. **Example**: an ore in Colo containing 21.5% Pb, the published base price at N Y being 6¢. Then 21.5, less 1.5 units assay deduction, is 20 units Pb, of which 90% or 18 units (360 lb per ton) is paid for at 6¢, less 1.5¢ for freight, refining and selling, or 4.5¢ per lb. Net return to seller for Pb, 360 lb at 4.5¢ or \$16.20 per ton ore. For old local schedules, see Bib 1, 6, 10, 13, 14. MODE OF ASSAY (Sec 30). WET ASSAY is exact, preferable for seller and now always used. DRY ASSAY (by fire) is usually lower (by 1% to 2%) than wet assay, and is antiquated.

Copper was formerly paid for on basis of the dry or CORNISH ASSAY, estimated at about 1.3 units less than the amount of Cu in the ore. This difference was supposed to cover loss of Cu in old methods of treatment. This assay is now seldom used, Cu being paid for on basis of the wet (electrolytic) assay, less a certain percentage (usually 0.5 to 1 unit) to cover assumed treatment loss. With present methods, this loss seldom reaches 1.3 units. After making deduction, remainder of the Cu is paid for on basis of N Y quotation (¢ per lb), less amount taken to cover cost of smelting, refining and treating, for bringing the Cu to merchantable shapes. The deduction (cts per lb) for Cu in ore sent to a lead smelter is much greater than for ore to a copper smelter. (For aver prices of metals, see Sec 25, Art 13).

These terms seem complicated and the question is often asked, why should not all ore be purchased with an outright and specific base charge? The reason is that, if the terms of payment for each metal do not allow for treatment losses, variations in grade of ore will materially affect reduction cost and losses. Then, if no allowance were made for the Pb loss in quoting for Pb, the base charge would have to be much higher for a rich than for a poor ore, and it would be difficult to frame a sliding scale to fit all conditions. Excessive allowances are often made for losses, but if proper terms are used the miner suffers

no hardship, since the smelter can name a lower charge than would otherwise be possible (5, 7, 8, 16, 23, 25).

Interest and commission are relatively small items. When ore is paid for at time of settlement of assay, interest is allowed on the value of metals, for say 30, 60 or 90 days, depending upon how soon they can be recovered. But, if the metals are not paid for until sufficient time is allowed for their recovery, no interest charge should be made. Commission for selling is usually allowed for in the net price received for refined metals.

Base charge. After arranging terms of payment for metals, premiums or penalties for character of ore, and penalties for impurities (Art 2, 3), a base charge is made. This charge, with other allowances, covers cost of smelting (and roasting, if necessary), treatment of by-products, freight on metals or products, refining of metals and profit to smelter. The base charge is sometimes less than smelting cost, in which case the margin on metals covers difference, and furnishes the profit.

Problem in ore-purchasing. Assume an ore containing: Au, 1 oz; Ag, 20 oz; Pb, 15%; Cu, 2.3%; Fe, 30%; CaO, 3%; S, 16%; SiO_2, 12%; Zn, 5%. Terms which might be used for such an ore are: Au, pay for 100% @ \$31.82 per Troy oz; Ag, pay for 95% at say 65¢ per oz, for U S production; Pb, pay for 90% of wet assay less 1.5 units, at N Y price, less 1.5¢ per lb (say 6¢ less 1.5¢ = 4 1/2¢ per lb) or \$0.90 per unit; Cu, pay for wet assay, less 1 unit at N Y price, less a deduction (say 14¢ less 6¢ = 8¢ per lb); Fe, pay for at 10¢ per unit; CaO, pay for at 5¢ per unit. SiO_2 is penalized at 11¢ per unit; Zn, if over 10%, penalized at 25¢ per unit in excess of 10%. Base charge per ton, \$2. Using these terms, the following statement results:

Method of Calculation

Analysis	Net amount paid miner		Total gross value of metals at smeltery	
Gold, 1 oz	100% @ \$31.82..................	\$31.82	@ \$34.85	\$34.85
Silver, 20 oz	95% @ 65¢ per oz..............	12.35	@ 0.65	13.00
Lead, 15% wet assay	90% of assay less 1.5 units @ 90¢ per unit.......................	10.93	@ 0.045	13.50
Copper, 2.3% wet assay	less 1 unit @ 8¢ net per lb..........	2.08	@ 0.08	3.68
		\$57.18		\$65.03
Iron, 30%	@ 10¢ per unit....................	3.00		
Lime, 3 %	@ 5¢ per unit....................	.15		
Sulphur, 16%		\$60.33		
Less Silica 12% @ 11¢ per unit..........	\$1.32	3.32		
Zinc 5%, no penalty..............				
Base charge....................	2.00			
		\$57.01		\$57.01
			Gross margin	\$8.02

Outcome:					
Gross margin........		\$8.02	Lead loss 10%.......	1.35	
Iron 30% @ 10¢.....		3.00	Silver loss 2%.......	0.26	
Lime 3% @ 5¢......		0.15	Copper loss 20%.....	0.74	
Silica 12% @ 11¢....	\$1.32		Profit to smelter *...	2.00	
Cost of roasting.....	1.50				
Cost of smelting.....	4.00			\$11.17	\$11.17

* In this statement, interest, amortization on plant, taxes, and expense of home office are not included, and may considerably affect the apparent profit shown.

This statement shows that the value of the metals at the smeltery is \$65.03, while the amount paid for them is \$57.18, a difference of \$7.85; which, deducting the Pb, Ag and Cu losses of \$2.35, leaves \$5.50 in favor of the purchaser. Though this is not an actual profit on metals, it enables the purchaser to fix a lower base charge; in this case, \$2 a ton, which is much less than the cost of roasting and smelting. If the margin on metals were reduced, the base charge would have to be correspondingly increased, to obtain the profit shown.

For reasons already given, it is advantageous to allow for losses in quoting on metals, and in so doing the seller suffers no hardship. The premium paid for Fe and CaO, and penalty levied for SiO_2, are considered in the outcome. The ore, because of its Fe and CaO content, has an added value equal to the premium paid, and the cost of SiO_2 which must be fluxed, is considered in treating, this excess being the amount of the penalty for SiO_2 in the purchase statement. When a deduction for Zn is considered in the gross margin, it might seem that it should also appear in the outcome as a cost. But this is difficult to arrange. Excess Zn increases losses and treatment cost, but the amount of increase for different classes of ore is not readily determined. For average ore, the losses and costs are ascertained from the metallurgical results, which furnish the only true data (5, 7, 8).

In certain localities, as in parts of Colo, ores of uniform character, having their chief value in Ag and Au, are sold on a FLAT SCHEDULE, no attention being given to ore composition. This schedule is based on a sliding scale, depending on value of ore (1). Treatment charge on low-grade

ore is such as to stimulate its production; higher-grade ore can stand a higher charge. The charge for a Pb or Cu ore frequently decreases as the value increases, because: (a) an ore of high metal content makes less slag; (b) the Pb or Cu is a valuable collector for Au and Ag.

Different forms are used for making ore purchase calculations. Form 2 is comprehensive, and

5. SMELTER SCHEDULES

The Govt action in increasing the price of gold, and of silver produced in the U S. has greatly stimulated the mining industry. There are now more small shippers of gold and silver ore and concentrate to the smelters than previously. Tables 1 and 2 are lists of the principal smelting plants, and their purchase schedules.

FOOTNOTES FOR TABLE 2

[1] Payments on gold are based on new mint price of $35 per oz (net $34.9125)
[2] Payments on silver are based on new mint price for new American-mined ore at 64.64¢ per oz
[3] Payments on lead are based on N Y quotation for common desilverized lead
[4] Payments on copper are based on the *Eng & Min Jour* quotations
[5] Less a deduction of 1 1/2¢ per oz
[6] Nothing paid for lead less than 5% wet assay
[7] Nothing paid for copper less than 1/2%
[8] Add 10% to base charge for excess value over $25 per ton
[9] 0.1% of wet-lead assay is free
[10] Pay for all at 6¢ per unit
[11] Pay for all at 5¢ per unit, if 5% or over
[12] Add 10¢ to base charge for each unit of lead under 30% and deduct 10¢ for each unit over 30%
[13] Siliceous ore schedule for ores and concentrates having excess of iron are identical, except that treatment charge is a flat $5 per ton
[14] Nothing paid for copper less than 1%
[15] No credit
[16] Schedule for gold concentrates
[17] Add 10¢ per ton per unit of iron short of 25 units excess over insoluble
[18] Schedule for crude siliceous gold ore
[19] Add 10% to base charge for excess value over $35 per ton
[20] 1934 schedule for irony ores and concentrates applies only to ores and concentrates containing 20% or more of iron excess over insoluble
[21] Excess over insoluble, all at 10¢ per unit, not to exceed $3 per ton
[22] Crude-ore open schedule
[23] When lead is over 9¢ per lb, deduct 25% of excess
[24] When copper is over 15¢ per lb, deduct 25% of excess
[25] Pay for iron plus manganese at 5¢ per unit, but credit is not to exceed charge for insoluble
[26] All at 8¢ per unit, if 10% or over
[27] Add 25% of gross value to base treatment charge, when value is between $8 and $10
[28] Add 10% of gross value to base charge, when value is between $10 and $50
[29] 1934 siliceous-ore special for ores with 50% excess insoluble
[30] On direct smelting ores containing over 5 oz gold per ton, price per oz for the excess will be left to mutual agreement between buyer and shipper
[31] No payment for lead under 3% dry assay
[32] Minimum deduction
[33] All at 6¢ per unit
[34] Based on 30% dry lead assay. Debit 10¢ for each unit under 30% and credit 10¢ for each unit above 30%
[35] Midvale smelter reserves right to reject any shipment containing more than 0.1% bismuth
[36] Lead ore open schedule
[37] Ore over 35 oz per ton, deduct 2¢ per oz
[38] No payment for copper under 1%, or when quotation is 8¢ per lb or less
[39] Based on 50% lead. Add 10¢ per unit when over 50%, and deduct 10¢ per unit when under 50%
[40] Penalty applies only to ore under 20% lead; no penalty for ore of 20% or over
[41] Siliceous-ore open schedule: ores containing no lead, or under 5% for which no payment is made (lead determined by wet method less deduction of 1 1/4 units)
[42] Between $20 and $35, $7 per ton; from $35 to $50, $7.50; from $50 to $75, $8; from $75 to $100, $8.50; over $100, $9 per ton

6. MILLING ORES (1)

Terms used in purchasing ore to be treated by amalgamation or cyanidation (Sec 33) are comparatively simple, the operations being much less complex than in smelting. The gangue composition is far less important, as there is no question of making a proper slag, and treatment losses are easily determined. The percentage of recovery of Au and Ag is less than in smelting, but the treatment cost is so much lower (especially in cyanidation) that many ores can be more satisfactorily milled than smelted. Au and Ag ore adaptable to milling usually contains but little Cu or Pb.

The "Open Schedule," given in substance in the 4 following paragraphs, is a good example of terms for treating milling ores and concentrates in western part of the U S (1938):

Treatment rates per ton for ores and concentrates: of value not over $8 per ton, $2.50; over $8 but not over $10 per ton, $3; over $10 but not over $15 per ton, $4; over $15 but not over $20 per ton, $4.50; over $20 but not over $40 per ton, $5.50; over $40 per ton, $6. Additional charges: for sampling any lot of less than 10 ton, dry wt, $5, and shipper pays for umpiring or check assaying; for re-sample of such lot, $5; when more than one lot is shipped in a car, $2.50 per lot; if ore is sacked, 10¢ per ton; if received frozen, 10¢ per ton; for each 1% moisture over 10%, 5¢ per ton. Minimum moisture deduction, 1%. These rates are subject to change without notice and are exclusive of freight charges, which must be prepaid or guaranteed by shipper.

Not accepted at this plant: ore containing over 0.2% non-sulphide copper, or over 3% total copper, or over 3% zinc. Concentrates are accepted at option of mill manager and payment is made for gold only. New shippers or those whose ore changes in character, or who move from one mine to another, must send a 5-lb sample, charges prepaid, to be tested before shipments are consigned.

To avoid demurrage and enable settlements to be completed, shippers must notify mill promptly of all shipments, by bill of lading or letter stating name of mine, owner, lessee (if any) and car number. Shipper agrees that, after sampling, the shipment (except the reserve sample) may be mixed with other ores, or otherwise disposed of; and agrees to settlement in accordance with standard practice at this plant. To insure prompt settlement shipper must compare assays promptly by telephone, assay certificate or letter, or authorize settlement on mill assays when consigning; without such information within 10 days of receipt of shipment, settlement will be made on mill assays. No umpires or re-samples are allowed on shipment of 0.25 oz gold or less per ton.

Payment. GOLD; no payment if less than .02 oz per ton; from .02 to 0.5 oz inclusive per ton, $32.26 per oz; over 0.5 but not over 5 oz per ton, $32.76 per oz; over 5 but not over 10 oz per ton, $32.76 for first 5 oz and $33.12 per oz for balance; over 10 oz per ton, $32.76 for first 5 oz, $33.12 for second 5 oz and $33.47 per oz for balance. For gold in truck shipments and shipments of less than 10 ton, deduct $1 per oz from above prices. SILVER; no payment if less than 1 oz per ton; from 1 to 5 oz per ton, 50% paid for; over 5 but not over 10 oz per ton, 65% paid for; over 10 but not over 20 oz per ton, 75% paid for; over 20 but not over 50 oz per ton, 85% paid for; over 50 but not over 100 oz per ton, 90% paid for; over 100 oz per ton, 95% paid for. Provided miner's silver affidavits are promptly furnished, as required by the Treasury Dept, payment is made under existing government regulations at 64.64¢ per oz; otherwise at the market quotation for date immediately proceding date of settlement, excluding fractions of cents; except that for ore exceeding 100 oz per ton, 2.5¢ additional will be charged for excess over 100 oz. SULPHIDE LEAD in crude ores only: no payment if less than 3%; if 3% or more, pay for 80% of wet assay less 1%, at N Y quotation for date immediately preceding date of settlement, less 2.5¢ per lb. Non-sulphide lead, no payment. (NOTE. The "Open Schedule" ends here.)

Copper ore. For Cu ore containing Au and Ag, but no Pb, or so little that it is not considered, terms of payment are illustrated by the following schedule, in force 1937:

Gold and silver on the same basis as for lead ore. Copper, pay for 100% of wet assay, less 8 to 15 lb per ton ore, *Eng & Min Jour* quotations, less 2.5 to 3¢ per lb. **Penalties.** Zinc, no penalty at many copper smelters, though some charge 30¢ per unit in excess of 6 units. As, Sb, and Sn are free at most plants, at others 50¢ to $1.50 for all in excess of 1 to 2 units. Bi, no charge, except at El Paso smelter, where all in excess of 0.1 unit is charged for at 50¢ per unit. Treatment charge, $2.50 to $6 per ton, based on gross value of ore up to $100; over $100, $8 to $15.

Example 1. Method of calculating returns on a shipment of ore based on preceding schedule: wet wt of lot = 36.28 ton; moisture = 8.5%; dry wt of lot = 36.28 (1.00–0.085) = 33.20.

Chemical analysis: gold, 1.27 oz per ton; silver, 2.10 oz per ton; copper, 1.2%; zinc, 6.4%; arsenic, .60%; antimony, .72%; bismuth, .08%; iron, 12.4%; sulphur, 19.1%; silica, 49.7%; alumina, 6.0%; total, 96.20%.

Payments: gold, 1.27 × $32.76 = $41.605; silver (2.10 − 0.5) × 64.64 = $1.034; copper @ 14¢ (avg) per lb, 20 (1.2 − 0.75) × (0.14 − 0.025) = $1.035; lead, none. Gross payment per dry ton, $43.674.

Deductions: treatment charge for ore of this value, $5.50. Penalties: zinc (6.4 − 6) × 0.30, .12; arsenic + antimony (0.60 + 0.72) − 2.0, none. Total deductions per dry ton, 5.62. Net payment per dry ton, $38.054.

Total returns by the smelter to the shipper, 33.20 × 38.054 = $1 263.39.

In Canada production of copper has become an important industry. Examples 2 and 3 show typical returns prior to 1938 from a Cu-Au-Ag ore, and a Cu ore from which iron pyrite is recovered and marketed, terms change, but form of computation is useful.

Example 2 (29). A copper mine in B C produced from 100 ton ore assaying 1.08% copper, 0.003 oz gold and 0.116 oz silver: 3.2 tons of copper concentrate assaying 27.63% copper, 0.06 oz gold and 2.45 oz silver, recovering 88.4% of copper, 61.2% of gold and 68.2% of silver. Value of the concentrates, which were shipped to a copper smelter in the U S, is calculated as follows:

Terms: copper assay, less 1.3 units at dollar equivalent of London copper price, less 2¢, 98% of gold at $35, 95% of silver at silver price less 1 1/2¢. Treatment charge $5 per ton. Assuming copper price 15¢, and silver price, 45¢: Copper, 27.63%, less 1.3% = 26.33% = 526.6 lb at 15¢, less 2¢ = 13¢ = $68.46; Gold: 98% of 0.06 oz = 0.0588 oz at $35.00 = $2.06; Silver: 95% of 2.45 oz = 2.3275 oz at 45¢, less 1 1/2¢ = 43 1/2¢ = $1.01; total, $71.53. Freight $1; treatment charge, $5 = $6.00. Net revenue per ton concentrate, $65.53; revenue from 3.2 ton concentrate (from 100 ton ore) at $65.53 = $209.70; revenue per ton ore, $2.10. Gross value per ton ore, 1.08% copper, 0.003 oz gold, 0.116 oz silver: Copper 21.6 lb at 15¢, $3.24; Gold 0.003 oz at $35.00, 10¢; Silver 0.116 oz at 45¢, 5¢; total, $3.39.

Example 3 (29). A copper-pyrite property in Quebec produced from 100 ton ore assaying 3.71% copper, 13.6 tons copper concentrates assaying 25.62% copper, with a recovery of 93.77%, and 51 1/2 ton of iron-pyrite concentrates, assaying 49% sulphur. Value of the concentrates, which were shipped to the U S, is calculated as follows:

Terms on copper concentrate: Copper assay less 1.3 units at dollar equivalent of London copper price, less 2¢. Treatment charge $5 per ton. Assuming Copper price 15¢: Copper, 25.62% less 1.3% = 24.32% = 486.4 lb at 15¢ less 2¢ = $63.23. Freight ($5) treatment charge ($5), $10.00. Revenue per short ton copper concentrates, $53.23. Terms on iron pyrites: 49% sulphur at 13¢ per long ton unit, $6.37; freight, $2.00. Net revenue per long ton pyrite concentrate, $4.37; 13.6 short ton copper concentrates at $53.23, $723.93, 51.5 short ton pyrite concentrates, *ie* 46 long tons at $4.37, $201.02; revenue from 100 short tons ore, $924.95; revenue per ton ore, $9.25.

Based on copper content, the gross value of this ore, assaying 3.71%, 74.2 lb at 15¢, equals $11.13. The revenue in this case compared to the gross value is increased by the sale of iron-pyrite concentrates. To make two concentrates, instead of allowing the pyrite to go with the tailings, entails higher cost of concentration; and the feasibility of such procedure depends on having a market for the pyrite concentrate at a low enough freight cost.

Zinc ores. The purchasing terms are entirely different from those for Pb and Cu. Zn ore is mostly sold in open market at a base rate per ton of sulphide ore (concentrate) containing 56 to 60% Zn, a premium of about $1 being paid per unit over 60, and $1 penalty charged per unit under 56. A charge may also be made for CaO, Pb and Fe. The flat price per ton varies with conditions.

The value of Zn ore is always determined basically by its Zn content, less an allowance for metallurgical loss, less a deduction for freight and treatment. This is expressed by the formula: $[(T - 8) \times 20 \times P] - R$, in which T is the Zn assay in percent, 8 the deduction for loss, 20 the lb per unit (changed to 22.4 if the long ton is used), P the price of Zn in cts per lb at the basing point and R the "returning charge" or deduction for treatment, in dollars per ton.

In the U S the principal source of Zn ore is the Tri-State district, where its value is determined by auction. At present (Feb, 1938) the Joplin quotation is $30 per 2 000 lb for standard ore of 60% grade (1 200 lb Zn per ton). From this the factor $(T - 8)$ indicates a yield of 1 040 lb or 86.67%, which is a fair figure for overall recovery from green ore. As the price for Prime Western zinc at St Louis is 4.75¢ per lb and the freight rate from Okla points to St Louis is 0.175¢, the quotation for Zn at point of origin is 4.575¢, at which the value of 1 040 lb is $47.58; and deducting $30 base payment for the ore leaves the metallurgist a margin of $17.58, which is R in the formula (W. R. Ingalls).

Example 4, showing the settlement price for Zn concentrate in the Joplin district, when base price and Zn content are lower than stated above, and penalties are levied on impurities. Base price is quoted each week per dry ton of 60% Zn concentrate, with flotation product at $1 per ton less than gravity grades. For concentrate of 56% Zn or more, the value of the Zn content equals the quoted base price divided by 60 and multiplied by the actual Zn assay in percent. For lower grades, this value is computed as though for 56% and reduced $1 per ton for each unit below 56% Zn. Lead-free Zn concentrate of 0.1% Pb or less usually commands a premium of $1 per ton above the quoted base price. Allowable Fe 3%, Pb 2%, CaO 1.5%; excess of any one constituent is penalised at $1 per unit.

For a $27 base price and a dry ton of concentrate assaying 55% Zn, 4% Fe, 3% Pb, and 2% CaO, the calculation is as follows:

$$\text{Value of 56\% Zn concentrate} = \frac{27}{60} \times 56 = \$25.20$$

Penalties, 1 unit Zn deficiency.........	$1.00	
1 unit Fe excess............	1.00	
1 unit Pb excess............	1.00	
1/2 unit CaO excess..........	0.50	$3.50
Settlement price........		$21.70

Formulas for purchase of Western ores are more complicated, due to occurrence of recoverable silver and lead. Such ore is usually sold to Au electrolytic refinery on basis of a special schedule prepared by the refinery.

The value of zinc ore delivered to European smelters is theoretically determined in the same way, but with more complications as to variation in the returning charge, according to the price for spelter, etc.

In Canada, the terms for concentrates from a Zn-Pb ore prior to 1938 were as follows:

Example 5 (29). A lead-zinc mine in B C produced from 100 ton ore (assaying 10.9% Pb, 14.7% Zn, 2.08 oz Ag) 12.5 tons Pb concentrate (assaying 80.5% Pb, 3.6% Zn, and 10.02 oz Ag) and 21.6 ton Zn concentrate (assaying 61.08% Zn, 1.09% Pb and 2.54 oz Ag). 92.6% of the Pb and 60.4% of the Ag were recovered in the Pb concentrates, and 89.9% Zn in the Zn concentrates. The value of the concentrates, which were shipped to Europe, is calculated as follows:

Terms on lead concentrates: 95% of Pb content paid for at London price. Return charge, 20 sh gold per gross ton, based on London lead price of £12 gold, with an added charge of 1s 6d for each £1 advance. Full content of silver at London price per standard oz for each fine oz content (as standard silver is 925 fine, this means a deduction of 7 1/2%). Assuming lead price £24, this equals £14.564 gold (with gold at 140s); return charge is therefore 23.846s gold, or 39.295s paper.

Lead: 95% of 80.5% = 76.475% at £24, 367.08s paper. Silver: 10.02 oz at 20d, 16.70s paper. Total 383.78s paper. Return charge, 39.295s paper; smelter payment per long ton, 344.485s paper; exchange at 4.97, $85.60; freight, $16.50; revenue per long ton lead concentrates, $69.10.

Many zinc smelters in the U S and most of those in Europe recover by-products, but their value is compounded in the zinc formula.

Terms on zinc concentrates: Assay, less 8 units at London zinc price. Return charge 40s gold per gross ton, based on London zinc price of £9 gold, with an added charge of 3s for each £1 advance up to £12; then 3s 3d for each £1 advance up to £15, and 3s 6d for each £1 advance thereafter. Assay basis, 52% to 54%, with 9d gold advance in the return charge for each percent above 54%. Assuming zinc price £22.5, this equals £13.654 gold (with gold at 140s); return charge is therefore 59.6855s gold, or 98 354s paper. 61.08% less 8% = 53.08% at £22.5, 238.86s paper; return charge, 98.354s paper; smelter payment per long ton, 140.506s paper; exchange at 4.97, $34.91; freight, $14.00. Revenue per long ton zinc concentrates, $20.91; 12.5 short ton lead concentrates, *ie*, 11.16 long ton at $69.10, $770.15; 21.6 short tons zinc concentrates, *ie*, 19.3 long ton at $20.91, $403.56; Revenue from 100 short ton ore, $1 173.71, = per ton ore, $11.74. Gross value per ton ore, 10.9% lead, 14.7% zinc, 2.08 oz silver. Lead 218 lb at 5.325¢ (£24, exchange $4.97), $11.61; Zinc 294 lb at 5¢ (£22.5 exchange $4.97), $14.70; Silver 2.08 oz at 45¢ (London 20d per standard oz), 94¢. Total $27.25.

7. MISCELLANEOUS ORES AND NON-METALLIC MINERALS

Iron ore is purchased at flat rate, depending on percentage of Fe, with penalty if it falls below a certain grade, and premium, if above. The base ore standard for bessemer (low phosphorus) and non-bessemer ores (high phosphorus) is 51.5% Fe; standard phosphorus content for bessemer ores, 0.045%. Above or below this standard, within small limits, the price paid for iron ore is slightly decreased or increased respectively.

At beginning of the shipping season in 1938, the rates (31) f o b Lake Erie docks, were: bessemer ore $5.25 to $5.10, non-bessemer ore $5.10 to $4.95, for the above standard grades, with penalty for a lower and premium for a higher content. Eastern ore is often sold at a stated price per unit of Fe. In the past (18) about 83% of ore mined in U S came from Lake Superior districts, 12% from Southeastern States (value at mines about $2.13 per long ton), 2% from Northeastern States (value at mines about $2.59 per long ton), remainder from the West and miscellaneous.

Manganese ore. A sliding scale is always used in purchasing. The higher the Mn content, the higher the price per unit; see following schedule, which was in effect by one consumer in 1924 (16). All prices are f o b at furnaces.

Metallic Mn, %	Fe, max %	SiO_2, max %	Phos, max %	Cts per unit per long ton
50 and over	5	12	15	68
48 to 49.99	5	12	15	65
46 " 47.99	6	13	15	60
43 " 45.99	6	14	15	50
40 " 42.99	5	14	15	45

For each 1% of SiO_2 in excess of the maximum stipulated here, there is a deduction of 25¢ per long ton, fractions in proportion. For each 1%, or fraction, of iron in excess of the maximum, there is a deduction of 25¢ per long ton.

The above gives in general the terms used, but prices have changed since 1924, as shown by following quotations for Mch, 1938 (30). Per long ton unit of Mn, c i f North Atlantic ports, cargo lots, exclusive of duty: Brazilian, 46 to 48% Mn, nominal; Chilean, 47% minimum, nominal; Indian, 50 to 52%, 45¢; Caucasian, 52 to 55%, 45¢. South African, 50 to 52%, 45¢; 44 to 48%, 40¢; nominal.

Chemical grades, per ton, coarse or fine, minimum 80% MnO_2, Brazilian or Cuban, $50 in carloads, to $55 or $60 barreled. Javan or Caucasian, 85% minimum, $60 to $62. Domestic, 70 to 72 per cent, $47 to $52 in carloads, f o b mines.

Domestic manganiferous ore, 10% Mn, 35 to 40% Fe, 22¢ per unit for manganese content and 5¢ per unit of iron, per long ton, delivered Birmingham. High-grade ore, above 40% Mn, low iron content, 40¢ per unit per long ton, delivered Birmingham; under 40% Mn, 30¢ (30).

Prices on foreign ore are quoted c i f Atlantic or Pacific seaport; duty and freight from port to destination paid by consumer.

Chrome ore (31), (lump) c i f Atlantic seaboard, per gross ton (1938): South African (low grade) $16.00; Rhodesian. 45%, $22.00; Rhodesian, 48%, $25.50; Turkish, 48–49%, $25.00 to $26.00; Turkish, 45–46%, $23.50 to $24.00; Turkish, 44%, $19.00 to $19.50. Chrome concentrates (Turkish) c i f Atlantic seaboard, per gross ton: 50%, $25.50 to $26.50; 48–49%, $25.50 to $26.00.

Tin ore or concentrate. No tin ore has been mined in the U S for many years. In foreign countries, practically all tin sold is in form of concentrate. Payment is usually made for 96 to 98% of the tin content (16), depending upon the kind of ore. When all tin is paid for, the base charge is higher. Concentrate is almost always purchased

on a 60% tin basis (Spurr and Wormser). For each unit, or fraction thereof above or below 60%, the returning charge is reduced or increased at rate of 5 shillings (English currency). Net returning charge has varied from £10 to £25.

The basic price for standard tin is generally taken at £170 per long ton, and the returning charge is increased or decreased at a fixed rate per lb above or below this figure. 1% S is allowed free; above this, the penalty is 10 sh per unit (22.4 lb). 5% Fe is allowed free; above this it is penalized. Other undesirable constituents are provided for by an increased base charge.

Tungsten ores are sold in sizes from say 3 in down to fine powder. By sorting or concentration, the material usually contains about 65% tungstic acid (WO_3). It is sold at a price per unit (the unit depending on the ton used). Foreign quotations, converted into U S currency at normal exchange, per unit (20 lb) was about $8.25 in 1923 (16), as low as $3 in 1921, and as high as $40.75 in 1916. Now (Jan, 1938) for Chinese ore, duty paid, $25. Domestic scheelite, $22 to $25. No accepted practice has been evolved concerning premiums and penalties.

Bauxite is the ore of aluminum. It is used in the chemical industry and to some extent for basic refractories. For the aluminum industry, bauxite must be treated to prepare practically pure Al_2O_3. Commercial bauxite usually contains 55–58% Al_2O_3 and not over 10–15% SiO_2. It is usually sold under long-term contracts. Prices have been quoted only in the last few years. Following table gives aver sales prices, as shown in annual reports of the U S Geol Surv (16).

Price of Bauxite per Long Ton, f o b Shipping Point (1913–23)

Year	Aver price, domestic bauxite	Year	Aver price, domestic bauxite	Year	Aver price, domestic bauxite
1913	$4.75	1917	$5.48	1921	$6.38
1914	4.87	1918	5.69	1922	6.25
1915	5.10	1919	5.85	1923	6.03
1916	5.40	1920	6.23	1933	$6 to $7.50

Jan, 1938, domestic commercial, $7.50; domestic abrasive, 70–84%, $12.50 to $15 (30).

Feldspar. No basis for determining the value of feldspar, based on actual composition, has been established. Price of pulverized feldspar per short ton has varied considerably. In 1913, extra fine pulverized sold at about $13 per ton f o b on cars at mills, in car lots. In 1916 the price advanced to $15, in 1918 to $20. Jan, 1938, potash feldspar, 200-mesh, $17. Glass-spar, white, 20-mesh, $11.75 (30). Price of the lower grade is about 0.75 of first grade.

Fluorspar is usually divided into 2 grades by analysis: (*a*) metallurgical or fluxing, minimum of 85% calcium fluoride and max of 5% silica; (*b*) merchantable acid spar, 97% calcium fluoride and not over 2% silica. These are again divided into gravel, lump and ground. Gravel is used extensively in iron, steel and aluminum smelting. In finely-ground form, in the manufacture of opal-glass and in enameling iron and steel ware.

Average Annual Prices of Domestic Fluorspar per Ton of 2 000 lb, f o b at Mines (16–19)

Year	Gravel	Lump	Ground	Year	Gravel	Lump	Ground
1913	$5.87	$6.88	$12.31	1919	$23.80	$30.38	$43.02
1914	5.21	8.45	11.78	1920	23.24	29.85	43.32
1915	4.89	7.51	10.80	1921	16.11	21.39	40.00
1916	5.34	7.94	12.38	1922	16.36	18.56	36.42
1917	9.61	13.68	17.59	1923	18.61	23.32	36.86
1918	20 05	24.12	31.21				

In Jan, 1938, prices for domestic fluorspar, f o b Ky and Ill mines: washed gravel, 85% calcium fluoride and not over 5% SiO_2, $18 to $19 per ton. No 2 lump, same content, $20. Domestic No 1, ground bulk, 95–98% calcium fluoride, not over 2 1/2% SiO_2, $31.50. Foreign, 85–5 c i f Atlantic ports, duty paid, $24.50 (31).

Pyrite. Used extensively for the manufacture of H_2SO_4. Value is based on percentage of sulphur in the ore, and is paid for at a price per unit (usual basis is ton of 2 240 lb). Foreign pyrite run from 50–51% S; domestic, 35–40%. Spanish per unit of sulphur, c i f Atlantic ports, 12¢ to 12 1/2¢. Domestic graded fines, lump and furnace size, 9¢ to 11¢. The impurities, usually present in small amounts, are Zn, Pb, Sb, As, and insolubles (including SiO_2). More than 3% Zn + Pb and more than 1% As are objectionable. If the cinder resulting from the burning of the pyrite contains Cu it is recovered by leaching. The cinder, whether leached or not, is frequently desulphurized, sintered and sold as iron ore.

Sulphur. Practically all sulphur mined in U S comes from the Gulf coast. Unit of weight, 2 240 lb. From 1909 to 1927 the prices ranged from $13 to $22 per ton. In 1909 it averaged $18.52; 1914, $18.17; 1915, $13.46; 1918, $22; 1923, $16.07. During the past 10 years the price has remained constant at $18 per ton.

8. ORE CONTRACTS

Contracts for selling and purchasing should be in legal form, and supervised by engineers or metallurgists having full knowledge of the technical conditions.

Following points should be covered: 1, duration of contract, in years; 2, approx amount of ore to be delivered; 3, rate at which the ore is to be delivered (if known); 4, point at which delivery is to be made from miner to purchaser; 5, arrangement respecting freight rates; 6, method of weighing the ore; 7, determination of moisture; 8, arrangement for representation of both seller and buyer; 9, manner in which the ore is to be sampled, and sampling paid for; 10, number of final samples to be taken, and disposition of same; 11, assay and analytical methods to be used in determining the ore constituents; 12, settlement of splitting limits (Art 2); 13, mode of settlement when determinations by seller and buyer are within the splitting limits; 14, arrangement for umpire, if difference exceeds the splitting limits; 15, mode of settlement in case samples are sent to umpire; 16, terms of payment for metals; 17, the effect, if any, which fluctuations in market price will have on terms of payment; 18, the effect, if any, which the value or composition of the ore will have on these terms; 19, dates on which metals are to be paid for; 20, statement of payments to be made and penalties to be levied for certain ore constituents; 21, the base charge on which settlements will be made; 22, amount which will be advanced (if desired) by purchaser to seller, at any time after settlement has been agreed upon and before final payment is made; 23, possible conditions which shall be considered as valid reasons for failure to deliver or receive ore under the contract (Sec 29); 24, arrangements for submitting disputes to arbitrators, instead of the courts (22).

SECTION 33

GOLD AMALGAMATION AND CYANIDATION

BY

EDWARD L. DUFOURCQ

CONSULTING ENGINEER

REVISED AND LARGELY REWRITTEN FOR THE SECOND AND THIRD EDITIONS BY

JOHN V. N. DORR

METALLURGICAL ENGINEER, NEW YORK CITY

GOLD AMALGAMATION

1. MILLING PRACTICE

Amalgamation of gold ores in modern plants is confined almost exclusively to recovery of the coarse free gold, as a secondary treatment, by BARREL AMALGAMATION of concentrates caught on blanket or corduroy strakes, concentration tables or jigs. PLATE AMALGAMATION, still found in older plants, is rarely installed today. Amalgamation is practically always in conjunction with or followed by CYANIDATION, FLOTATION, or a combination of both processes, and preparation of the ore is usually planned with reference to the requirements of such processes.

The advisability of making a preliminary recovery of Au by amalgamation or corduroy tables, when this is to be followed by cyanidation, must be determined for each individual ore. Where much coarse free Au occurs, often 40–80% of it can thus be recovered directly, at a lower cost than by precipitating and refining from cyanide solution. Also, by diverting the coarse Au from the cyanide plant, the time of treatment in the latter can be reduced and a satisfactory final residue obtained with coarser grinding; examples, Homestake mine, So Dakota, and West and Central parts of the Witwatersrand. Where flotation is used, the preliminary removal of as much free Au as possible is of first importance, since it has a tendency to be depressed under reagent conditions suitable for flotating sulphides. If there is no coarse Au, and fine grinding is required to release the Au from the gangue, practice tends to eliminate all forms of amalgamation or concentration; example, Far East part of the Rand. Improvements in cyanide extraction and precipitation, risk of amalgam theft, mercurial poisoning of workmen and tying up of amalgam within tube-mills, have contributed toward elimination of amalgamation at many large plants. Also, grinding in cyanide solution can not be taken advantage of where amalgamation is used.

Crushing and grinding (Sec 28). Ores must be reduced to such fineness that the Au or Ag is sufficiently freed from gangue to be attacked by mercury. Recent practice is to eliminate stamps; to crush by jaw or gyratory crusher to about 2-in size, with secondary crushing by rolls or fine gyratory-type crushers to a product at least all minus $^3/_4$ in, followed by two-stage grinding in ball- or tube-mill, or a combination of the latter. Recent installations of stamps are limited to cases where a moist, sticky ore would tend to choke a crusher, if crushed to less than about 2-in pieces.

Where size of plant does not warrant stage crushing and grinding, a gyratory crusher is used to produce a size approx 1.5 in, which is ground direct in ball- or tube-mill. For stamps, preliminary crushing is in jaw or gyratory crusher to about 2 in; tendency being toward heavy stamps and low discharge, crushing rather coarse (0.5–0.75 in), and grinding stamp-mill discharge in ball- or tube-mill.

2. PLATE AMALGAMATION

Due to adoption of coarse battery crushing, which causes rapid scouring of inside plates, inside battery amalgamation has been practically eliminated.

Amalgamation may follow the stamp battery (Sec 28) or grinding mills. When much of the coarse Au is liberated in the primary grinder, the plates should follow this unit to avoid accumulation of Au in the secondary grinder, with a second set of plates after the latter.

Apron plates following a stamp battery are wide, shallow, sloping troughs, full width of mortar and made of $^1/_8$-in annealed copper, to prevent buckling with consequent uneven flow of pulp. They are almost always silver-plated. They rest on heavy wooden tables, which, though adjustable, should be rigid and non-warping.

Amount of Ag for plating varies from 1 to 2 oz per sq ft to as high as 5 oz. Plates are resilvered after 1–3 years' use. In some mills replating is not practiced; new plates are installed when necessary, the old plates being melted down. Apron plates following a rod-, ball- or tube-mill are 1–4 ft wide, depending on requirements and constructed as for stamps.

Area of plates depends mainly on size of gold particles to be caught. Fine Au requires slower flow of a thinner layer of pulp over tables; hence, greater area. Modern practice

limits amalgamation to recovery of coarser particles of Au, and an area of 1.5–4.5 sq ft per ton milled per day is usual (Golden Chariot and Argonaut mines). Many small mills in western U S, that depend chiefly on amalgamation for recovering Au, use an area of 10–12 sq ft per ton.

Mercury traps are advisable, as apron plates may then be kept softer, with less chance of losing Hg or amalgam. Good practice avoids having much loose Hg about. An efficient trap consists of a simple transverse trough a few inches deep. The sand and Hg settling in the trap are cleaned out at intervals and returned to battery or mill.

Slope of apron plates varies from $1^1/_4$ to $2^1/_2$ in per ft; best practice, about 2 in. Flat slope requires more water. Tables for supporting plates may be adjustable, for varying the slope. This should be such as to give a pulp velocity high enough to keep the heaviest particles of ore moving, but not so high as to prevent adherence of gold to the Hg surface. Viscosity of pulp is another factor of importance, and densities over 20% of solids should be avoided, as sinking of gold through pulp layer is impaired.

Dressing and care of plates, with maintenance of maximum battery output, are the principal factors in successful amalgamation. In general, unless the gold is very coarse, too much Hg on the plates is better than too little and it should not be too thoroughly removed when dressing and scraping. Apron plates are usually dressed each day, depending on richness of ore and how bright the plates remain. In some mills, having 2 parallel plates in front of each mortar, a diverting launder throws all the feed to one plate while the other is being dressed or cleaned up. Single plates may be divided into 2 parts by a longitudinal wooden strip and one-half dressed at a time. This avoids hanging up the stamps, but the flow of battery water must meanwhile be reduced.

Details of dressing plates. Hg is first sprinkled over the plates, to soften the amalgam. This is rubbed in lightly, after which the amalgam is scraped up from lower end toward head, with a rubber or hard-wood scraper or a rag. Near the head end, scraping is done with an amalgam knife or chisel, so handled as not to cut or groove the plates. After the amalgam is removed, fresh Hg is sprinkled over the plates, more being generally used on upper end. Sprinkling is best done from a small iron bottle of gas pipe, the mouth of which is covered with muslin. When freshly wet with Hg, the plate is well rubbed until the Hg is evenly distributed. A whisk broom is generally used to distribute the mercury over the plate. A stiff broom, which will break up tough amalgam without injuring the plate, is made by stitching an extra binding across a new broom, about $^1/_3$ the way down from handle and then cutting broom to one-half length. Plates should be frequently inspected.

Amalgamators are a recently perfected kind of amalgamating trap, combining the functions of apron plate and the typical Hg trap, and in some instances have replaced the use of plates altogether. In these devices a series of amalgamated trays and deflecting baffles in troughs cause accumulations of amalgam, which increase the chance of contact between Au and Hg, while occupying far less floor space than plates. The Clark-Todd amalgamator, as used at the Homestake mine, is an example. Placed at the ball-mill discharge, the device includes a receiving box with protecting screen, a short length of transverse launder, lined with a copper box, and a longer cross launder with silvered copper plates. Scrap iron and oversize are effectively removed, while the amalgam accumulates in the boxes. Each section is covered with a locked guard screen.

Condition of mercury. The Hg fed to battery or grinding mill must be free from impurities, which SICKEN the MERCURY and form patches on the plates that will not amalgamate the gold. The sickened condition is due to fine particles of Hg becoming coated with thin films of manganese or iron sulphates, arsenides, antimonides, tellurides, clay, oil, or grease. Oil or grease must be carefully kept away from the mortar and plates. Squeezing of Hg through chamois, canvas, or muslin bags will not remove these films, and if mercury sickens it must be cleaned with weak acid, lye, or cyanide solution, or even retorted before using again. Addition of a little sodium amalgam will sometimes assist in the amalgamation of refractory gold or tellurides.

Flouring. When mercury is held too long in crushing machinery, or when too much Hg is fed, FLOURING will take place. This is very fine breaking up of the Hg, in which condition it will not amalgamate, nor will the particles reunite, as the surface tension is very great compared to the wt of the particles.

Clean-up, which is made monthly (or oftener with high-grade ore) when stamps are used, consists in thoroughly cleaning out the battery and scraping and dressing the plates, as above. With rod-, ball-, or tube-mill, a satisfactory clean-up can be made only when these mills are being relined, during which period they are thoroughly cleaned. The serious accumulation of amalgam in rod-, ball-, or tube-mills, often during a year before it can be recovered, has discouraged the adding of Hg to these units. The upper loose sands from stamps or grinding mill, containing but little amalgam, are returned to the unit after starting; the lower sands go to the clean-up room. Here the sands are treated with additional

Hg and water in a clean-up barrel or pan, and panned down over the sink to separate the amalgam, the washed sands being returned to battery or grinding mill. The amalgam thus recovered, and that scraped from the plates, is also washed with more Hg to make it liquid. Particles of iron are removed with a magnet. In large mills, the amalgam is worked over in the clean-up barrel or pan, with excess Hg; in small mills, it is ground in a Wedgwood mortar.

Cleaned amalgam is then put in a conical funnel of canvas or heavy unbleached muslin, through which the excess Hg drains off; the remaining amalgam is squeezed by hand through chamois or cloth, or in large mills by a hand or power press. Chamois is expensive to use as it wears out rapidly. Skimmings and dross from surface of the Hg strained out in cleaning amalgam are saved for separate treatment. When the ore contains much sulphide, antimonide or arsenide, the mud settling out of the washings, and the dross from cleaning amalgam, may be saved and shipped to smelters. Amalgam, squeezed quite dry and hard, contains 25 to 40% bullion. The squeezed amalgam is finally retorted for distilling off the Hg.

3. CORDUROY TABLES

Corduroy-blanket tables are generally of same size and slope as those for plate amalgamation. They are generally placed at the ball-mill discharge. Surface of table is covered with transverse strips of corduroy, placed to overlap one another a few inches; they are not fastened down, as the wet blanket clings to the table surface. But care is taken to "iron out" the air bubbles formed underneath when laying the blankets. An even distribution of the feed pulp, correct pulp velocity and density, etc, are as important as in plate amalgamation. The transverse ribs of the corduroy act as riffles, the spaces between gradually filling with a concentrate containing the free gold and consisting largely of pyrite and black sands.

An unclassified pulp, with up to 20-mesh sand at 4–5 to 1 dilution, will flow down a slope of 1 $^3/_4$ in per ft, and more dilute and finer pulp requires even less slope. Roughly, 1 sq ft is required for every 3 tons of pulp per day.

Blankets are removed for washing at intervals of about 4 hr, depending on how badly the riffles tend to pack. To change blankets, pulp is first turned off and water allowed to flow over blankets for a few minutes, to wash off surface sand; blankets are then folded up to retain the concentrates and taken to the washing box, while a clean set is put down. The washing is done by immersing the blanket, with the riffle side down, in the water and shaking it. The concentrate that falls and is washed off passes through a stout locked screen near top of the box. With 2 washing boxes, each day's concentrates can be kept separate.

Corduroy *vs* amalgam plates. There is a tendency for corduroy and other methods (see concentrating tables and jigs) to replace use of amalgam plates for the following reasons: corduroy will collect "rusty" gold and platinum-group metals, as osmiridium, which can not be caught on plates; they then require $^1/_4$ to $^1/_5$ the surface area for the same tonnage; unskilled labor can be used and less attention required; also, danger of mercury poisoning, loss of amalgam and theft are eliminated.

Prior to 1921 the Witwatersrand mills recovered 50–75% of their production by plate amalgamation, variations in percentage of recovery being due to differences in degree of grinding, perfection of equipment, and characteristics of the ore. During the following few years, however, there was an almost complete substitution of plate amalgamation by corduroy blankets, which, in one form or another, are today used almost exclusively on the Rand.

Cleaning concentrate. Corduroy concentrate, amounting to around 1% or less of the ore treated, is usually fed to a concentrating table, set rather flat and operating with a short stroke. Three products are made: clean Au, pyrite (including any iron coming from the milling machinery), and a siliceous tailing, which flows back to the mill circuit. The concentrate is collected separately in boxes having filter bottoms, and transported to the clean-up room for barrel amalgamation.

Johnson concentrator, developed on the Rand, is a continuous-discharge corduroy, consisting of a rotating cylinder slightly inclined and having a rubber liner grooved like the rifling of a gun barrel. Feed enters at the upper end, while gold and pyrite collected in the riffles are carried up out of the pulp and discharged at the highest point by sprays into a launder leading out of the cylinder.

Jigs, of the Cooley and Richards pulsating type, are finding increasing use in the ball-mill classifier circuit for removal of coarse gold as soon as it is released by grinding. The improved Denver Equipment and Pan American machines have high capacities and make clean enough concentrates for direct barrel amalgamation.

Hydraulic traps, unit flotation cells and concentrating tables, usually provided with scalping screens for removing oversize, are all in use for preliminary recovery of coarse gold, ahead of the cyanidation or flotation circuit.

Barrel amalgamation. The concentrate from tables, jigs or traps (mentioned above) is ground and amalgamated in a standard clean-up barrel, after which the amalgam is separated by panning and treated in usual manner (Art 2). These barrels are preferably cast in one piece, to avoid use of liners which tend to hold up amalgam. From 2 to 14 hr are allowed for grinding with a light ball or rod load, after which the mercury is added and another 1 1/2–2 hr allowed for amalgamation. Tailing from the barrel is returned to the main plant circuit.

Recovery of Au by corduroy tables is slightly lower on the Rand than was formerly obtained by plate amalgamation, but final residues after cyanidation have not been affected. It is reported that the Hg consumption, since introduction of corduroys, is only one-tenth of what it was before.

4. RETORTING AND MELTING

Retorts, when of large size, are horiz C-I cylinders built into a brick furnace setting, and with a pipe from the rear end to an open Hg receiver. This pipe is surrounded by a larger pipe or jacket, in which cold water is circulated for condensing the Hg. The end of the pipe is covered with wet cloth or flannel, dipping into water in the receiving pot. The level of the water in the pot must never be allowed to rise high enough to cover the end of the pipe; otherwise, if the temp of the retort falls, water may be drawn back into the hot retort, causing an explosion. Small retorts are vertical C-I pots with condenser pipe connected to the cover. Retorts are lined with chalk or wood ashes before charging, and the lumps of amalgam are often wrapped in paper, to keep the bullion from adhering to the iron. Vertical pot retorts are filled not over 2/3 full of amalgam, to avoid having particles of amalgam thrown up into the pipe in case the Hg boils due to overheating. This would clog the pipe, and might cause an explosion.

Charging retort. Amalgam is charged in horiz retorts in semi-cylindrical C-I trays (usually 4 in number), which are slid into place. The retort cover is luted with a mixture of fire clay and wood ashes, or clay with a small admixture of clean slimes. Or, gaskets can be used, cut from thin asbestos sheets, heavy oil being first applied to the joint faces. The cover is clamped on securely with a yoke and steel wedges.

Firing. The retort is gradually heated by wood or coal fire or by oil (according to design of the furnace), water running continuously through the condenser jacket, until Hg begins to pass freely into the receiver. Heat is then decreased, but should be maintained sufficiently to distil the Hg continuously. When distillation ceases, the heat is raised to a dull red and so maintained for about 0.5 hr, after which the fire is allowed to die out, and the retort to cool before it is opened. During the final heating the condenser pipe should be occasionally tapped to dislodge the last drops of Hg. Even with large retorts, distillation should be complete in 5 to 6 hr; with small pots, in say 3 hr.

Melting. The retorted mass (RETORT METAL) is melted in a graphite crucible, in a coke or coal-fired (or oil) furnace, the latter being preferable for ready control of temperature.

The crucible is gently heated before use to drive off moisture, and should be well supported in the furnace to avoid tilting. After raising it almost to red heat, a portion of flux is first charged and melted, after which the retort metal is added, a few pieces at a time, care being taken not to drop them in with a splash. The crucible may, if necessary, be charged about 0.75 full. FLUX generally used is largely borax glass, with about 0.5 the amount of sodium bicarb and a little niter. If the retort metal contains much sulphide, stirring with a heated iron rod will cause formation of a matte, but the amalgam itself usually contains enough particles of metallic iron to combine with the sulphur. Enough niter must be used to oxidize base metals, but an excess will rapidly eat away the crucible. In presence of much metallic iron, SiO_2 may be added to the flux, but not enough to form a viscous slag, which may carry shots of the bullion. Very base bullion may require 5% or more flux to produce a clean bar. After being kept molten for 20 min, the metal should be well stirred with an iron rod, to insure a homogeneous bullion, and the slag (and matte, if any) are skimmed off, or the pouring may be done with the slag.

Molds are of C I, well heated, and coated with graphite, resin smoke, or lamp-black mixed with heavy oil; oil alone, paraffine, or tallow may be used.

After cooling sufficiently the bars are plunged into cold water, or into water with a little H_2SO_4 or HNO_3. The slag (and matte, if any) are hammered off and the bar scrubbed, numbered, weighed, and drilled for assay sample. Six staggered, 3/32-in drill holes on each side (top and bottom) of the bar and about 1 in deep, give a fair sample, the surface drill-

ings being rejected. The matte is saved for separate refining, or is collected until there is enough to ship to smelter. Slags are returned to the clean-up pan or barrel, or are washed free from graphite and returned to the battery. Yield of retort metal from the amalgam should be from 30 to 40% by wt, according to amount of gold or silver in the ore. Loss in smelting is slight, if amalgam has been properly cleaned.

5. SALIVATION

Mercurial poisoning may result from absorption of Hg through the skin, from breathing Hg vapor, or swallowing soluble Hg salts.

General symptoms are: soreness of gums, tenderness of jaws, excessive secretion of saliva, swollen, inflamed gums and foul breath, later resulting in looseness of teeth, swelling of face, with fever and depression. ACUTE MERCURIAL POISONING is accompanied by tremors of arms and hands, irregular heart action and general weakness. It may result finally in loss of teeth, necrosis of the jaw bone, and in some cases in cirrhosis of the kidneys.

Salivation of the workmen in an amalgamating mill is easily prevented. Gloves should be worn when cleaning amalgam, and care taken not to breathe the Hg vapors when plates are being steamed, when Hg is being cleaned with hot water, or from leaky retorts. Men who may be exposed should maintain an active condition of bowels and kidneys, and pores of the skin should work freely. These precautions are also the principal means of eliminating Hg from the system, in cases of salivation. For acute poisoning, where mercurial salts have been swallowed, albumen or emetics are administered, or the stomach may be washed with albuminous water and magnesia solution.

CYANIDE PROCESS

Introduction. The cyanide process extracts gold and silver from ores by means of the solvent action of an alkaline cyanide solution on these metals. The first commercial application was to Au ores, in 1887–88 (McArthur-Forrest process); treatment of silver ores came later. First cyanide mills were built: 1889, at Crown mine, New Zealand; 1890, on the Rand, So Africa; 1891, Utah, U S.

Later improvements. CHEMICAL: zinc-dust precipitation of the dissolved gold and silver; aeration of leach solutions and de-aeration before precipitation; cyanide regeneration systems and, in the case of refractory ores, pre-treatment with lime, and in some cases carefully controlled roasts. MECHANICAL: replacement of stamp batteries by stage crushing and ball- or tube-mills; continuous thickening and counter-current decantation; all-slime plants; use of vacuum filters; and flotation-cyanidation processes.

The fundamental principles of the process have changed little since its inception. Improvements have been mainly mechanical, having effect of increasing extractions and lowering treatment costs. They include advances in grinding circuits and classification, resulting in more highly selective grinding on the refractory portions of the ore; the elimination of the sand-slime circuits and use of single, continuous circuits; more efficient precipitation; and, frequently, the preliminary concentration by flotation of the precious-metal values into a small bulk for cyanidation in a comparatively small plant.

Gold and silver ores containing no other valuable metal are today practically all treated by the cyanide process, either exclusively or following a primary treatment by amalgamation, flotation, or some other form of concentration.

6. ADAPTABILITY OF ORES

Nearly all gold and silver ores can be treated by cyanidation. In case of gold ores, tellurides may cause interference, but can usually be rendered soluble by very fine grinding and long agitation with excess lime.

Interfering conditions. OXIDIZED ZN AND CU ORES cause high consumption of cyanide, due to ready solubility of their oxides, carbonates, and hydrates. SULPHIDES of Cu, Ni, Co, Pb, Zn, and Fe react but slightly with cyanide solutions, though pyrrhotite tends to oxidize and acts as a cyanicide, while certain copper sulphides, as chalcocite, cause increased cyanide consumption. Some sulphide combinations of Ag with Pb and Zn are only slightly attacked by cyanide, even when finely ground. SOLUBLE SULPHIDES (especially alkaline sulphides) interfere seriously, both by combination with cyanide and by re-precipitation of the Ag and Au. ARSENICAL AND ANTIMONIAL ORES tend to be refractory and often cause high cyanide consumption, due to the formation of compounds having a strong reducing

action in the working solutions. Preliminary roasting may favorably prepare such ores for cyanide treatment. CHROMIUM compounds are some of the worst interfering substances, but can often be precipitated by adding lead nitrate. MANGANESE combined with Ag often prevents successful cyanidation. A preliminary reducing roast may increase extraction, as, for example, when conditions permit the successful application of the Caron-Clevenger process. METALLIC MERCURY (often present in tailings from amalgamation) is not readily dissolved by cyanide, and, in small quantities, may assist in precipitating soluble sulphides; present in larger quantities, Hg causes waste of Zn in precipitation boxes. A pulp containing metallic Au and Ag in COARSE PARTICLES, may require so long a cyanide treatment for complete solution of the metals as to make the process uneconomic. In such cases, preliminary removal of the metallics by amalgamation, jig or table concentration (Art 1) would be resorted to. CARBONACEOUS MATTER, if ground with the ore, tends to act as a reducing agent and re-precipitate Au and Ag before the solutions can be freed from suspended solids. The remedy is preliminary flotation to remove carbonaceous matter, or the cyanidation-flotation methods of the Edquist or Chapman processes.

Overcoming adverse conditions. The refractory nature of an ore can often be overcome by fine grinding, but as yet microscopic and chemical analysis alone can not determine the adaptability of an ore, and systematic testing is required to work out the many variables involved.

Laboratory experiments must be conducted to determine: possibility of leaching Au and Ag from coarser sands; necessary fineness of grinding; acidity of pulp and amount of lime required to neutralize it; amount of soluble sulphides in the pulp and quantity of lead acetate or oxide to be added; amount of cyanide consumed in treating the ore for the time required to effect satisfactory extraction; kind and amount of cyanicides present, and effect of pre-treatment with lime, excessive aeration, preliminary water washing or roasting of the ore. An ore not amenable to direct cyanide treatment, owing to presence of much sulphide (either mechanically including the precious metals or forming excessive quantity of cyanicides in the pulp), can often be treated by removing part of the sulphides by flotation before cyanidation.

7. CHEMISTRY OF CYANIDATION

Cyanogen (CN or Cy), a compound radical, is a colorless gas combining actively with metals. In manufactured forms it is available as KCN or NaCN. It combines with nearly all metals to form a single cyanide, and with many metals to form double cyanide groups which are only very slightly ionised in solution.

Chemical reactions occurring during solution of Au and Ag in the cyanide process have not yet been precisely determined. They vary with the nature of the ore, presence of base metals, and conditions under which solution is effected. Following fundamental reactions are generally accepted:

$$\left.\begin{array}{l} 2\,Au + 4KCN + O + H_2O = 2\,AuK(CN)_2 + 2\,KOH \\ 2\,Ag + 4KCN + O + H_2O = 2\,AgK(CN)_2 + 2\,KOH \end{array}\right\} \text{Elsner's equations.}$$

Similar equations apply when NaCN is used. They all represent the combination of CN with metallic Au and Ag, assuming the necessary presence of O. But, it is probable that an intermediate reaction takes place before formation of the double cyanide of Au or Ag, *viz*: $2\,Au + 2\,KCN + O + H_2O = 2\,AuCN + 2\,KOH$, which, with an excess of KCN, yields $AuCN + KCN = KAu(CN)_2$.

When silver sulphide is attacked, the reaction may be: $Ag_2S + 5\,KCN + O + H_2O = 2\,KAg(CN)_2 + KCNS + 2\,KOH$, or $Ag_2S + 4\,KCN = 2\,KAg(CN)_2 + K_2S$. Potassium thiocyanate (sulphocyanide) is often found in working solutions, affording a basis for the former of these two equations.

Variations in reactions are caused by presence of base metals, as sulphides or other salts, and by soluble salts of alkaline earths, always present in ores.

In practice, oxygen is absolutely necessary for the reaction, though its function is considered by some to be largely depolarizing. In certain modified processes it is supplied chemically by addition of $KMnO_4$, MnO_2, or other oxidizing salts; but this generally costs more than to bring O into contact with the pulp by mechanical aeration, or by successive leachings and drainings.

Relative solubilities of certain metals in cyanide solutions are stated by Clennell to be the same as their electrochemical activity in such solutions, in following order: Mg, Al, Zn, Cu, Au, Ag, Hg, Pb, Fe, Pt; hence any metal would replace all metals following it in the above order, and would precipitate them from a cyanide solution by what is known as a typical displacement reaction.

NaCN *vs* KCN. NaCN is generally preferred to KCN, because it is considerably cheaper and has more available CN per unit of wt, 53% against 40%; the dissolving power of NaCN is therefore 32.65% greater than that of KCN. Commercially, the strength of NaCN is sometimes quoted in percentage of equivalent KCN, though the recent tendency is to figure working solutions on basis of the NaCN actually used.

Oxidizing agents. A number of oxygen-bearing salts, when added to cyanide solutions, increase the rate of solution of precious metals, and sometimes have increased the total extraction: among these are K_2MnO_4 (potassium permanganate), Na_2O_2, and MnO_2. Their beneficial effect appears to consist in partial oxidation of interfering substances, and rapid supply of required O, but their excessive use may result in destruction of cyanide.

Nascent CN. $K_3Fe(CN)_6$ and BrCN react, without presence of O, to liberate CN in a cyanide solution, and nascent CN has greater affinity for precious metals than when in combination as KCN or NaCN. Liberation of CN by these salts is shown by:

$$K_3Fe(CN)_6 + KCN = K_4Fe(CN)_6 + CN, \text{ and } BrCN + KCN = KBr + (CN)_2$$

The latter equation represents the supposed basis of the BrCN process, in which the reaction in presence of Au is stated to be: $BrCN + 3\,KCN + 2\,Au = 2\,KAu(CN)_2 + KBr$. The reactions in this process are not thoroughly understood; probably the greater affinity of nascent CN for Au makes it possible to dissolve Au in such telluride ores as are not attacked by simple solutions of KCN or NaCN. So far as determined, no bromide of Au is formed by the use of BrCN.

When ferrocyanides are present in working solutions, $HgCl_2$ may be used to disintegrate them, by formation of double mercuric cyanides, which dissolve precious metals without additional O. The cost of $HgCl_2$ limits its use.

Strength of solution. The average Au ore requires solution strength of 1 to 2 lb NaCN per ton, and the average Ag ore 3 to 5 lb per ton. Percolation usually requires stronger solutions than agitation, probably because the necessary oxygen fails to reach the pulp as quickly and effectively.

Selective solubility. The base metal sulphides dissolve relatively slowly in cyanide solutions. Though their oxidized compounds apparently dissolve as rapidly as Au and Ag, certain of the resulting cyanides (*e g*, that of copper) are known themselves to be solvents of Au and Ag, whence the effect of such base metals is often rather to increase cyanide consumption than to lower ultimate recovery, provided free KCN or NaCN is kept up to strength.

It has been supposed that presence of certain metals retards solution of Au and Ag, but in case of such interference the cause is apt to be elsewhere. Thus, in treating certain tailings in New South Wales, in which the Au was contained in Sb_2S_3, it was found that the Sb caused no consumption of cyanide except when the solution was too alkaline; in a neutral solution, the only difficulty lay in disintegrating the Sb_2S_3 to reach the fine Au.

Heated solution frequently yields higher extractions in laboratory tests; commercially it is generally found that the increase is not appreciable, and excessive heating of solutions may destroy part of the cyanide, while also increasing its solvent action on base metals, with entailed losses of cyanide. Heating of solutions also expels oxygen, thereby necessitating increased aeration of pulp.

Chemistry of precipitation. Recovery of precious metals from cyanide solutions is based, theoretically, on the reaction: $2\,KAu(CN)_2 + Zn = K_2Zn(CN)_4 + 2\,Au$. Practically, precipitation takes place only in presence of free cyanide, thus: $KAu(CN)_2 + 2\,KCN + Zn + H_2O = K_2Zn(CN)_4 + Au + H + KOH$.

Interfering conditions. In actual operation there is always an excess of Zn, which is also dissolved by the KCN as $K_2Zn(CN)_4$, without necessarily precipitating any Au. In the precipitation boxes, other metals are generally present, forming electric couples with Zn, which electrolyze the water, liberating O and forming $Zn(OH)_2$. This combines with free cyanide, forming a soluble double cyanide (possibly an alkaline zincate). Unless excess of cyanide be present, precipitation of $Zn(OH)_2$, ZnO, or perhaps $Zn(CN)_2$, will take place, covering the Zn shavings with a white deposit, and impeding precipitation of precious metals. Free alkali, or excess of cyanide, prevents formation of this white deposit by redissolving the Zn precipitate; hence a solution to be precipitated should always contain excess cyanide or be strongly alkaline. But, the double ferrocyanide of Zn and K, which frequently deposits on the Zn shavings, is but slightly soluble in alkaline or cyanide solutions, and may form enough deposit to interfere with precipitation of the precious metals before the Zn shavings have been completely consumed, thus necessitating an earlier clean-up than otherwise required.

To a slight extent, Al_2O_3, SiO_2, CaO, and Fe may be precipitated on the Zn, retarding precipitation of Au and Ag. Cu interferes still more, as it will completely coat Zn shavings. If the shavings in the first precipitation box compartments be coated with Pb, nearly

all the Cu can be precipitated before the solution reaches the compartments in which the Au and Ag are to be collected. Zn may be thus prepared by dipping in a 10% solution of $Pb(C_2H_3O_2)_2$ (lead acetate); Pb shavings also may be mixed with the Zn in the first compartments, to furnish a Zn-Pb couple. As, Sb, and Fe are also thrown down on the Zn; but, while often causing trouble in subsequent treatment of precipitate, they do not generally interfere with the precipitation reactions.

Zn shavings and Zn dust. The use of Zn shavings has been largely replaced by Zn dust, as being more efficient, requiring a smaller installation, and showing marked economies in operation.

Aluminum dust has been successfully used instead of Zn for precipitation, especially when the ore contains considerable As. It has the advantage that Al does not replace precious metals in cyanide solution by forming a CN compound; hence the fouling of solutions with Zn and As is avoided. While not so efficient a precipitant for Au alone, in the case of solutions carrying Ag, the precipitation of both metals is complete. The presence of lime should be avoided, or soda ash added to the circuit, because any calcium aluminate formed will foul the precipitate.

The reaction is possibly: $6\ NaAg(CN)_2 + 6\ NaOH + 2\ Al = 6\ Ag + 12\ NaCN + 2\ Al(OH)_3$. The $Al(OH)_3$ is redissolved in the excess alkali to form $Na_2Al_2O_4$. Another reaction, with evolution of H, is: $2\ NaAg(CN)_2 + 4\ NaOH + 2\ Al = 2\ Ag + 4\ NaCN + Na_2Al_2O_4 + 4\ H$.

Charcoal, especially soft-wood charcoal, has been used as a precipitant. The reaction at time of precipitation is not yet understood, but it has all the characteristics of an adsorption phenomenon, and the activity of the freshly prepared charcoal has been ascribed to occluded gases, probably H or CO, which act as reducing agents. There seems to be no reaction between C and the soluble double cyanides. Gold so precipitated is not readily redissolved in KCN solution; and there is known to be a loss of KCN during precipitation.

Continued re-use of solutions ultimately results in accumulation of Zn salts, and even if proper strength of free cyanide be maintained, the solution may become foul and lose part of its dissolving power. It has been advanced that the fouling of solutions is due in part to formation of double cyanides of Zn with other alkaline earths besides Na or K, or of double cyanides of other base metals and alkalies. It has been proposed to add enough H_2SO_4 to decompose double cyanides, and then some hydrate to precipitate alkaline sulphates, with regeneration of the cyanide.

Cyanicides; loss of cyanide. A cyanicide is a substance in an ore which either combines with CN or decomposes alkaline cyanides, so that a solution loses its dissolving power. Some loss of CN may also occur, by decomposition, without presence of cyanicides. KCN and NaCN are deliquescent, and are slowly decomposed by moisture.

Loss by HYDROLYSIS is represented by the reaction $KCN + H_2O = KOH + HCN$, the CN escaping by volatilization. Loss by ABSORPTION OF O occurs thus: $2\ KCN + 2\ O + 4\ H_2O = K_2CO_3 + (NH_4)_2CO_3$. In presence of CO_2, decomposition takes place thus: $KCN + CO_2 + H_2O = HCN + KHCO_3$. In practice, the losses of CN represented by above equations are very small.

Losses due to cyanicides in the ore may be very serious. They are caused chiefly by soluble sulphides, sulphates, and arsenates, and by some salts which are insoluble in water but react with cyanide solutions. Fe, Cu and Zn salts, especially in oxidized or semi-oxidized ores, are apt to react by the formation of double cyanides of the metals with K or Na. Free acid in an ore causes liberation of HCN; obviated by maintaining sufficient alkalinity in the pulp. In the solution of sulphide ores, K_2S or Na_2S is formed; if then the cyanide solution be allowed to become weak, these alkaline sulphides may accumulate sufficiently to reverse the reaction and re-precipitate Ag as sulphide; or the alkaline sulphides may oxidize into sulphates, or may form thiocyanates, thus consuming either the available O or the CN, and decreasing the dissolving power of the solution.

Both Mg_2SO_4 and $CaSO_4$ decompose alkaline cyanide solutions; arsenates of Fe and other metals also react with CN solutions and destroy their dissolving power. While FeS_2 does not react with cyanide quickly, nor to an appreciable extent, ferrous sulphide and ferrous and ferric sulphates combine actively. Untarnished sulphides of Cu and Zn are practically unattacked by cyanide solutions, but their carbonates, oxides, and sulphates react rapidly.

8. OUTLINE OF THE PROCESS

Recovery of Au and Ag by cyanidation consists broadly of 4 operations: (*a*) preparation of the ore; (*b*) solution of precious metals; (*c*) separation of dissolved metals; (*d*) precipitation and refining of product. After preparing an ore, the pulp may be classified into coarse and fine products (SANDS AND SLIMES) which may be treated separately; or, all the

ore may be ground very fine and treated together by the ALL-SLIMING process. Variations in preliminary treatment will be described in general outline, but many ores present problems requiring special modifications.

Sands, when treated separately, are usually charged into vats or tanks having filter-bottoms, where they are given a succession of percolation leaches with cyanide solution, followed by weak solution and water washes.

Slimes refer strictly to the colloidal and semi-colloidal portion of the pulp; but in practice they are usually considered as being the portion that is composed largely of particles that will pass a 200-mesh screen. They can be treated by cyanide solution in agitation tanks, followed by separation of the metal-bearing solutions from the solids by settling and filtration.

Precipitation of precious metals from the pregnant solutions, formerly done by Zn shavings, is now almost exclusively by Zn dust. Other methods that have found restricted use include electrolytic action, sodium sulphide, aluminum, or charcoal. The precipitate is dried, melted with fluxes, refined and cast into bars.

Cyanidation of concentrates. Concentrates derived from Au and Ag ores by gravity or flotation methods consist mostly of heavy sulphide minerals, commonly FeS_2, mixed with particles of gangue.

When applied to concentrate, cyanidation must be modified. Percolation methods have not been found satisfactory, owing to the comparatively long treatment required for extraction, the difficulty of maintaining protective alkalinity during the application of successive washes, and insufficient aeration of charges.

Preparation of concentrate for cyanidation by air-agitation generally demands very fine grinding. If the concentrate must be stored to accumulate a satisfactory charge, it should be protected against exposure to air and oxidization, with formation of soluble sulphates and free acid. It has sometimes been necessary to roast concentrate; also a preliminary filtration with neutral or acid wash, or pre-liming treatment, has been used to remove oxides of base metals, and counteract the effect of flotation reagents.

Besides fine grinding, the points requiring special attention are: a sufficiently strong solution, long enough agitation to secure proper aeration, maintenance of protective alkalinity, and avoidance of settling and packing of the pulp in agitation tanks. In estimating the probable cost, the loss of more solution through fouling must be counted on than when treating ores, and also a greater destruction of cyanide in the solution. To reduce cyanide consumption, higher pulp dilutions than in direct ore treatment are desirable, and successive addition of small amounts of KCN is beneficial.

Strength of solution for continuous treatment varies from 2 to 4 lb NaCN per ton, depending on Ag content; but larger quantities may be required for the batch treatment of refractory ores. On certain Calif concentrates, as short a time as 22 hr has sufficed to extract 99%, while in New Zealand, 10 days' agitation with an 8-lb solution has been necessary to extract 96%. In some South African mills, concentrate is ground in a 4-lb solution, followed by 72 to 78-hr agitation in a 12 to 16-lb solution, the extraction being only slightly over 90%.

Advisability of cyanide treatment of concentrates depends on both metallurgical and economic factors. Where gravity methods followed by barrel amalgamation are used, the amalgamation tailing can usually be returned to the main circuit. Where flotation can be used, the cyanidation of the concentrate often results in a large enough saving over shipping to a smelter to pay for cost of plant installation. The question of all-cyanidation *vs* flotation-cyanidation is usually a matter of the association and flotability of the gold and gold-bearing minerals present. The combination-type plant is usually cheaper to build and, if the gold is not too finely disseminated in gangue material, such a plant usually yields higher net returns.

9. PREPARATION OF ORES

Crushing (Sec 28). Run-of-mine ore is crushed in jaw or gyratory crushers to approx. 2-in size. One or two stages may be used, depending on size of plant. Following the primary crushers, practice varies. Modern stamp mills tend toward heavy stamps, with comparatively coarse screens (0.25–0.75 in). If stamps are eliminated, secondary crushing is usually practiced, reducing the ore to at least all minus 0.75 in, by rolls or fine gyratory crushers, such as the Symons' short-head cone crusher and the Type B Newhouse.

Hand sorting, for removal of waste or high-grade shipping ore, may immediately follow the first crushing (Sec 28). When ore is wet and dirty, it must be screened and washed before sorting. Practice of sorting out waste is declining, due principally to improved effic of underground work in sending cleaner ore to the mill.

Screening. Best practice employs grizzlies or shaking screens ahead of primary crushers to take out undersize, and shaking or vibrating screens, closed-circuited with secondary machines, to make a uniform product for fine grinding. Slotted, or ton-cap, mesh is more generally used than square mesh, as crusher capacity is thereby increased without corresponding reduction in grinding capacity; explained by the fact that rock slivers passing such openings are broken down relatively easily.

Grinding may be in single- or multiple-stage. Crusher or stamp-mill product is reduced to the final size required by ball-, rod-, tube-mill, or a combination of these.

Under certain conditions the ore may be reduced from the primary crushers to finished product in one mill. The modern tendency is to reduce the ball-, rod-, or tube-mill feed to at least all minus 0.75 in. With multiple-stage grinding the first stage is usually carried to about 20–30 mesh in ball- or rod-mills; subsequent grinding in ball mills using a smaller ball size, or in tube-mills, using steel balls, flint pebbles, mine rock or composite loads.

To obtain max effic from any type of grinding mill, the mill should work in closed circuit with a classifier. This CLOSED-CIRCUIT GRINDING consists of operating the mill and classifier so that the mill discharge passes to the classifier, and all finished material is overflowed. Oversize material is returned to the mill. Ratio of tonnage passing in a given time through the mill to original tonnage is the CIRCULATING LOAD; within certain limits, the capacity of a ball- or tube-mill varies directly with this load. Modern practice is to carry circulating loads in these mills of 300–500%, with tendency to go higher; in rod-mills, about 175%.

Fineness required for highest economical extraction differs for each ore and can be determined only by experiment. In exceptional cases of very porous ore, satisfactory extraction can be made by percolation from sands as coarse as 0.25 in. Fineness usually must be at least 30 mesh, varying from this to all minus 200 mesh.

On the Central Rand, ore is ground to approx 75–85% through 100 mesh; on the Far East Rand, practically all the finished product is 90 mesh, about 75–85% being 200 mesh. In Ontario, Au ore is ground to about 85–90% through 200 mesh, and in some recent Canadian practice to all minus 200 mesh. In the cyanidation of concentrates it is not unusual to grind the product to all minus 325 mesh.

In general, Ag ores require finer grinding than Au ores. Mexican practice, in "all-sliming" plants on Ag ores, is to grind to approx 75–80% through 200 mesh. Nipissing mine, Cobalt, Ontario, grinds to about 98% through 200 mesh.

Grinding in cyanide solution is customary unless the ore requires preliminary washing to remove cyanicides (Art 7), or undergoes preliminary amalgamation or other treatment. The recovery by amalgamation in cyanide solution is reduced. Grinding in water causes accumulation of solution, and a part must be sent to waste. In Au ores using very low strength of cyanide (1.0 to 1.5 lb), this loss may be small, but in Ag ore, generally using a much stronger solution (3 to 5 lb), the loss of cyanide would be serious.

Preliminary treatment may consist of roasting or washing the ore before the secondary crushing, concentrating after primary or secondary grinding, floating with unit cells in the grinding circuit, or after final reduction of all the ore. If the ore contains much clay, roasting dehydrates it and renders it more porous and brittle; or, if of low value, the clay can be removed by washing. Cost of roasting is usually greater than the benefit derived. Preliminary aeration with lime may also reduce the effect of cyanicides.

Roasting also decomposes tellurides, arsenides, and antimonides. If not a dead roast, the resulting oxidized salts injure rather than aid cyanidation, and a washing step should be introduced. Roasting will not remove $CaSO_4$ or $MgSO_4$ and may not eliminate all the ferric arsenate. There is usually no appreciable loss of Au or Ag by volatilization during roasting, provided chlorides are absent and temperatures not too high.

Preliminary treatment by flotation will often remove cyanicides and interfering minerals. Addition of oil during grinding often eliminates re-precipitation of precious metals by graphitic schist. Oil apparently coats the graphite particles, rendering them inert during the process.

Tube-mills, 14–22 ft long by 4–6.5 ft diam, were formerly common for fine grinding, but are now used only where supply of pebbles is ample, as on the Rand. Current practice uses shorter mills of larger diam, with rods or balls.

Earliest mills had peripheral discharge; modern mills have a false end-screen liner and lifting scoops to assist discharge, or overflow through the discharge trunnion. Scoop feeders to assist closed-circuit classifier arrangements are desirable, though in using mine rock as a grinding medium, an open-trunnion feeder may be the only practicable device for getting the ore into the mill. Combination scoop and trunnion feeder is also used.

Speed of tube-mill depends on diam; 31 rpm is recommended for 4-ft mill, 28 rpm for 5-ft, 25 rpm for 6-ft mill. Grinding media depend on local conditions; mine rock has almost entirely replaced imported flint pebbles, but where these are not suitable, steel or white-iron balls may be used, or a composite load of balls and pebbles or mine-rock.

Lining of tube-mills may be silex blocks set in cement, steel, or white iron. Discarded rails can often be used, bolted or wedged against a false plate liner. The pebbles roll over the bars and grind on the surface of the plates. Many other types of corrugated and over-lap special steel liners are in use.

Ball-mills (Fig 1–3), cylindrical or conical, use steel or C-I balls for coarse primary grinding; length of mill, approx equal to diam; balls up to about 5 in. For finer grinding, mills are longer and, for comparatively fine original feed, balls are smaller. Initial ball charge should comprise balls of various sizes; subsequent charges, all of largest size.

Rod-mills resemble cylindrical ball-mills, but have steel rods lying horis along full length of mill. Possibly they consume less power than ball-mills, per unit of work. Initial charge of rods is of various sizes. They are of special high-carbon steel, so that when worn down they will break up instead of winding around the larger rods. Rod mills tend to produce less fines, as the grinding is more by crushing and attrition than impact. Hence, they are less suitable for very fine grinding than ball mills.

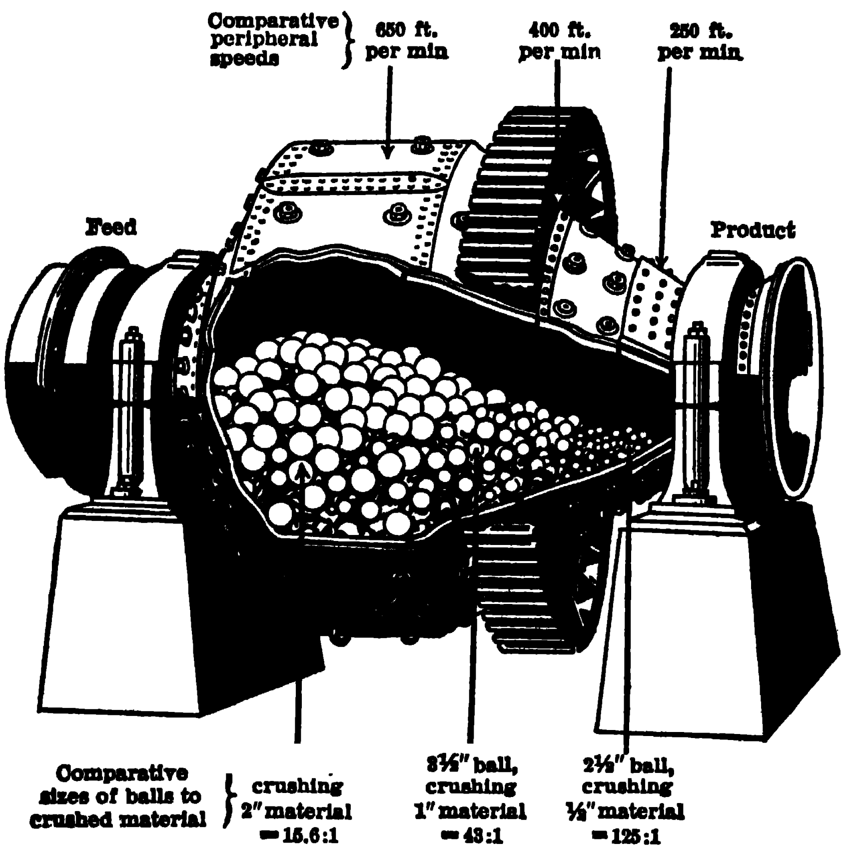

Fig 1. Conical Ball-mill (Hardinge Co, York, Pa, Bull 13-c)

Capacities and hp of mills. A tube-mill 5.5 ft diam by 22 ft long takes a pebble load of approx 14 tons, and will crush about 150 tons per 24 hr from $-{}^3/_8$ in to -90 mesh with feed rates up to 350 tons, and uses about 100 hp. Some 30–40% more power is required for starting. Diameters vary from 4 to 6.5 ft, the latter requiring 250-hp motors. A cylindrical ball mill 6 ft diam by 5 ft long, with grate discharge, will take a ball load of about 7 tons, will use 90 hp, and crush 150 tons of ${}^1/_4 - {}^3/_8$-in feed through 65 mesh. Mills 8 ft diam by 6 ft long will handle close to 500 tons per 24 hr, using about 200 hp. Corresponding conical mills for similar capacities would be about 7 ft diam by 36 in, and 8 ft diam by 60 in. The above are approximations only; actual figures in specific cases depend on the grinding characteristics of the ore and type of grinding-classification circuit employed.

Cost of tube-milling varies greatly, according to cost of power, labor, and pebbles, and is dependent also on character of ore, size of feed, and fineness of grinding. Costs range from 9 to 40¢ per ton, with 20¢ an aver figure under favorable conditions, where power represents about 30% of total cost, labor 20%, and pebbles and repairs 50%.

Classifying. All grinding in ball-, rod-, or tube-mills should be done in closed circuit, with a classifier. Change from open- to closed-circuit often increases mill capacity 25–60%. Cones were formerly always used for classification, but have given way to mechanical

classifiers, as the Akins, Dorr and Esperanza, or drag type. Disadvantages of cones are their relatively large head room, failure to handle high circulating loads, and need of constant supervision. Dorr classifier, both single-stage and bowl type, is most widely used.

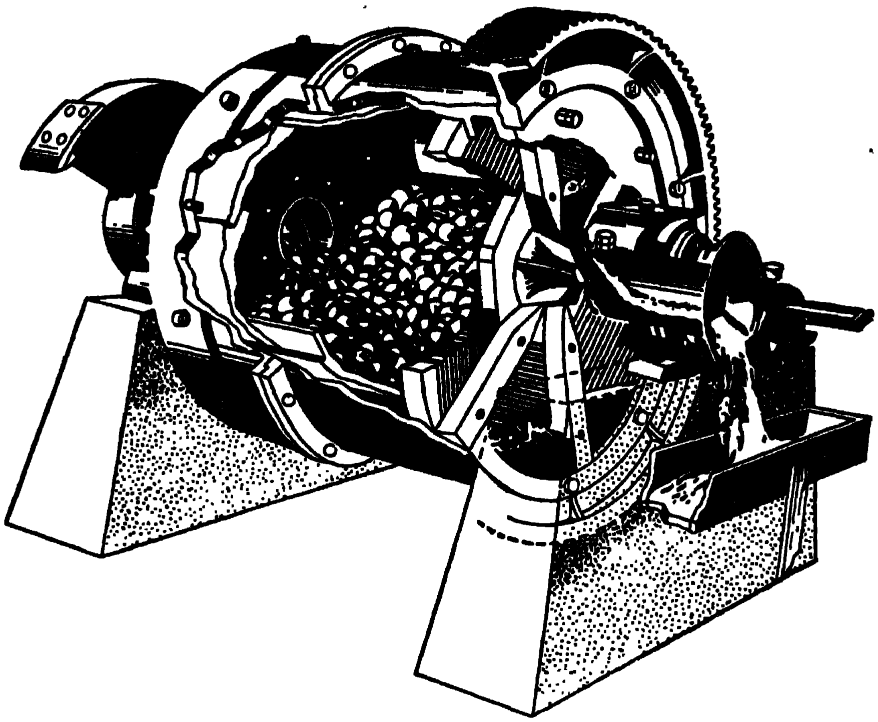

Fig 2. Marcy Cylindrical Ball-mill

Types of classifier. DORR CLASSIFIER, single-stage, consists of a settling tank in form of an inclined trough open at upper end. Feed enters near center, and the liquid and slow-

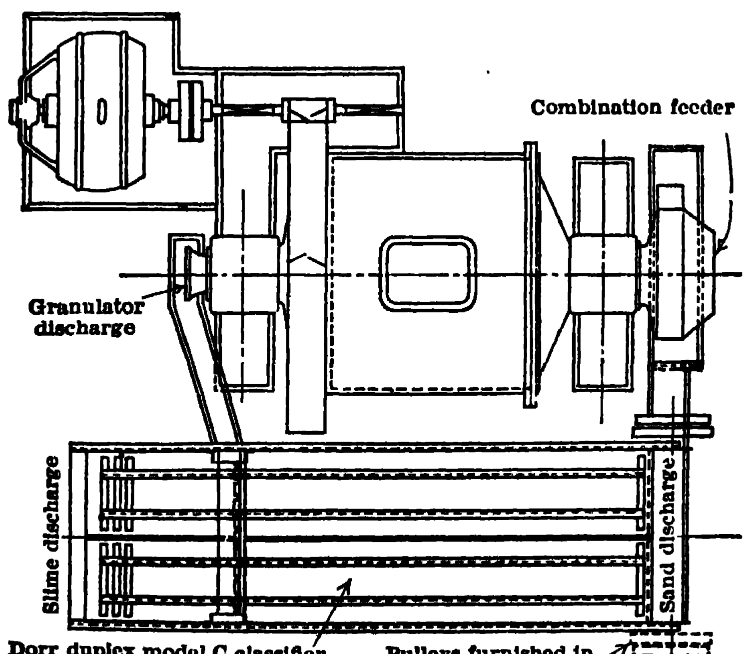

Fig 3. Allis-Chalmers Ball Granulator in Closed Circuit with Dorr Duplex Classifier

settling solids overflow at closed end; while sands or quick-settling solids are conveyed along the bottom by mechanical reciprocating rakes, and, after emerging above the liquid, are discharged at open end. All parts moving on one another are above the liquid, thus

minimizing wear. This classifier is made to handle tonnages from 4 to 1 500 per day, and at separations from 10 mesh and finer. Bowl type (Fig 4), a development of the Dorr classifier, is well suited to separations at 80 mesh and finer, especially where a clean rake

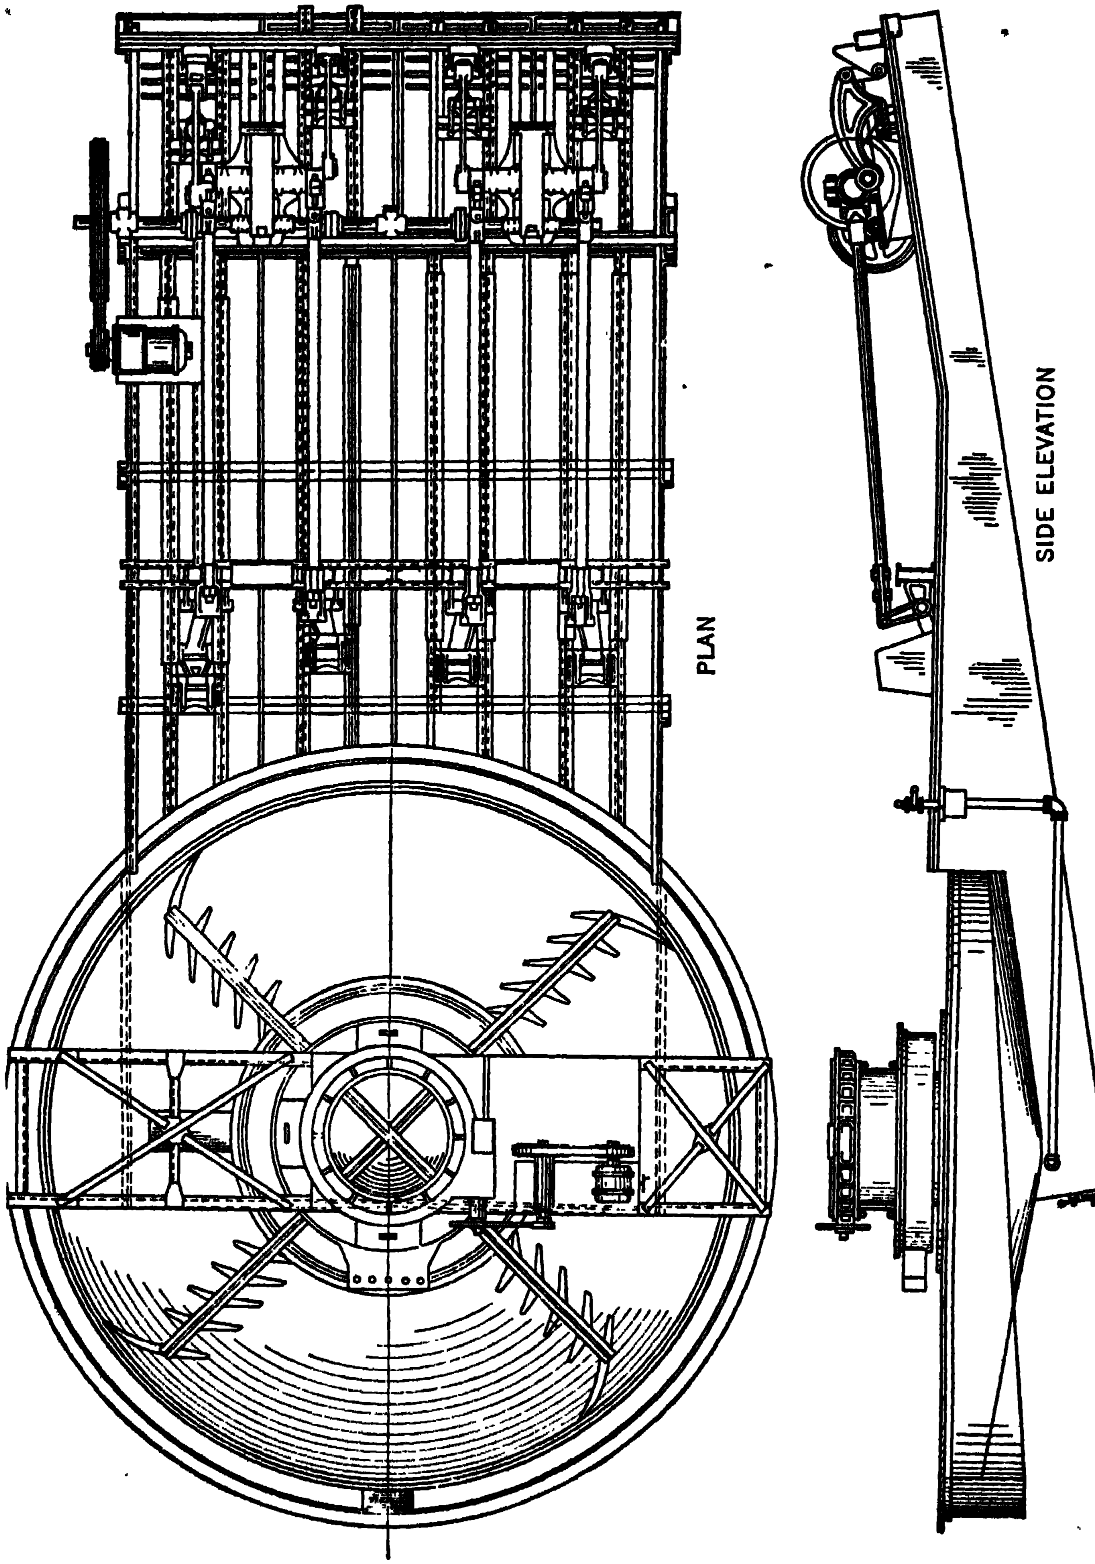

Fig 4. Dorr Turret-bowl Classifier

product is required. It is a two-stage automatic baffled return classifier, feed being introduced through a shallow well at the center. Fines overflow the periphery, and are carried off by the overflow launder. Sand or oversize is plowed to center of bowl, and discharged

into the main tank, whence it is removed by reciprocating rakes as in the single-stage machine. Wash water or solution is sprayed onto the sands just before they leave the pulp level. This type is now used almost exclusively in new plants to separate sands and slimes in a "two-product" process. Clean sands can be sent directly to treatment, eliminating costly transfer in older installations using cones or spitzkasten. AKINS CLASSIFIER (Fig 5) consists of a large-diam spiral conveyer, set in an inclined semi-circular trough. Oversize quick-settling material is conveyed by the spiral to upper discharge end. ESPERANZA CLASSIFIER is a tank placed similar to the Dorr. Oversize is removed by a continuous-flight drag line, revolving on pulleys set at both ends. This machine has found its principal use in El Oro district, Mexico.

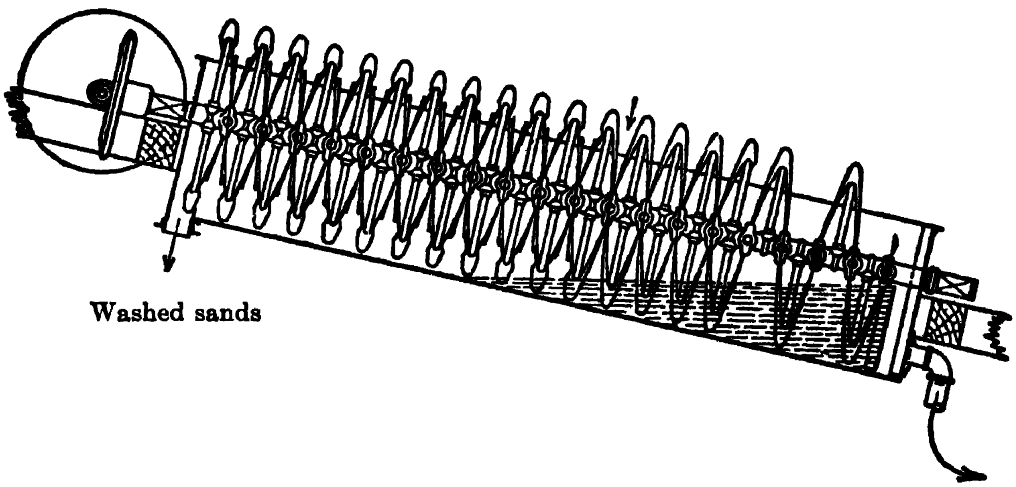

Fig 5. Akins Classifier

Dewatering and thickening. Finely ground product from classifiers, or slimes from a sand-slime separation, are dewatered or thickened in a continuous thickener.

Dorr thickener (Fig 6) is almost exclusively used for this purpose. Its mechanism may be installed in a tank of convenient size, with a circular overflow launder and a central discharge pipe. A central shaft carries radial arms with short rakes, which, by revolving slowly, move the settled slimes toward central discharge. Bottom of tank may be slightly conical, conforming to inclination of the radial arms; or, if the tank be flat, the accumulated slimes soon form a conical bottom surface. Feed enters at a central well, discharging below the overflow level to avoid surface currents. A thickener under 50-ft diam requires less than 1 hp. A diaphragm suction pump regulates the discharge and elevates it to the top of tank.

A recent development, the Torq thickener, eliminates the superstructure and employs a centerpiece carrying rakes, so supported that they ride over resistant areas in the tank. For heavy-duty work the Traction thickener has a rake drive carried on the rim instead of at the center of tank.

Balanced tray type consists of two or more superimposed thickening compartments in one tank, with radial rakes attached to a common shaft. Each compartment has a hydrostatically balanced feed and its own overflow pipe, while the thickened sludge discharges through a central opening in bottom of tank.

Combination type (Fig 6), used for counter-current decantation (Art 12), consists of a single thickening compartment superimposed on a series of tray compartments. The thickened feed passes to the agitators (not shown), and after treatment is returned to the first tray mixed with overflow wash solution from the tray immediately below. This process is repeated one or more times, and the washed pulp finally discharged from the bottom. The thickening zone is separated by an air seal, and the washing zones by an inverted cup and seal. Fig 6 shows normal design. For chemical work, with hot or caustic solutions, the tank and box are covered, and overflow is controlled by adjustable sleeves, operated from outside of box.

10. SAND TREATMENT

Tanks. Sands, after separation from slimes, are charged into tanks fitted with filter-bottoms, consisting of a grating overlaid by cocoa matting and canvas. Sometimes a layer of sand is charged on the filter proper, and over this is spread a grating to limit shoveling of the tailings when the tanks are discharged.

Bottom grating is arranged to insure free circulation of the filtered cyanide solution on the tank bottom towards the solution discharge pipe; there should be always enough orifices through the supporting frame of the bottom grating to allow all parts of the tank bottom to drain freely towards the discharge. The canvas, placed over the cocoa matting, is calked around the edge with rope; it is also calked around the discharge gate when the tank is discharged through the bottom by shoveling, sluicing, or by a mechanical excavator.

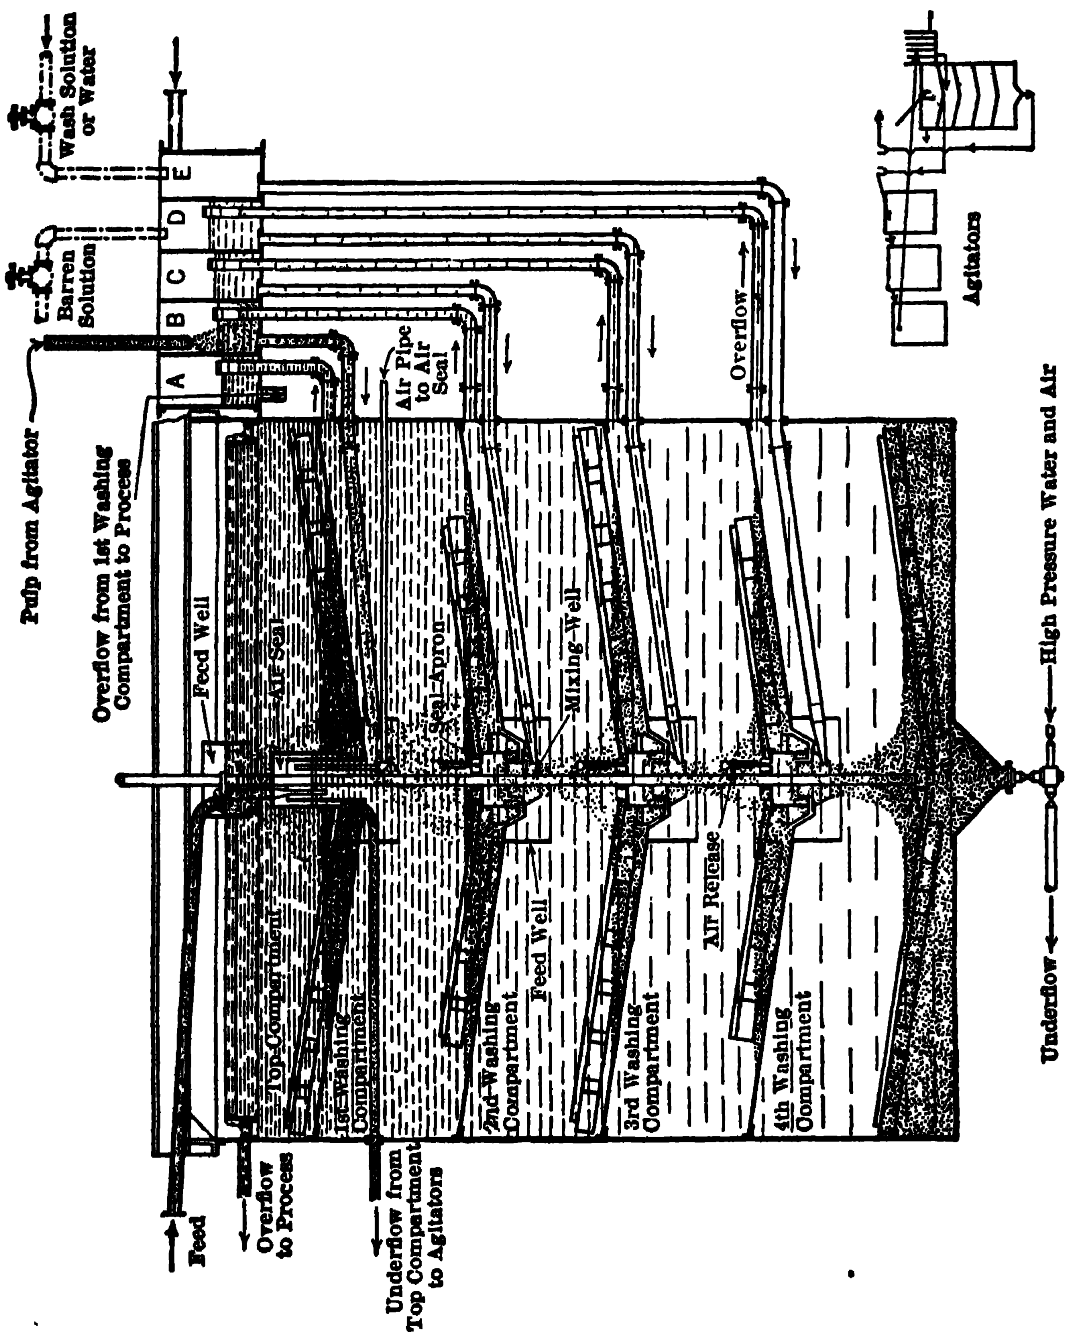

Fig 6. Dorr Washing Thickener (Combination Type)

Depth of tank depends on fineness of sand and amount of slime carried. With clean coarse sand, tanks may be deeper; in practice, depth is 6 to 10 ft. Depth is decided upon after experimenting with the ore to be treated, to determine the RATE OF PERCOLATION. This rate should be between 1 and 3 in or more per hr for satisfactory results and the pulp should be so classified that the resulting sands shall have at least this rate of percolation. The length of treatment being determined, and rate of percolation and depth of tank decided, the area of tank is made such that one or a number of tanks will hold approximately one day's mill run. Tanks have capacities from 30 to 900 tons each.

Operation. The tank is generally filled with wet pulp from the classifiers, evenly distributed by some automatic device. This usually consists of revolving pipe-arms with perforations, or modification of this device. After filling, the sands are drained, and, if crushing has been done in solution, the solution is stored for re-use until it is high enough in precious metal content to be effectively precipitated. After the first draining, the first and generally the strongest mill solution is run into the tank to cover the charge. Practice varies as to admitting the solution at top or bottom of the tank.

Experiments determine the strength and number of the successive cyanide solutions used before washing with clear water. A variation of practice is to use downward percolation; continuously drawing off the cyanide solution from the bottom, and adding fresh solution at the top until the desired extraction has taken place. But this practice does not aerate the pulp so well as intermittent flooding and draining of the charge, which generally gives a higher extraction.

Necessary precautions for percolation of sands: charge should be evenly distributed in the tanks and free from slimes which pack and prevent passage of solution. In a few cases it has been possible to treat clayey material by segregating the feed and using methods of filling tending to agglomerate the fines, and so avoid serious loss of permeability.

Variations of practice in percolation of Au ores show following range: draining off water from wet charged tank, 8 to 18 hr (aver, 13 to 14 hr); leaching, 12 to 18 hr (aver, 15 hr); washing, 16 to 22 hr (aver, 20 hr). Most mills use 1 strong and 2 weak-solution treatments, and 1 with wash water. Some mills have increased extraction by forcing air up through the filter bottom before each application of solution. Pressure used is only sufficient to aerate slowly without forming channels in the sands. Vacuum drainage is used in certain plants on the Rand.

Discharging the tanks by shoveling costs most, and is used in small plants where water is scarce. Sluicing is cheapest, and is used where water is plentiful. Mechanical excavators (radial arms, carrying circular plows that are lowered into the sands and move them to the central discharge door) are high in first cost and are adopted only for large plants. Their operating cost is generally betwen that of sluicing and shoveling.

Size of material treated, AMOUNT and STRENGTH OF SOLUTIONS used, and TIME OF TREATMENT, must be determined experimentally for each ore. An ore especially adapted to sand treatment. due to its porosity, freedom from slimes, and easy solubility of the Au, may be successfully leached by percolation, to as coarse as $^3/_8$-in size. Certain siliceous ores have given good extraction when crushed as fine as 100 mesh. A typical all-sand treatment is that of the Mountain Copper Co, Calif, where a gossan of limonite and quartz carrying \$1.85 gold is profitably leached, crushing to $^3/_8$-in size. Treatment is in ten 276-ton vats, as follows: 195 tons of 0.8-lb NaCN solution over 16 hr; 90 tons of 0.5-lb solution over 24 hr; 180 tons of 0.4 lb solution over 20 hr; and 75 tons water wash over 7.5 hr. Indicated extraction, 73% at cost of 43¢ per ton. The plant cost \$75 000.

11. SLIME TREATMENT

Agitation of thickened slimes may be done in tanks by mechanical stirrers, compressed air, or, more efficiently, by a combination of these. As oxygen is required to dissolve the Au and Ag, some aeration is always necessary.

Dorr agitator (Fig 7) is the best known device using both mechanical stirring and air. It consists of a central pipe carried by a hollow revolving vertical shaft, which has 2 arms with plows like those of the Dorr thickener. The plows draw the settled slime toward the center, where a jet of air raises it through the central shaft. From top of this, the pulp is distributed by revolving launders over the surface of the pulp in the tank. By certain modifications the Dorr agitator can be used for either continuous or batch agitation. A size 40 ft diam by 25 ft deep requires less than 3 h p.

Devereaux and Turbo agitators are mechanical types, the first employing an open propeller near bottom of tank; the other, a high-speed bladed rotor, running within a similar stator and operating on the turbine principle. Both types draw in air by a vortex action.

Brown or Pachuca tank (Fig 8). Where only compressed air is employed, this is the common type as developed in New Zealand. It is a high steel tank with conical bottom and central tube; the pulp is raised to the top, overflowing back into body of tank. A favorite size is 15 ft diam by 45 ft high. The colloidal slimes of Mexico tend to build up on the sides of the tanks, so that they require cleaning out every two weeks. As the comparatively granular slimes of the Rand are free from this tendency, the size in recent installations has been increased to 22 ft diam by 45 ft high.

A Dorr agitator, requiring less than half the power (mechanical and air) of the Brown, uses a tank of convenient size for saving in pulp elevation, and can be equipped with a

positive scraper for cleaning the tank sides. The high Brown tanks require a substantial foundation.

Dilution of pulp. To the thickened pulp charged in the agitating tanks enough stock cyanide solution is added to bring the pulp to the required consistency, at the same time maintaining the proper strength of cyanide in the charge. Dilution of the pulp depends upon character of the slime; thick clayey slime requires greater dilution for prompt extraction.

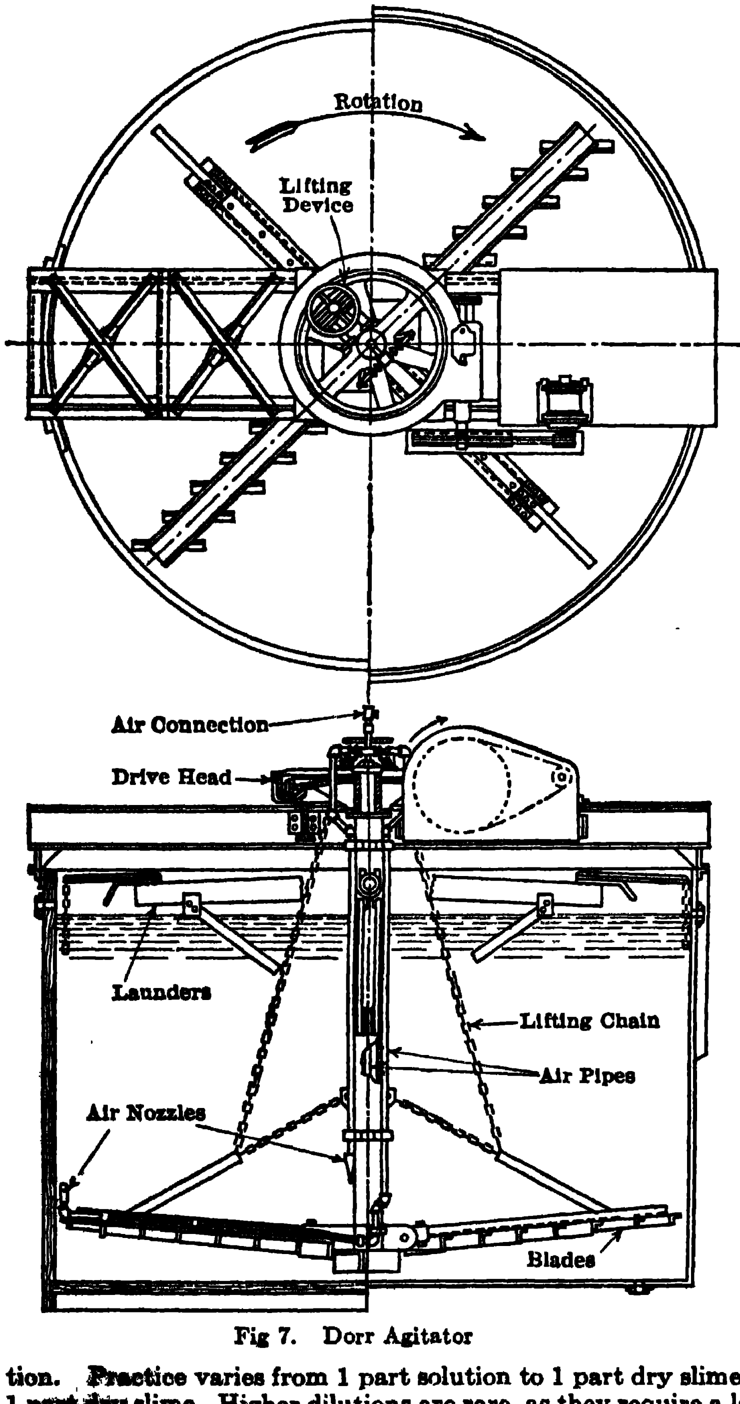

Fig 7. Dorr Agitator

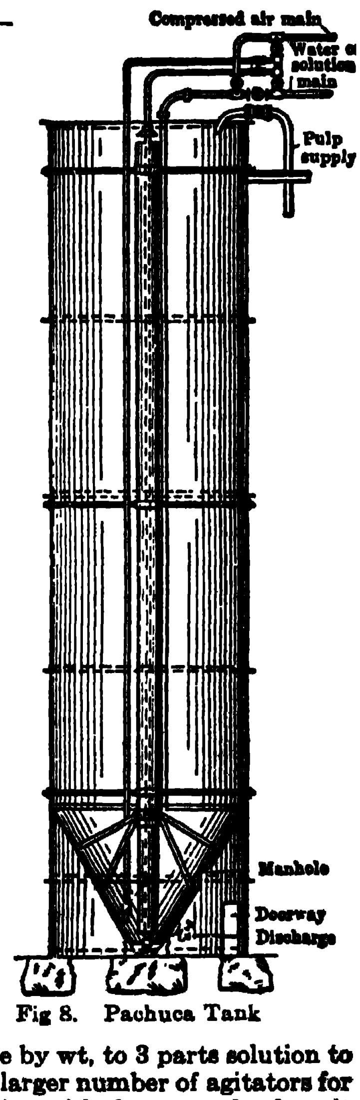

Fig 8. Pachuca Tank

Practice varies from 1 part solution to 1 part dry slime by wt, to 3 parts solution to 1 part dry slime. Higher dilutions are rare, as they require a larger number of agitators for a given treatment time. Accompanying table is useful in dealing with the sp gr of pulps; it is based on a sp gr of 2.5 for dry slime. Intermediate values in the table may be interpolated. In practice, it is usual to take samples of the thoroughly agitated pulp in a weighed flask of known capacity, and from the net wt of the pulp calculate the sp gr, the other data being obtained from sp gr tables.

Strength of solution. The amount of cyanide in the solution which forms the pulp in

the agitation tanks is determined by experiments on the ore, and varies greatly in different places. The strength may be expressed in terms of lb or per cent, but it is customary to express the strength in lb of NaCN equivalent per ton. In general, for Au ores, from 0.5 to 2.0 lb NaCN covers the range of strength of solution. For Ag ores, the range is 2.0 to 5.0 lb. Where battery crushing or tube-mill grinding has been done in solution, the strength of solution used is generally much lower than that named above, and, to bring the pulp up to the proper percentage of cyanide, a stronger solution is added in the agitation tanks to the thickened pulp; or, if the pulp reaches the agitation tanks already sufficiently dilute, cakes of cyanide are dissolved in the charged tank when agitation commences. At the same time the proper amount of lead acetate is added, which is generally done by suspending in the charge a loose burlap bag containing lead acetate corresponding in amount to that needed for the treatment of the number of tons of dry slimes in the tank.

Dry slime in pulp, %	Parts of sol to dry slime	Sp gr of pulp	Wt of 1 cu ft of pulp, lb	Cu ft pulp for 1 ton dry slime
16.67	5 : 1	1.111	69.5	172.9
20.00	4 : 1	1.136	71.1	140.8
25.00	3 : 1	1.176	73.4	108.8
28.57	2.5 : 1	1.206	75.3	93.4
33.33	2 : 1	1.246	77.8	77.7
50.00	1 : 1	1 429	89.2	44.8

The charge should also be tested for protective alkalinity; the proper amount of lime to insure this is generally crushed with the ore in the battery, or milk of lime is added to the charge in the tube-mill.

Some trouble has been experienced in air agitation, due to excessive use of lubricating oil in the compressor cylinders. Some plants use soapsuds or graphite lubricant for the air cylinders, and claim that extraction is thereby increased.

Quantity of air required. In practice a Brown tank, 15 ft diam by 45 ft high, uses 50–75 cu ft free air per min, at a press of 30 lb per sq in. A Dorr agitator, 30 ft diam by 12 ft deep, uses not over 25 cu ft free air per min at 10-lb press. From 5 to 10 hp is required for both air and mechanical operation. Violence of agitation does not necessarily increase extraction; constant agitation is needed, which will move every particle of material reaching the inlet of the air-lift. Control of aeration is important, for an excess can increase consumption of lime and cyanide, without improving extraction.

Time of agitation varies greatly with different ores; the economic limit can be determined only by laboratory tests. With Au ores, 18–36 hr generally suffices, but with Ag ores 36–60 hr is common and 90 hr are often required. A longer period often permits use of a lower-strength solution.

Agitation may be either in batch treatment or continuous. If continuous, not less than 3 agitation units should be employed to insure against short-circuiting of part of the pulp. Continuous agitation has been adopted in most districts.

12. CONTINUOUS COUNTER-CURRENT DECANTATION

A series of continuous thickeners, or a washing thickener unit, operates in such manner that the solids, with a small portion of liquid, pass successively from one thickener, or

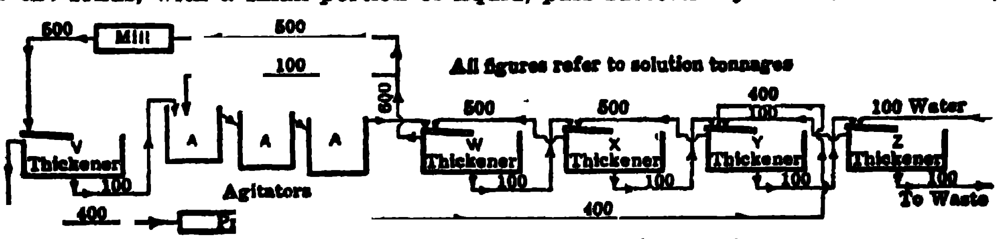

Fig 9. Diagram of Counter-current Decantation

thickening compartment, to the next, being finally discharged as tailings (Fig 9), or as a product to be further washed and dewatered on a continuous filter. The main body of liquid moves in a direction opposite to the course of the ore and is gradually enriched. By each step a large volume of low-grade solution is mixed with a very small amount of high-grade solution, so that the value of the solutions entering each successive thickener with the solids is materially reduced.

Calculations for dissolved value loss. Assume (Fig 9): 100 tons per day crushed in cyanide solution; 50% solids in thickener underflow; $10 value dissolved per ton of ore, (75% in the mill, 25% in the agitators); solution value reduced to 2¢ in the precipitation section; agitation carried out at 2 : 1 solution to solids. Then, if V, W, X, Y, Z are values in dollars per ton of solution discharged from thickeners, equations are as follows, equating in and out of each thickener:

$$
\begin{aligned}
&(1)\ 100\ V + 400\ V = 500\ W + (0.75 \times \$10 \times 100)\\
&(2)\ 100\ W + 600\ W = 500\ X + 100\,W + (0.25 \times \$10 \times 100) + 100\,V\\
&(3)\ 100\ X + 500\ X = 100\ W + 500\ Y\\
&(4)\ 100\ Y + 500\ Y = 100\ Z + 100\,X + (400 \times 0.02)\\
&(5)\ 100\ Z + 100\ Z = 100\ Y + 100 \text{ tons of water, value nil}
\end{aligned}
$$

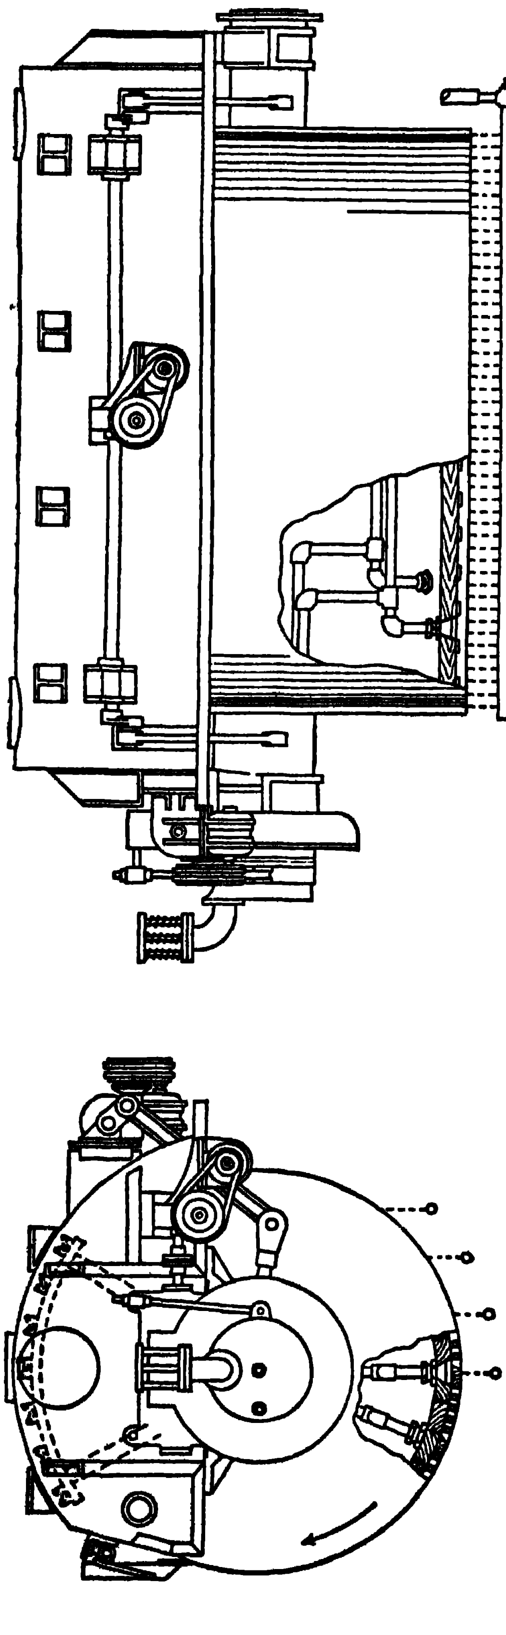

Fig 10. Oliver Continuous Cyanide Filter

Solving, $V = \$2.51332$; $W = \$1.01332$; $X = \$0.21332$; $Y = \$0.05332$; and $Z = \$0.02660$. Mechanical loss of cyanide and lime can be similarly calculated.

13. FILTRATION

Filtration by gravity (Art 10) is employed for percolation of sands. Filter presses or other appliances separate solutions from pulp in the treatment of slimes. Pressure filters, formerly used for treating granular or crystalline slimes, have practically disappeared in favor of the VACUUM FILTER for all pulps. Following are brief descriptions of the principal mechanical filters.

Oliver filter, a continuous filter of vacuum type, consists of a revolving drum partly submerged in a tank about one-third full of thickened slimes (Fig 10). During a part of the revolution of the drum, the surface of which carries the filtering medium, the solution is drawn off by a vacuum pump, connected through a rotary valve on the drum's trunnion. During passage of the drum through the slimes, a cake is formed on the drum exterior. The slime cake is sprayed through succeeding arcs with barren solution and wash water, which in turn are drawn off by the pump, and sent to weak solution storage or used in countercurrent washing in the preceding thickeners. During the final arc in the drum's revolution, the rotating valve cuts off the vacuum and connects the leaves as they pass that point with a compressed air supply. The compressed air, assisted by a scraper, discharges the slime cake for its removal to waste. ADVANTAGES: low initial cost and operating cost, continuity of operation, few complicated parts and low repair costs. Capacity of the filter varies with character of pulp, but for an aver slime is about 800–1 200 lb dry solids per sq ft of filter surface per 24 hr.

American filter is of continuous vacuum type, consisting of one or more filter disks mounted vertically about a central shaft (Fig 11). Each disk is divided into 8 or more sectors, each of which is a rigid frame holding a wire body and covered with a cloth bag clamped in place. Individual sectors are interchangeable. Drainage conduits connect each sector to a rotary valve. Cycle of operation is like that of the Oliver filter. ADVANTAGES: economy in floor space per unit of filtering area, no wiring required

for holding down the canvas, and ease with which worn or choked sectors may be replaced. **Disadvantages: considerable difficulty in obtaining effective displacement with wash water.**

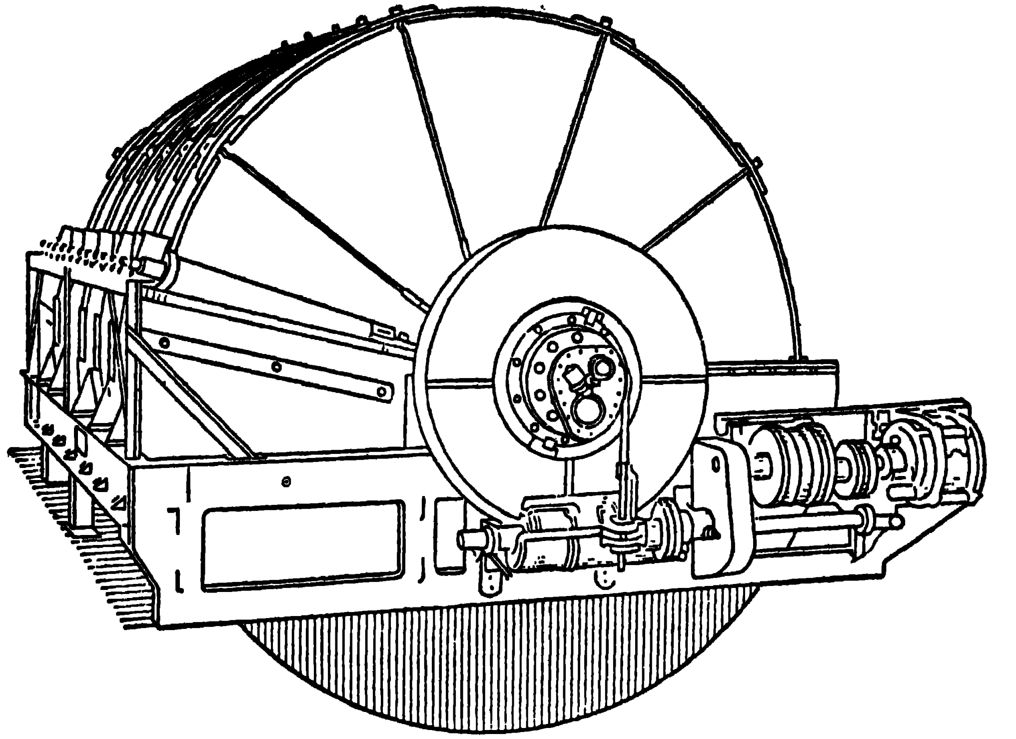

Fig 11. American Filter

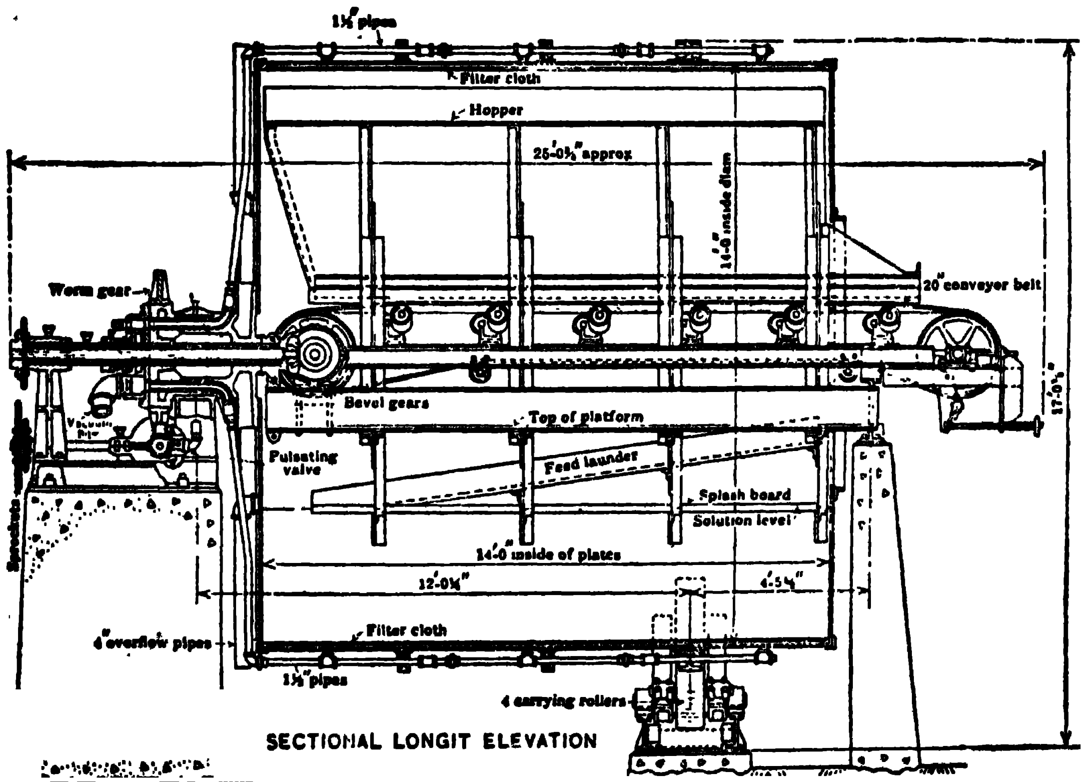

Fig 12. Dorrco Filter (Shimmin)

Dorrco filter (Shimmin) is a more recent vacuum machine, especially adapted for filtering pulps containing granular material; it consists of a rotating drum, on the inside of which is a filter medium. Fig 12 is a sectional view of the 14 by 14-ft machine, showing

the belt conveyer which removes the cake after discharge. One end of drum is open, for receiving the feed, removing the cake, and inspecting the operation. The drum itself is a container for the pulp, eliminating need for a tank and agitating mechanism to keep the pulp in suspension. Segregation of the pulp materially aids filtration, as the coarser particles fall by gravity upon the filtering medium. Hence, the action is the reverse of other vacuum filters using tanks; in the latter, segregation is a detriment, because heavy material goes to the bottom of the tank and is difficult to get onto the filter cloth. Also, the finer material is drawn onto the filter cloth first, and tends to clog it more than if the coarser particles were deposited first. The cake forming on the drum is carried around to a point at or beyond the top. At this point the filter cloth is caused to expand and contract quickly, by use of a valve which subjects the cloth alternately to pressure and vacuum, so that the cake falls from it freely, and the filter meshes are kept clean. The main vacuum for picking up the cake is applied to the drum by pipes, which terminate in the ports of a rotating valve, as for the Oliver filter (Fig 10). The cake, on being blown off the filter cloth, drops into a hopper, whence it is removed by a belt conveyer, operated by the main filter drive. The filter cloth is not wire-wound, nor is there a scraper or roller at the discharge point.

This machine can be used not only for fine pulp, but also for much coarser material than can usually be handled by vacuum filters. This is because no artificial means are required to get the coarse material onto the filter, the act of feeding the machine being sufficient.

Butters filter is a noncontinuous type and comprises a series of filter leaves, suspended vertically in a steel or wooden tank. The leaves are perforated pipe frames, supporting a filtering medium of cocoa matting and canvas cover. Each filter leaf is connected to a common pipe header. Tank is charged with slime and vacuum applied to leaves until cake is formed of sufficient thickness. Retaining a partial vacuum on leaves, excess pulp is withdrawn back to storage and tank filled with barren wash solution. Full vacuum is again applied until pregnant solution originally contained in the cake is sufficiently removed; vacuum is again lowered, excess wash solution withdrawn and cycle repeated with wash water. After being thoroughly washed, cake is dropped to bottom of tank by reversing the air pressure on the leaves and sent to waste. Time of cycle and capacity of filter vary with character of pulp and local conditions; aver, about 8 cycles per day and about 75 lb dry solids per sq ft of filtering surface (counting both sides of filter leaves) per 24 hr. ADVANTAGES claimed over continuous type of vacuum filter; better control of washing cake, enabling filter to take pulp directly from agitators, thus eliminating intermediary counter-current washing thickeners that are usually found advantageous ahead of continuous filters. DISADVANTAGES: higher initial and operating cost than continuous type; intermittent batch operation.

Acid treatment of filter surface is necessary every week or two, to remove accumulated lime from the filtering medium. The filter leaves are submerged or scrubbed in a weak solution of HCl, while under a slight vacuum.

Clarifying of solution. Pregnant solution obtained from filters or by decantation is usually cloudy. To clarify it before going to precipitation, it is filtered by gravity through beds of clean, fine sand; or, better. by a small Butters filter, using a wet vacuum pump. Several manufacturers have special pressure filters for this work.

14. PRECIPITATION AND REFINING

Precipitation on zinc shavings, still used in some of the older plants, has given way to zinc-dust precipitation in most modern plants. The clarified solution passes to a series of boxes containing the shavings. The solution overflows from one box, drops down a baffled partition and rises through the bottom of the next, and so on to the last. Each box has a false bottom, and all are contained in a longitudinal tank. The boxes, 6 or 8 in number, may be 12 to 30 in or more in width and height, with a total length of 12 to 20 ft or more, and are of wood or sheet steel.

The Zn shavings rest on a screen bottom, and are most effective when cut about $^1/_{16}$ or $^1/_8$ in wide and extremely thin, generally not exceeding $^1/_{500}$ in thick. The shavings, prepared by special automatic lathes from zinc cylinders, are packed uniformly in each compartment to insure an even flow of the solution through them. Amount of Zn is calculated at about 1 cu ft of shavings for each 1.5 ton of solution to be treated per day. The Zn is sometimes dipped in a solution of lead acetate, to form a Zn-Pb couple, making the precipitation more effective. Before cleaning the precipitate from the Zn, the strength of the cyanide solution running through is materially raised for an hr or more; the Zn is then washed or shaken in a separate receptacle and the loose precipitate is washed down into the bottom of the trough or launder containing the Zn boxes. The clean Zn is moved up from one compartment to the next, until all have been cleaned, fresh Zn being added to the lower

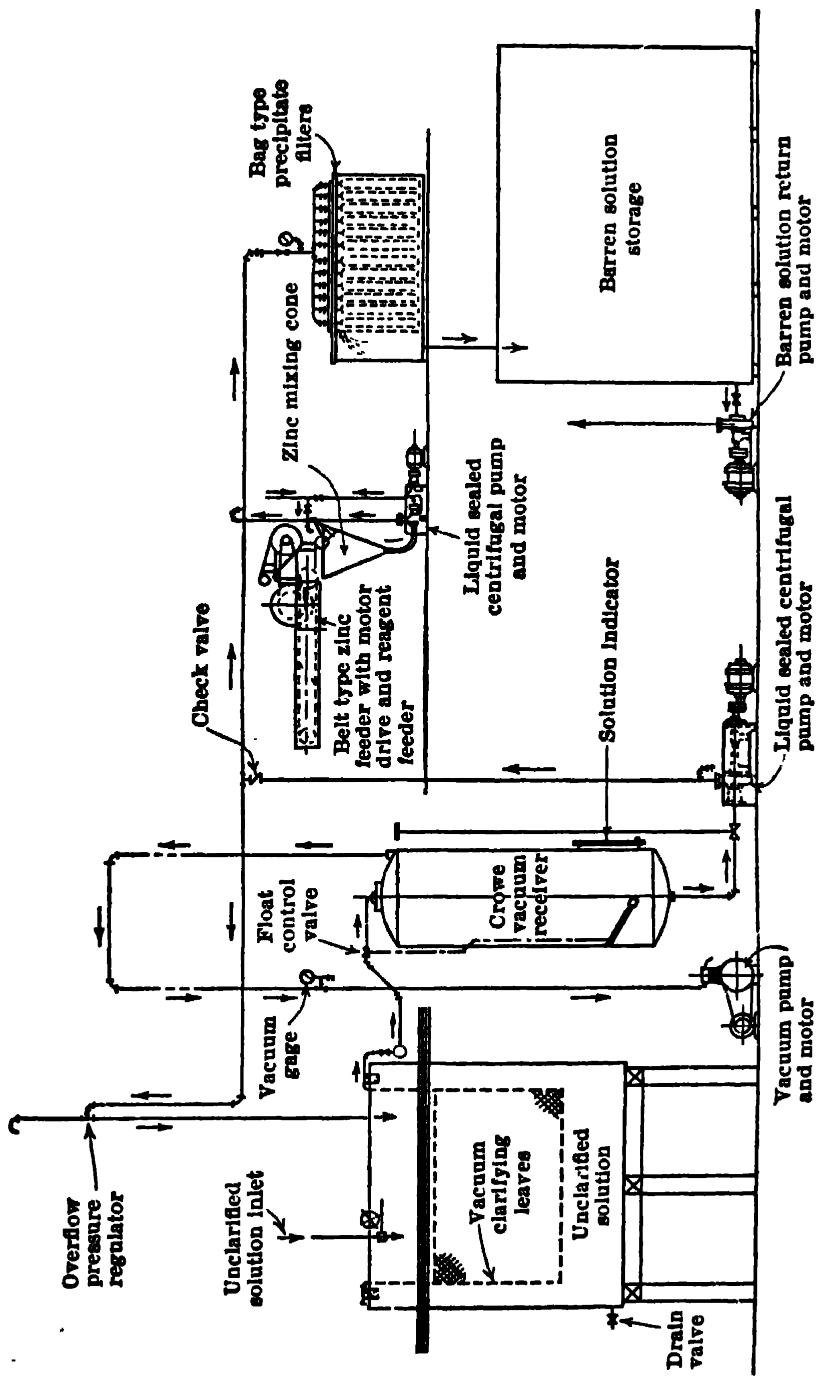

Fig 13. Merrill-Crowe Bag-type Precipitation, using Zinc Dust. Dorr's "Cyanidation and Concentration of Gold and Silver Ores," p 192

compartments. The precipitate, with such fine or "short" zinc as may have fallen with it, is then dried preparatory to further treatment.

Precipitation by zinc dust. The Merrill process of continuous zinc-dust precipitation is used in all modern plants. The dust is fed automatically into a small part of the pregnant solution, and this mixture is added to the main stream of solution going to precipitation.

The pregnant solution mixed with the Zn dust is pumped into a filter press or pressure bag filters. The bags, which are submerged, have inner and outer portions, the inner filtering medium being thoroughly washed or burned after scraping off the Au precipitate. Precipitation takes place almost immediately; the Au and Ag (and any excess of Zn dust) remaining on the filtering medium. When enough cake is formed (indicated by rapid rise of pressure), pumping is stopped and sometimes a little wash water forced through; air is then forced through the line for a few minutes, partly to dry the precipitate; the press is opened or bags disconnected, as the case may be, and the cake removed in trays for further treatment.

A modification of the Merrill process has been to use vacuum leaves in place of pressure filtering, the apparatus resembling a small Butters filter, with a wet vacuum pump. The mixture of Zn dust and pregnant solution flows by gravity to tank and is drawn through the filter leaves. An automatic control assures a submerged filter leaf, so that the Zn dust is not exposed to the air. The mixture of precipitate and solution circulates continuously over the filter leaves, assuring a uniform layer of solids on the cloth. Advantages: reduced first cost and simpler clean-up.

Crowe process. The de-aeration of pregnant solution prior to precipitation by this process has been the most striking improvement in cyanidation in recent years. It is adapted to precipitation by either Zn shavings or Zn dust, the latter being preferable (Fig 13). Few local conditions would warrant its omission from any plant. De-aeration is done by subjecting thin films of the liquid to a vacuum action within a dispersion tower or receiver. Practically all dissolved air is removed through the vacuum pump, and the solution is sent to precipitation without further opportunity to absorb air. Recent improvement in apparatus allows receiver to be placed on same level as other precipitation equipment, while vacuum clarification is made an integral part of the de-aeration system. Corresponding to importance of de-aeration prior to precipitation, the barren solution should be thoroughly aerated before its re-use in the dissolving circuit.

The Merrill-Crowe processes have reduced Zn consumption to about 0.05 lb per ton milled on the Rand, and to less than 0.5 lb per lb of bullion from Ag ores in Mexico.

Precipitation by aluminum resembles that by Zn dust. It is advantageous in some cases; but lime must be absent from the solution, as it results in the formation of insoluble calcium aluminate, which produces low-grade precipitate.

Precipitation by charcoal has been used with some success in Australia, and has possible advantages where the solutions are badly fouled with contaminating substances which interfere with Zn-dust precipitation. The combination cyanidation-charcoal precipitation-flotation processes of Edquist and Chapman have already been mentioned (Art 6).

Sodium sulphide precipitation is satisfactory where Ag only is to be considered. Advantages: low cost and regeneration of part of the cyanide. Used at Nipissing mill, Cobalt, Canada.

Regeneration of cyanide is partially accomplished by sodium sulphide, as well as sulphurous and sulphuric acid. There are (1938) as many as seven regeneration plants in operation, with an aggregate daily capacity of some 10 000 tons of solution.

Mills-Crowe process is most generally used for recovering cyanide as calcium or sodium cyanide from used mill solutions. It is claimed there is a nearly complete recovery of cyanide from the free cyanide and double cyanides of Zn and Cu. By special reagents, a partial recovery can be made from the ferrocyanide.

Process consists in acidifying the cyanide solution with sulphurous acid; the acidified solution passing through additional dispersion towers, in which the solution flows countercurrent to a relatively large volume of low-press air. The air removes practically all the cyanogen in form of HCN. By passing the air through similar towers, in which alkaline absorbent solution is circulating, the HCN is absorbed and sent out for re-use. Sulphurous acid is obtained by burning sulphur or by roasting sulphide ores (see Art 16 for costs).

The General Engineering Co uses $ZnSO_4$ to precipitate free and combined cyanide. The relatively small amount of precipitate is then acidified, the HCN re-absorbed, the $ZnSO_4$ regenerated for further use, and insoluble residues recovered by smelting.

Melting and refining. Method depends on local conditions as to quantity and quality of precipitate to be handled. Au precipitate is usually first treated with 10% solution of H_2SO_4 to dissolve out excess Zn, special precautions being taken to vent out of the building any HCN that is formed. It is then dried, fluxed and melted in graphite crucibles; Ag precipitate is generally treated in a reverberatory furnace. Silver bullion is partly cleaned

by blowing air through the molten mass, the melted bullion being poured into molds and the bars sold direct to refineries. In the Tavener process the precipitate is melted in a reverberatory furnace with litharge, the lead bullion formed being cupelled in a special furnace, producing fine bullion.

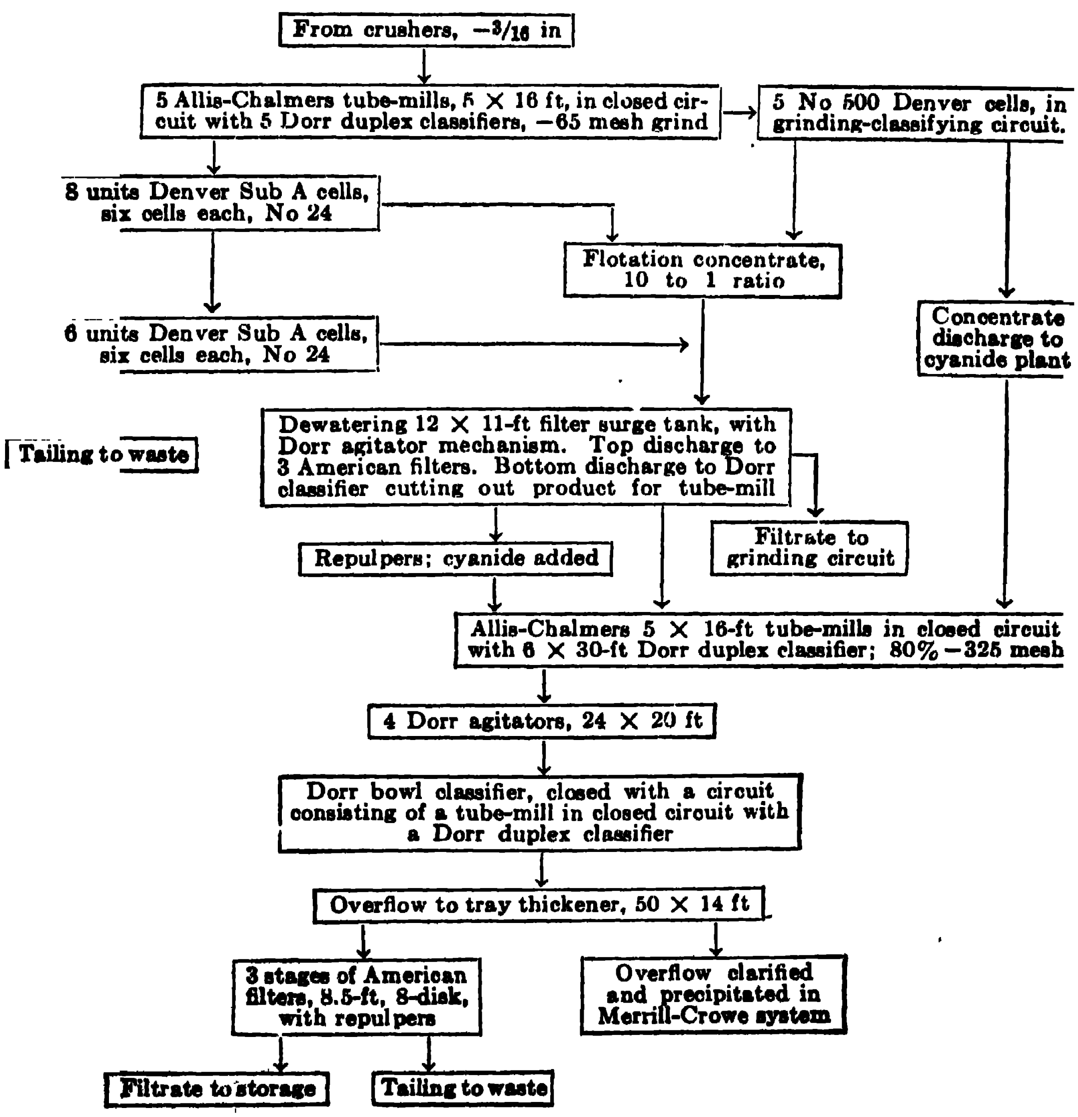
Composition of flux. For Au, aver flux is 30% Na_2CO_3, 10% clean SiO_2, and 60% borax glass. Weight of flux is 18–35% of weight of precipitate; and up to 85% if precipitate is high in Zn. A little $NaNO_3$ may be used (3–10% of wt of flux), but an excess rapidly scours the crucible. If precipitate carries much base metal, the proportion of SiO_2 may be larger. Slag and matte (if any) are saved, and re-treated or shipped when enough accumulates.

Short zinc. In using Zn shavings, short broken pieces of Zn accumulate in excess of the amount that can be returned to the boxes. They are best disposed of by treating with H_2SO_4 and adding resulting residue to final precipitate.

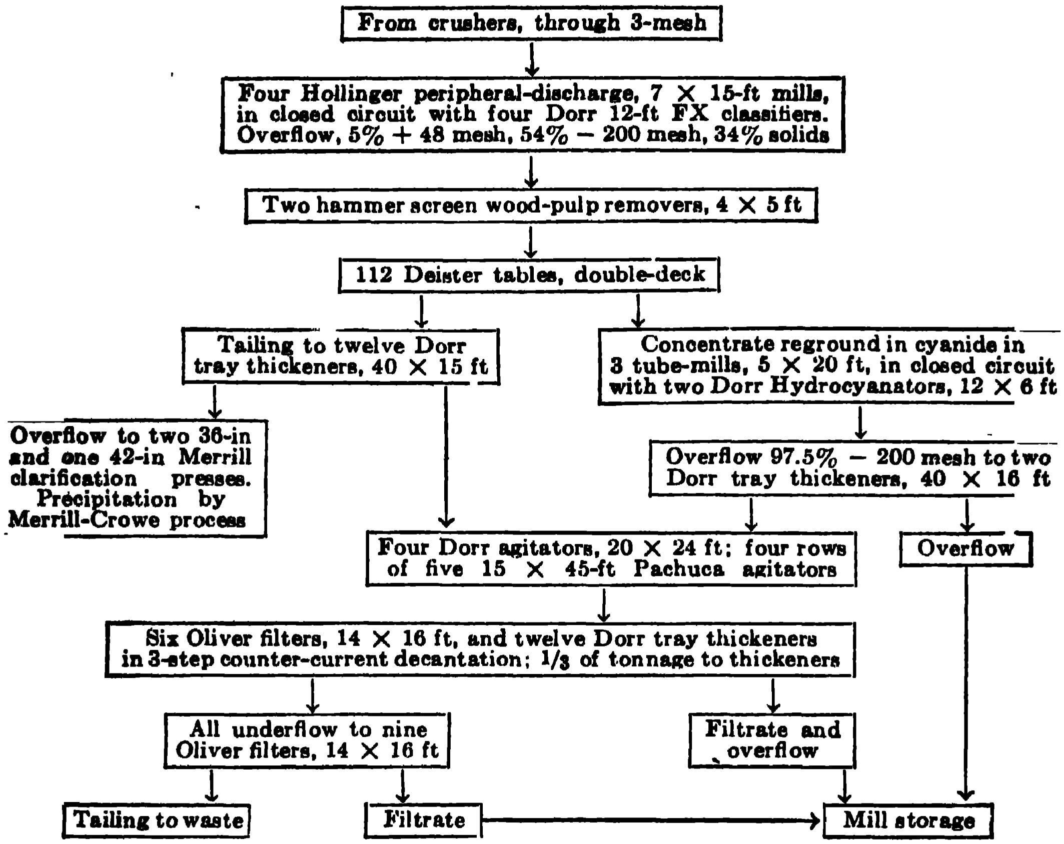
15. FLOW-SHEETS OF TYPICAL MILLS

Following are typical flow-sheets of mills operating on widely different ores.

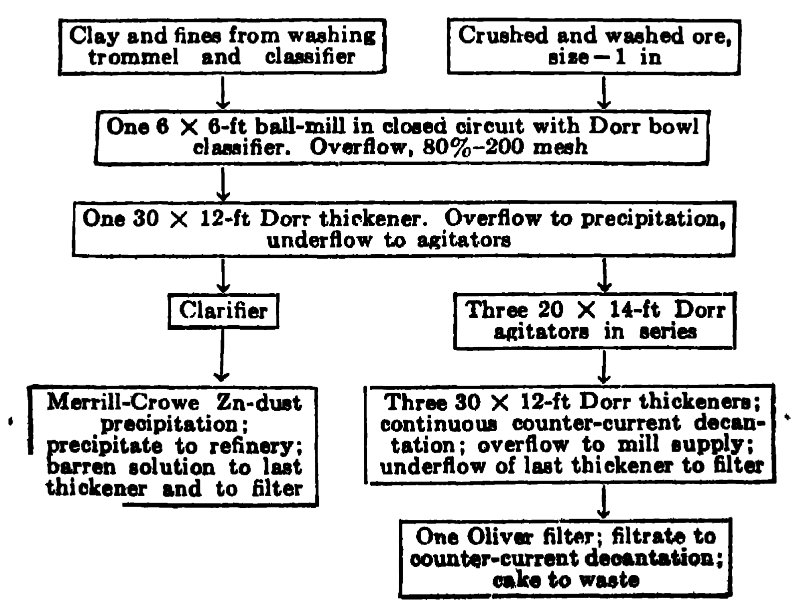
McIntyre mill, Ont, Canada. 2 400 tons daily. Gold ore, 0.218 oz per ton, in quartz, porphyry and schistose basalt, containing 8% pyrite. Grinding with unit flotation cells in mill-classifier circuit, finished tailing by main flotation circuit, regrinding and cyanidation of concentrates.



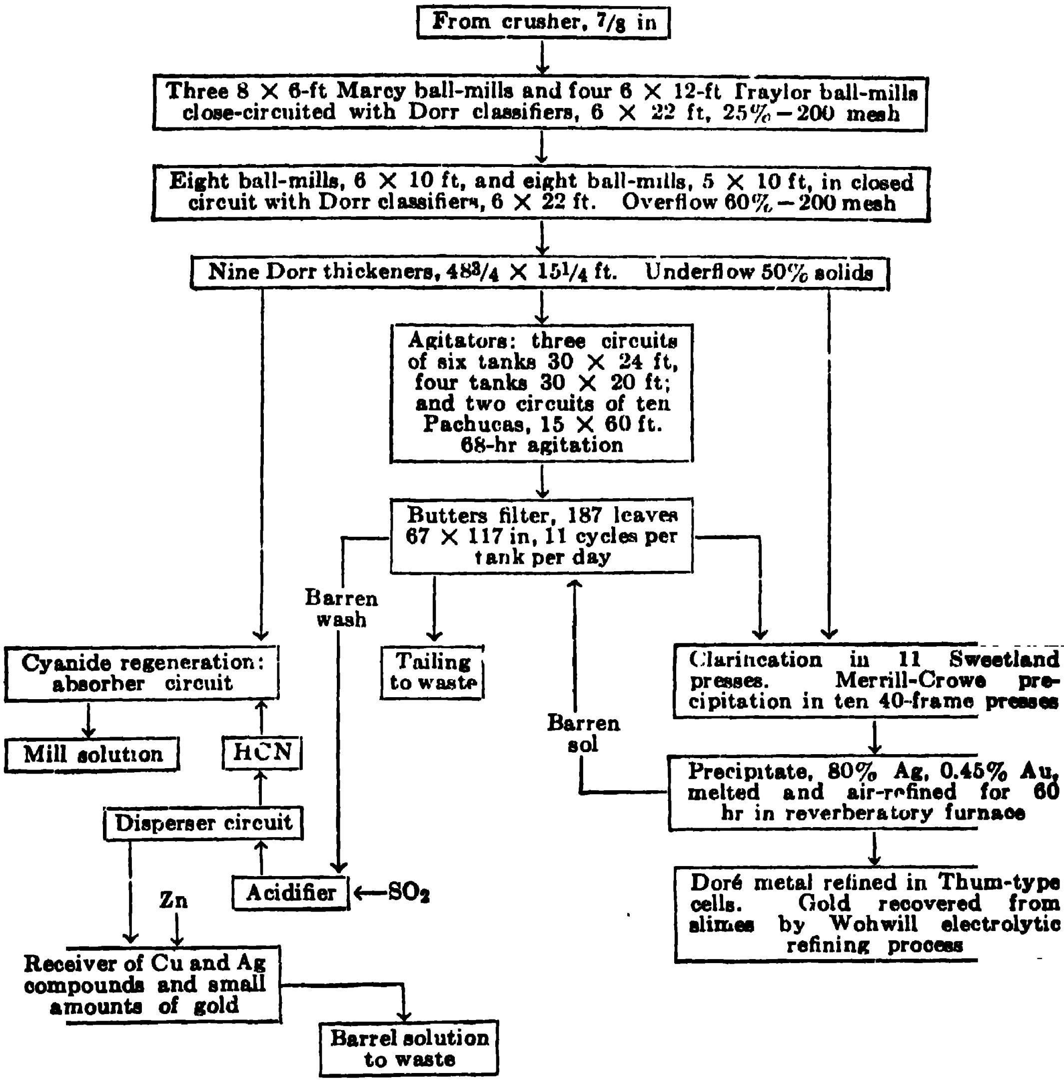
Hollinger mill, Ont, Canada. 5 000 tons daily. Gold ore, approx 0.25 oz per ton in siliceous schist containing about 4–5% pyrite, of medium hardness and 2.9 sp gr. Grinding in cyanide solution, table concentration of sulphides, concentrate reground, counter-current decantation, and two-stage filtration.



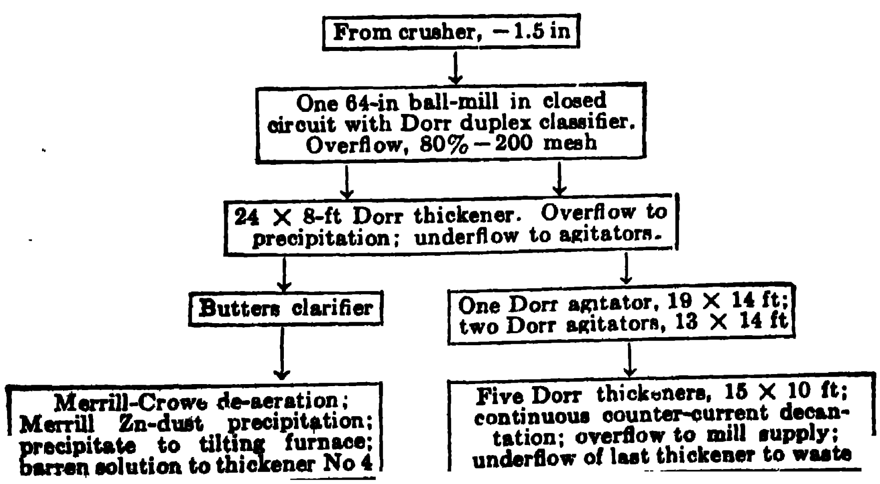
East Mindanao mill, Philippine Is. Gold ore, 100 tons per day. All-sliming and counter-current decantation, followed by a filter. Clay washed out before secondary crushing and by-passed to ball-mill. Mill heads approx 23 pesos per ton; tailings approx 1.5 pesos per ton (par value of peso, 50¢ U S cur).



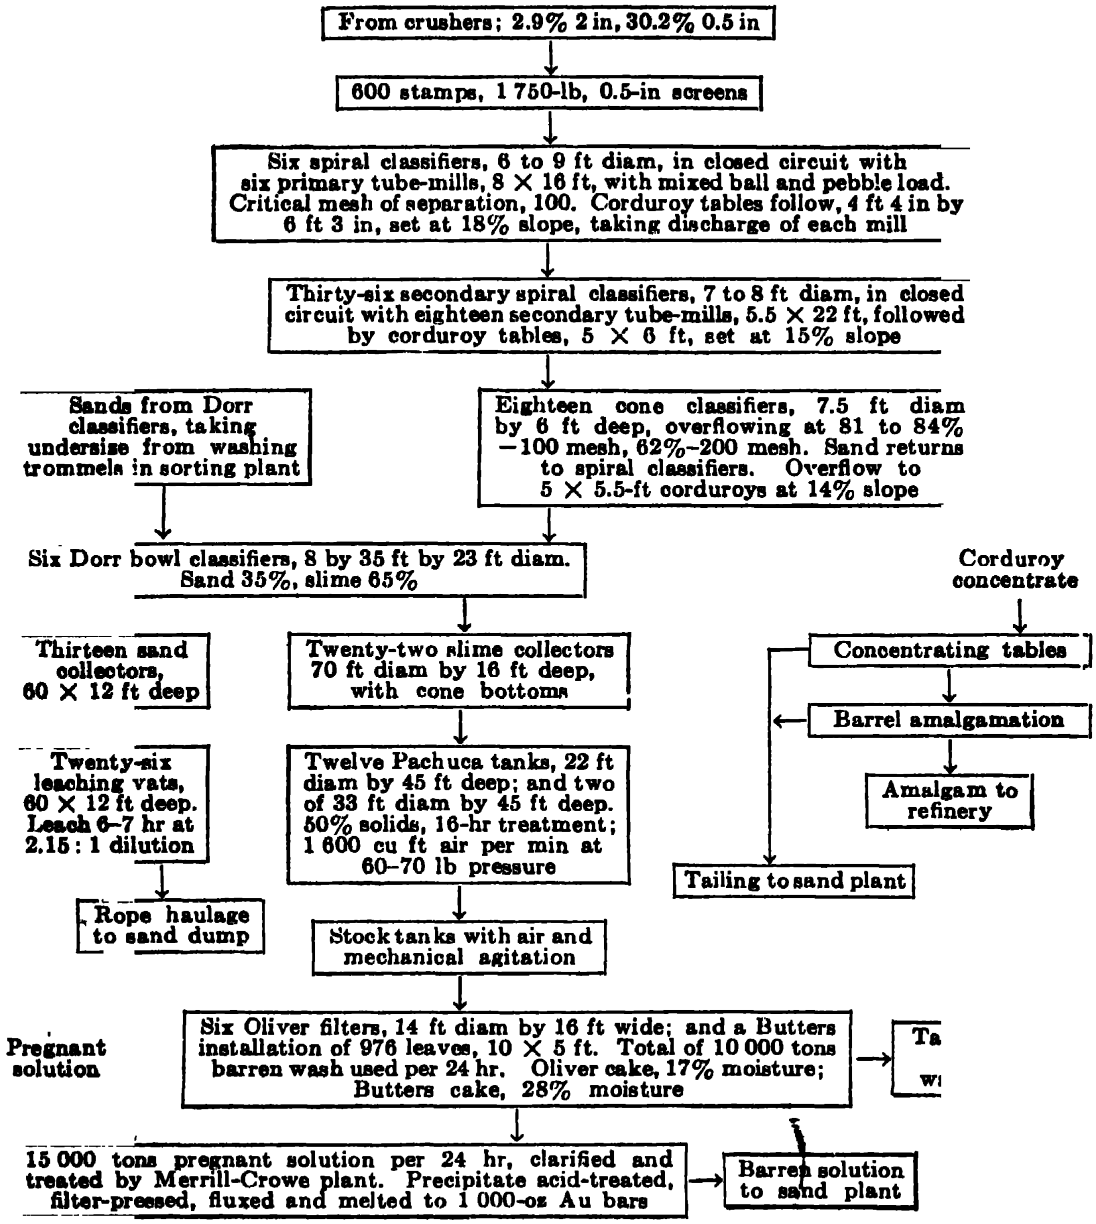
Loretó mill, Pachuca, Mex. 4 200 tons aver daily capacity; the world's largest silver cyaniding plant. Silver ore, Ag probably about 20 oz, Au 0.2 oz per ton. Two-stage grinding with ball-mills, mechanical and air agitation, Butters filtration and cyanide regeneration plant.



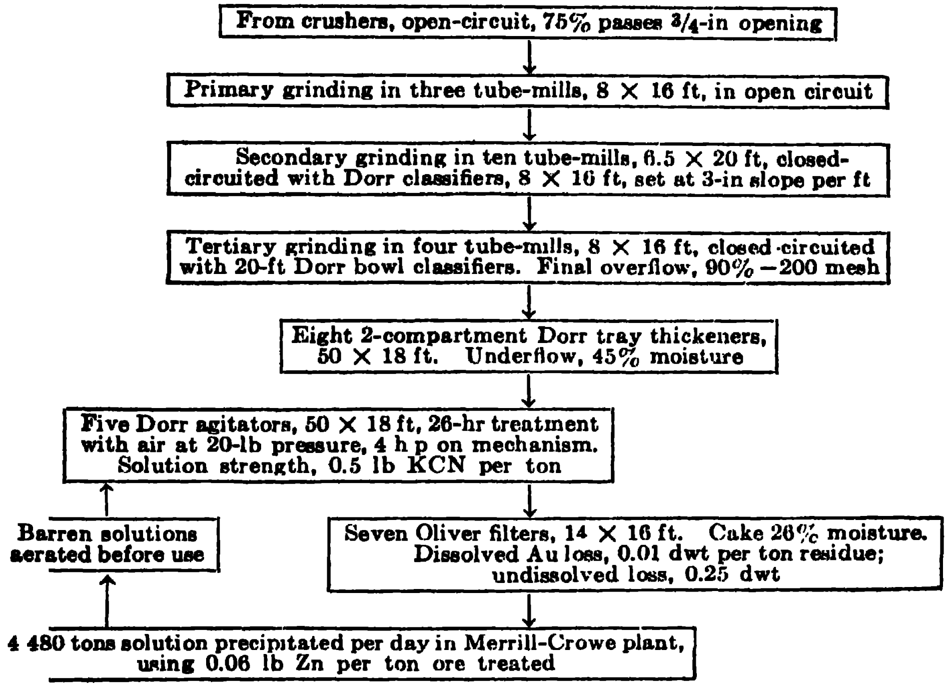
Big Jim mill, Oatman, Ariz. Gold ore, 50 tons per day. All-sliming and counter-current decantation. Hard quartz and calcite ore.



Randfontein Estates, Witwatersrand, So Africa. 12 000 tons per day; largest mill on the Rand. Gold ore, 3.76 dwt per ton. Stamp milling, corduroy concentration, tube-milling with separate sand and slime treatment. Extraction, 95.4%.



East Geduld, Witwatersrand, So Africa. 3 200 tons per day (400 tons rejected by sorting). Gold ore: 7 dwt Au, 0.7 dwt Ag, 3% pyrite. A recent all-sliming plant on East Rand. Tertiary grinding in tube-mills in water. Dorr thickeners and agitators. Extraction, 96%. Total cost of treatment, 60¢ per ton. Cyaniding, 19¢.



16. EXAMPLES OF COSTS

Homestake Mining Co, Lead, So Dak. Treating 1 400 000 tons per year by a fairly simple process of amalgamation and cyanidation. Costs per ton (1929); crushing, 3.8¢; milling, 27.6¢; cyaniding, 18.9¢; total, 50.3¢.

At the South plant (milling only); stamps, 8.9¢; rod-mills, 8.4¢; amalgamating, 1.4¢; tube-mills, 1.4¢; assaying and refining, 1.3¢; superintendence, 1.1¢; miscellaneous, 1.0¢; total 23.5¢ per ton.

Hollinger Gold Mines, Ltd, Ont, Canada. Schistose ore. Aver value, $8.70 (1935). 5 000 tons per day. Total cost, $0.647 per ton milled:

	Cents per ton		Cents per ton
General and superintendence	4.17	Filtration	4.02
Crushing	6.16	Tailings disposal	2.05
Tramming and shoveling	2.42	Precipitation	1.87
Milling (grinding)	15.28	Refining	1.36
Thickening and pumping	2.55	Cyanide and lime	8.50
Agitating and decantation	1.62	Assaying, sampling, testing	2.33
Table concentration	3.40	Heating and lighting	1.84
Sulphide treatment	3.29	Maintenance and alterations	3.88
		Total	64.74

Milling cost is subdivided into: rod-mills, 7.29¢; pebble-mills, 5.98¢; classifiers, 1.07¢; other charges, 0.94¢. Grinding was 2–3% + 48 mesh and 65% − 200 mesh.

Cyanide consumption per ton milled,	0.479 lb.	
CaO " " "	2.11 "	
Lead acetate per ton solution precipitated,	0.0085 "	
Zinc dust " " " "	0.0454 "	

McIntyre Porcupine Mines, Ont, Canada. Quartz, porphyry and schistose ore, 3–15% pyrite. Aver value in 1935, $7.61. 2 400 tons per day. Total cost, $0.698 per ton milled.

Of gold recovered, 76% is made in the unit cells in ball-mill classifying circuit. Costs per ton: crushing and conveying, 10.37¢; flotation, 27.64¢; cyanidation (concentrate treatment, see below), 26.92¢; refining, 2.24¢; assaying, 1.43¢; mill alterations, 1.20¢; total, 69.80¢. Cost of concentrate treatment, from Apl 1, 1935 to Mch 31, 1936, is shown in table.

	Cents per ton		Cents per ton
Tube-milling and classification	4.00	Precipitating	1.37
Agitation	0.94	Reagents	11.50
Thickening and pumping	2.85	Heat and light	0.37
Filtering and clarifying	3.91	Supervision	1.98
		Total	26.92

As ratio of concentration was 9 or 10 to 1, cost of treatment was approx $2.50 per ton concentrate. Consumption of chemicals per ton milled: cyanide, 0.628 lb; lime, 1.106 lb; Zn, 0.084 lb; lead acetate, 0.012 lb.

Pachuca district, Mex (1934). Costs for a 400-ton cyanide mill in this district (Bryan and Kuryla *Trans* AIME, Vol 112, 1924) are shown in table.

Prevailing rate of exchange (1934), 3.60 pesos per U S dollar.

	Pesos per ton	Distribution	Pesos per ton
Crushing and grinding	1.27	Labor	1.38
Cyanidation	1.75	Supplies	2.04
Precipitation and melting	0.30	Power	0.72
Water supply	0.14	Miscellaneous	0.24
General expense	0.92		
	4.38		4.38

Costs on the Rand in 1934 for 3 typical installations, recalculated in cents per ton (Wartenweiler, *Trans* AIME, Vol 112, p 782):

Plant No 1 treats 79 000 tons per month, rejecting 27% as waste and grinding 77% of mill feed through 100 mesh. Plant No 2 treats 208 000 tons, discarding 23%, all mine fines passing direct to tube-mills, and 92% ground through 100 mesh. Plant No 3, East Geduld, all-sliming treats about 100 000 tons per month, rejecting 12.5% as waste. Grinding to 90% – 200 mesh is done in 3 stages of tube-milling (see table for details).

	Coarse crushing and stamp milling		Fine crushing and tube-milling, East Geduld
	Plant No 1	Plant No 2	
Ore transport from shaft to plant	0.96	4 56	....
Crushing and sorting	12.22	10.20	13.0
Stamp milling	13.56	10.58	....
Tube-milling	15.48	21.94	27.0
Cyaniding	21.86	18.58	19.0
	64 08	65.86	59 0

Big Jim mill, Oatman, Ariz (U S Bur Mines, *Inf Circ* No 6824, Feb, 1935). Cost per ton milled in 1933: assaying and supervision, $0.197; crushing, $0.104; grinding, $0.686; cyaniding, $0.802; refining and marketing, $0.036; total milling cost, $1.825. Rental of mill, $0.612. Total, $2.437.

East Mindanao mill, Philippine Is (*E & M Jour*, May, 1937). Cost in pesos per ton milled, Oct, 1936: crushing and washing, 0.252; grinding and classification, 0.188; thickening, 0.044; agitation, 0.032; filtration, 0.069; clarification and precipitation, 0.069; refining, 0.107; water supply, 0.008; chemicals and reagents, 0.467; sampling and assaying, 0.166; superintendence, 0.637; miscellaneous, 0.071; total, 2.110 pesos (par value of peso, 50¢ U S cur).

17. CYANIDE POISONING

Causes and symptoms. Cyanide poisoning may result from taking cyanides internally or from inhaling HCN gas. CHRONIC form of poisoning, due to long exposure to the fumes, is manifested by disturbance of vision, pain in the forehead and in region of the heart, palpitation, difficult respiration, vertigo, coughing, and attacks of suffocation. Symptoms of ACUTE poisoning, as when taken internally, are, besides the above, constriction of throat or general contraction of muscles, and dilated pupils. Face becomes pale and bloated, nails blue, sometimes frothing at mouth. Convulsions occur, followed by coma, and death ensues from asphyxia.

Treatment. If poisoning is caused by breathing fumes, and the case is not severe, relief may be afforded by inhaling ammonia fumes and remaining in fresh air. If gas has overcome the patient, a number of hypodermic injections of 2 or 3% solution of H_2O_2 may be made, or a 10% solution of it given internally.

Artificial respiration may be resorted to; or, if available, O alone may be administered. Hypodermics of ether, strychnine or whisky are given to prevent collapse. If the cyanide has been swallowed, an efficacious antidote is $Fe(OH)_2$, which must be freshly prepared. To have this remedy ready for prompt use (as cyanide's effect is very rapid, there must be no delay), there should be kept prepared at cyanide mills the following measured quantities: a 25% solution of $FeSO_4$, a 5% solution of NaOH or KOH, and phials containing a gm of powdered MgO. These 3 ingredients are kept in well-stoppered bottles, separately. To use them, 30 cc of each of the 2 solutions are mixed with 2 gm MgO, the whole being diluted with a glassful of water and given immediately. After being retained for a few moments, the stomach should be pumped out or vomiting induced. In absence of this antidote, the stomach may be washed with a 0.3% solution of KNO_3, or a dilute solution of $Co(NO_3)_2$.

Prevention. Cyanide poisoning can be largely prevented by providing a safe supply of drinking water in the works and good ventilation.

Workmen in the melting and refining room must not expose themselves to the fumes; poisoning may be caused by HCN, and H, alone, often given off in treating precipitate with acid, will not support life. When As is present in the precipitate, AsH_3 may be produced, which is quite as poisonous as HCN. Workmen must not enter tanks that have been left closed or covered with cyanide solution, as decomposition of cyanide may give off enough gas to cause poisoning. A slight poisoning of the skin is often caused when the hands have been cut or scratched; avoided by wearing gloves in cleaning Zn boxes or handling precipitate.

SECTION 34

PREPARATION AND STORAGE OF ANTHRACITE COAL

BY

PAUL STERLING

MECHANICAL ENGINEER, LEHIGH VALLEY COAL CO

PREPARATION AND STORAGE OF ANTHRACITE COAL

1. MARKET SIZES OF ANTHRACITE

Classification. Run-of-mine coal is classified, during preparation for the market, into: lump, steamboat, broken, egg, stove, chestnut (or nut), pea, buckwheat (or buck), rice, barley, buckwheat No 4 and buckwheat No 5. The large number of sizes is due to the fact that anthracite burns best when nearly of uniform size, thus permitting easy passage of air through the voids.

Use of market sizes is about as follows: lump, for locomotives; steamboat, for blast furnace and forge; broken for domestic furnace and gas; egg, stove and nut, for domestic furnace and range; pea, for domestic furnace and range, and steam boiler; buckwheat and rice for steam boiler and domestic stoker; barley, for steam boiler. Buckwheat No 4 and No 5 are used in mechanical stoker plants, to replace rice and barley and pulverized fuel.

Table 1. Market Sizes of Anthracite Coal

(Screen openings, in inches, over and through which each size is made)

Size of coal	Punched plate, round hole: Over	Through
Lump	6 1/2	
Steamboat	4 1/2	6 1/2
Broken	3 1/4	4 1/2
Egg	2 3/8	3 1/4
Stove	1 9/16	2 3/8
Chestnut	3/4	1 9/16
Pea	9/16	3/4
Buckwheat	5/16	9/16
Rice	3/16	5/16
Barley	3/32	3/16
Buckwheat No 4	3/64	3/32
Buckwheat No 5	1/32	3/64

"Prepared sizes" is the trade name for: broken, egg, stove and chestnut, which constitute about 60% of the total production. General demand for lump and steamboat has ceased, these sizes being now "broken down" into broken coal and smaller.

"Steam sizes" is the trade name for: pea, buck, rice, barley, and buckwheat No 4 and 5. These are the degradation products, resulting from mining and handling a brittle or laminated material, and are not especially desirable.

Run-of-mine is the unsized mixture of coal and impurities, as dumped into the beaker. According to method of loading cars in the mines, it may be divided into:

Class 1. Hand loaded (as in flat workings), containing lumps up to about 150 lb and relatively free from impurities in coarse lumps.

Class 2. Chute or steam-shovel loaded (as in steeply pitching seams or in strippings), containing lumps up to about 2 000 lb, and frequently wet and dirty.

Impurities in run-of-mine vary with character of seam, and with method of loading. During hand loading they may be partly removed, but in chute loading the entire seam, including all impurities and foreign matter, as clay, top and bottom rock, and broken timbers, must be loaded into the car. Impurities in Class 1 usually range from about 7 to 25%; in Class 2, 10 to 55%.

Table 1a. Run-of-mine Coal: Approximate Per Cent of Sizes from Flat and Pitch Workings, and Per Cent of Refuse in Each Size

Size	Run-of-mine, % of size		Percentage of refuse in each size			
	Flat	Pitch	Northern Field	East Middle	West Middle	Southern
Lump and steamboat	12	6	16	38	30	29
Broken	12	6	20	38	30	39
Egg	15	13	18	38	32	34
Stove	14	13	17	28	20	34
Nut	25	20	17	23	16	33
Pea	6	10	12	18	12	32
Buckwheat	7	18	12	18	12	36
Rice	5	7	....	....	....	32
Barley	3	4	....	....	....	33
Dirt	1	3	....	....	....	....

Standard of preparation designates the percentage of over or under size and of impurities allowed in each size of coal (Table 2). BONE (mixed coal and slate) is defined as containing between 40 and 65% carbon.

Mine car yield is a local term, usually indicating number of long tons of marketable coal shipped from the mines for every 100 cu ft of mine car capacity dumped. This measurement, for hand-loaded cars, is somewhat misleading. For chute loading, the car capacity is figured at its water level; to this, for hand loading, is added a volume equal to the horizontal area times 6 in. The added height of 6 in, above top of car, is called TOPPING. Should the topping exceed required 6 in, no account of excess is made in estimating mine car yield, nor is it practicable to do so. The exact method would be to figure mine car yield on the weight of loaded mine car. The present method admits a fair comparison between mines operating under similar conditions. A "yield" below a previously established record is at once detected, the trouble is investigated, and, if possible, corrected.

Table 2. Standards of Preparation

(Percentage of impurities and of over and under size allowed in each size)

Size of coal	Each size may contain			
	% of		% of next larger	% of next smaller
	Slate	Bone*		
Broken	1 1/2	2	....	15
Egg	1 1/2	2	5	15

Rice	12 ash	....	5	20
Barley	12 ash	......	5	20

* If slate is entirely removed, the percentage of bone may equal total slate and bone.

Shipments of prepared coal from a mine, per 100 cu ft of car capac (not including steam sizes), may vary from 0.75 ton, with very dirty run-of-mine, chute loaded, to 3.50 ton in clean seams, hand loaded.

Loss in prepared sizes underground depends upon: varying conditions in the coal seams; kind of explosives used; methods of loading (hand *vs* chute or steam shovel); shocks in running over poorly constructed track; bumping of cars during gravity runs or mechanical haulage; frequency of dumping. Loss in the breaker is due to: poorly constructed dumps; high drops of coal; long running chutes with abrupt turns; poor types of rolls and over-crowding of rolls; breakage in or on mechanical cleaners, scraping or belt conveyers and bucket elevators; drawing coal under pressure from deep pockets. None of these losses can be entirely eliminated, but they can be minimized by careful management and supervision over mining and transportation methods, and by painstaking design and construction of the breaker.

Breaker products. Table 3 gives average percentage of each size in run-of-mine, for Classes 1 and 2, percentage of rock or impurities, and value of pure coal in the mine

cars, with prices at mines, as of 1938, assuming 1 000 tons of material delivered to breaker.

Table 4 gives percentage of shipments of each size made by preparation of the 1 000 tons of run-of-mine in Table 3, and the average and total amounts realized, assuming each size to contain the allowable percentage of impurities, as in Table 2. Each size in Table 4 contains no under or over size, and if the maximum amounts allowed (Table 2) were put into the highest-priced sizes, the average price per ton would be increased. In practice it is impossible to screen coal without under or over size. Hence, tests are made, and the screen mesh increased or diminished, so that the greatest allowable percentages of over or under size are carried in the highest-priced sizes; or the screen mesh is adjusted to produce maximum amount of sizes required to supply the market. Usually all the barley coal, and sometimes part of the rice, is required for the colliery boiler fuel, in which case the aver price per ton does not include these sizes. Fuel burned at the colliery approximates 5 to 10% of total production. In Table 4, Class 2 shows a loss of $1 530.48,

compared with Class 1, due chiefly to difference in amount of impurities in the run-of-mine (Table 3). There would also be a further financial loss due to increased preparation cost in handling and removing the higher percentage of impurities.

Breaking down large sizes. If the lump, steamboat, broken, and egg coal, from 1 000 tons of Class 1, run-of-mine, Table 4, were broken down to stove, nut, and the steam sizes, the approximate shipments in tons and amount realized would be as shown in Table 5. The loss, $50.84, is attributable to the breakage of coal into the smaller sizes.

Table 5. Results of Breaking Down Large to Smaller Sizes of Coal

The 19.3% of pea and smaller sizes is due to use of inefficient rolls. With slow-speed rolls, having sharp teeth, this percentage should reduce to approx 12%. Breaking-down losses may be partly offset by the additional percentage of impurities which the broken-down coal is allowed to carry; in Table 5 the 171.2 tons of stove may be increased by approximately 13 tons, the 95.4 tons of nut by 9.5 tons, 16 tons of pea by 2.4 tons.

Economic principle in preparation of coal is to make large shipments in prepared sizes of highest priced coal, each size containing the maximum allowable percentage of impurities. Varying percentages of the different sizes in the run-of-mine, and the impossibility of adjusting crusher and re-breaking rolls to produce, at will, a fixed proportion of any one of the prepared or steam sizes, prevent accurate prearrangement of shipments. Hence, the problem of economic preparation must be worked out in detail for each particular breaker, by frequent tests of run-of-mine and prepared coal, and the machinery must be adjusted to give results as near the ideal as possible, and consistent with market demands.

2. GENERAL COMPARISON OF METHODS OF PREPARATION

Classification: *A*, dry preparation; *B*, dry and wet preparation; *C*, wet preparation. The method to be adopted depends on the quality of coal as mined. Fig 1, 2, 3, 3*a* and 3*b* (Art 4–6) show outline flow-sheets of these three methods.

Class A is employed when the coal seams are dry, or are practically free from impurities, or when the benches of slate in them cleave free from the coal and may be removed during hand loading, the run-of-mine containing generally not over 7 or 8% of rock or slate, which may be removed by hand-picking or by dry mechanical separators. Class *A* offers the ideal breaker. Its advantages are: low cost of construction, operation, and maintenance. Shipments of dry coal are preferred by the trade, being free from risk of freezing in cars and consequent difficulties in unloading. Due to exhaustion of thick, clean veins, Class *A* is nearly obsolete.

Class B is employed when run-of-mine contains a high percentage of impurities, including rock, slate, and bone. Though this percentage may be as high as 55%, the run-of-mine must contain large pieces of pure coal, to be handled as a separate product, as in Class *A*. The remainder is sized and cleaned by wet methods to improve its appearance and to remove impurities. Class *B* possesses to some extent the advantages of dry-coal shipments, but is higher in first cost, operation, and maintenance than Class *A* or *C*. This class is now practically obsolete; it is replaced by Class *C*.

Class C is adopted when run-of-mine is high in impurities and is discolored, as is the case near an outcrop; or when entire product comes from wet, dirty seams, requiring a thorough washing to remove dirt and discoloration; or when character of the seam is such that the run-of-mine contains no large lumps. Class *C* permits no dry shipments and is higher in first cost, operation, and maintenance than Class *A*.

General design. Referring to the flow-sheet diagrams. while designers may vary the combinations of machinery, using conveyers and elevators to transfer the product from one point to another, one set of rolls to break each size of coal to the next smaller, gravity picking chutes in place of movable picking tables, different kinds of mechanical cleaners to remove impurities, and stationary bars or revolving screens in place of shaking screens, yet the general plans of preparation are identical, and the diagrams are standard for their respective classes.

Ideal breaker (Fig 1) includes the following features: dump direct from mine cars into the breaker receiving hopper; automatic feeders from hopper to breaker, and feeders to all sizing and crushing machinery; sufficient height, so that all coal may gravitate from receiving hopper to loading gates; short chutes with automatic devices to control flow of coal; minimum breakage during preparation and in loading from storage pockets; mechanical cleaners for all sizes of coal, when practicable, and shipment of dry coal; adequate outside facilities to load box and gondola RR cars quickly and with minimum breakage; sufficient empty and loaded car standing track to hold a full day's output, tracks being graded to operate by gravity or mechanical haulage.

3. GENERAL METHOD OF PREPARATION

Outline is the same for the 3 classes of breaker. Coal is dumped into receiving hopper and fed automatically, or by a hand-operated gate, on to the dump screens at the top ("head") of breaker. Lump, steamboat, and broken are sized from the run-of-mine (always the first 2 sizes, and often the broken also) and are cleaned of impurities by hand-picking. This cleaned coal is the "pure-coal" product, and is handled separately, except in a Class *C* breaker. It requires no additional attention except to be broken down, when necessary, sized and delivered to loading pockets. The prepared and steam sizes from run-of-mine (including the broken coal, when not handled with the pure coal) are

called "mud-screen product." This gravitates from dump screens to sizing mud screens, from which each size flows to its respective mechanical cleaner and then runs to storage pockets. In Class *A*, the pure and mud-screen coal are mixed and go to same pocket. In Class *B*, these sizes go to separate pockets, when dry coal is desired or practicable; otherwise they are washed together and mixed. In Class *C*, the sizes are always mixed.

Breaker refuse, of slate, bone, or rock, as removed by hand or mechanical cleaners in all classes of breakers, is conveyed by gravity or otherwise to a central point for final disposition, for which there are two general methods: (*a*) Refuse is returned into the mines to fill openings left by extraction of coal. This, called SILTING, involves crushing (in a rock breaker) the large pieces of refuse, from broken coal and larger sizes, to about egg size. This material, with all other breaker refuse, is run through a pulverizer, reducing the product to 0.5 to 0.75 in, and hydraulicking it into the mine through pipes (Sec 10). (*b*) Refuse is deposited on the surface in BANKS, by chain or belt conveyer, or by dump cars, or by hydraulicking all or part of it in open wooden troughs.

Silting should be given preference, because it adds to stability of the remaining mine pillars and helps to support the roof. When surface disposition of refuse is necessary, the hydraulic method is best, when topography permits, and there is plenty of water. When hydraulicking is not practicable, the conveying system is used, if dumping ground adjacent to breaker is available. Banks can be carried to height of 100 ft or more, and extended in length by added horiz conveying lines or use of sheet-iron chutes around top of bank. To eliminate trouble from large pieces in conveying lines, coarse refuse is crushed to about egg size. When breaker is not close to refuse bank, dump cars are advisable, as coarse refuse can then be handled without breaking.

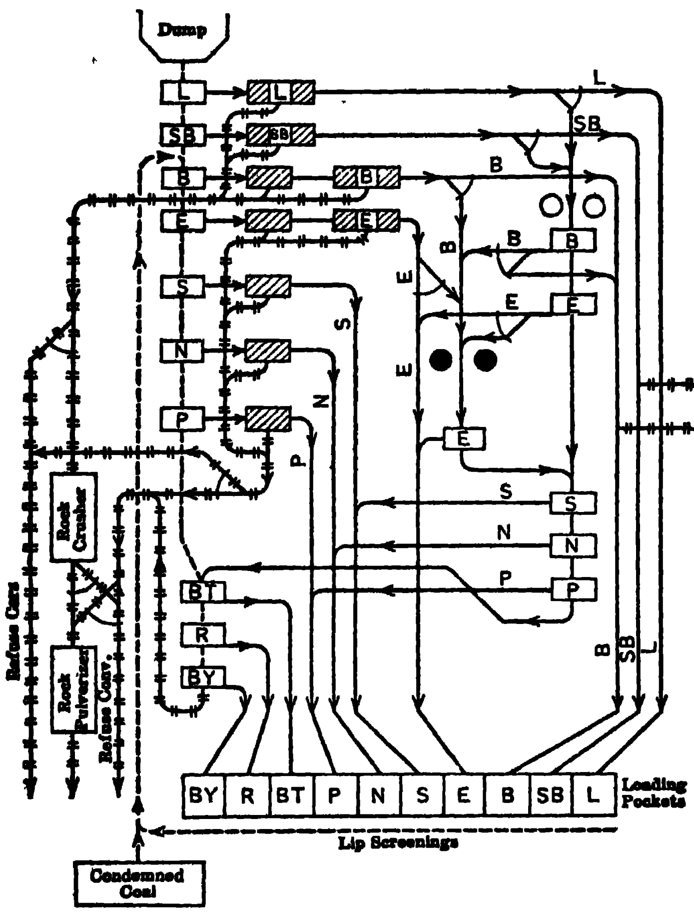

Fig 1. Flow-Sheet of Dry Preparation

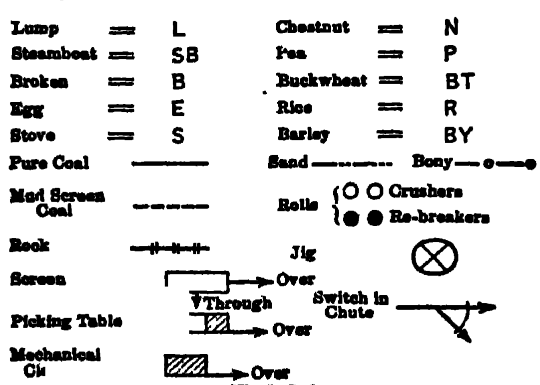

Key to Fig 1, 2, 3

Fig 1. Flow-sheet of Dry Preparation

4. CLASS A BREAKER

Details of preparation (see Fig 1). Shipment of all sizes of coal is provided for, with arrangements to break down any size larger than stove into the next smaller size, or all sizes into stove, nut, and steam sizes, in order to supply varying market demands.

Run-of-mine is elevated to a receiving hopper at the head of the breaker, from which it is fed, mechanically or by hand, over a "bank" of sizing screens. Top screen removes

lump size, the remainder going through to the second screen, which removes steamboat, and the third removes broken. Material passing through the broken-coal screen is the MUD-SCREEN PRODUCT, and is sized into egg, stove, nut, and steam sizes. Sized lump, steamboat, and broken gravitate to their respective picking tables (either moving or stationary), are inspected, and the pure rock, slate, or other impurities are removed by hand to a refuse or rock chute. Pieces of rock to which coal adheres are placed on special tables, where the coal is chipped loose by hand and returned to its table. PURE-COAL PRODUCT, cleaned coal from picking tables, may go direct to its pocket; or, when there is no demand for lump, it is broken by "crusher" rolls to broken and smaller. When there is no sale for broken size, the rolls are adjusted to break it, as well as the lump, into egg and smaller. The pure-coal product from the rolls flows to a bank of 3 screens, sizing broken and egg coal. This broken coal may go direct to its pocket or to the RE-BREAKER ROLLS, which may be adjusted to make either egg or stove and smaller. The pure broken coal from crusher rolls may be mixed with the broken from picking table and gravitate with it to its pocket, or the product is divided, part going to the re-breaker rolls and the remainder to its pocket, or the entire product may go to the re-breaker rolls The pure egg coal may go direct to its pocket or to the re-breaker rolls, or may be divided in the same manner as the broken. Pure-coal product from re-breaker rolls flows to a broken-coal screen, the broken going to its pocket, while the undersize mixes with the product falling through the egg screen, set above the re-breaker rolls, and the combined material is delivered on a bank of screens arranged to size pure egg, stove, nut, and pea coal. MUD-SCREEN PRODUCTS, egg, stove, nut, and pea (the first 3 invariably and the pea usually), contain impurities in excess of that stated in Table 3, which must be partly removed, to keep within the allowable limit for marketable coal. Each size gravitates from its sizing screen to a mechanical cleaner or separator, which automatically removes impurities, the coal flowing to its pocket and the refuse to a point for disposal. Occasionally the mud-screen buckwheat requires cleaning, in which case it is handled in a similar manner; when such cleaning is unnecessary, the mud-screen buckwheat, rice, and barley are mixed with the corresponding pure-coal sizes and delivered to the buckwheat, rice, and barley screens, where each size is separated and delivered to its pocket, while the fine material through the barley screen goes with the refuse. If it is desired to make buckwheat No 4, an additional screen is installed. While loading into cars for shipment, the fine dust and screenings made during preparation are removed by passing the coal over punched steel plates or woven-wire LIP SCREENS. The lip-screen product is elevated to the sizing screens to be re-sized and returned to the pockets. After loading, the coal is inspected for size and purity, in conformity with Table 2. If it fails in this inspection, it is condemned, unloaded, and elevated into the breaker and re-treated.

Design in Fig 1 contemplates an ideal breaker. For 1 500 to 1 800 tons daily capacity, total height above loading track would not exceed 115 ft. Coal passes through breaker by gravity, eliminating conveyers and elevators. One conveyer only is required to handle lip screenings and condemned coal. Roll tests show highest percentage of prepared sizes when breaking only from one size to next smaller; that is, steamboat to broken, broken to egg, etc. The breaker would then require 4 sets of rolls, thus increasing the height, unless re-broken material is re-elevated, but the increase in prepared sizes would not warrant this installation. In practice, the steamboat and broken screens, immediately below crusher and re-breaker rolls, are omitted; because a sufficient percentage of steamboat is usually made from the picking table, in proportion to other sizes shipped and required for market, and the crusher rolls will break lump or steamboat direct into broken without oversize of steamboat, which would condemn the broken. Sufficient egg can be made above the re-breaker rolls, and any oversize will be carried by the stove. Mixing the pure and mud-screen prepared and smaller sizes is advantageous. When pure coal from the tables is broken down, each size usually carries less impurity than stated in Table 2; hence, mud-screen coal from the mechanical cleaners may contain excess of impurities without causing the resulting mixture of pure and mud-screen coal to exceed the allowable percentage.

5. CLASS B BREAKER

Details of preparation (Fig 2). This type provides for separate shipment of pure and mud-screen coal of all sizes, except buckwheat, rice, and barley. General method of preparation is practically the same as for Class *A*, except that it is not necessary to remove all impurities, but only that portion which would condemn the finished product. If run-of-mine is Class 1, one mechanical cleaner on each mud-screen size will usually suffice. If the product is Class 2 (high in impurities) a preliminary mechanical cleaner is installed for each size of mud screen coal, to remove part of the impurities. This partially cleaned

product gravitates to a second mechanical cleaner for final preparation, before going to pocket. Ordinary mechanical cleaners (except the jig) may be adjusted to remove about 50% of impurities from any one prepared size, without constant attention; and where used as a preliminary cleaner it is thus adjusted. The remainder is handled by a second cleaner under supervision of an attendant, who adjusts it to suit the varying impurities, so that the coal going to pocket will pass inspection. Broken coal is usually handled with the pure coal for Class 1 run-of-mine, and with the mud-screen coal for Class 2. If average run-of-mine contains lumps larger than 2 cu ft, this lump coal is usually broken down in a separate pair of rolls, another pair being used to break the steamboat. This prevents the

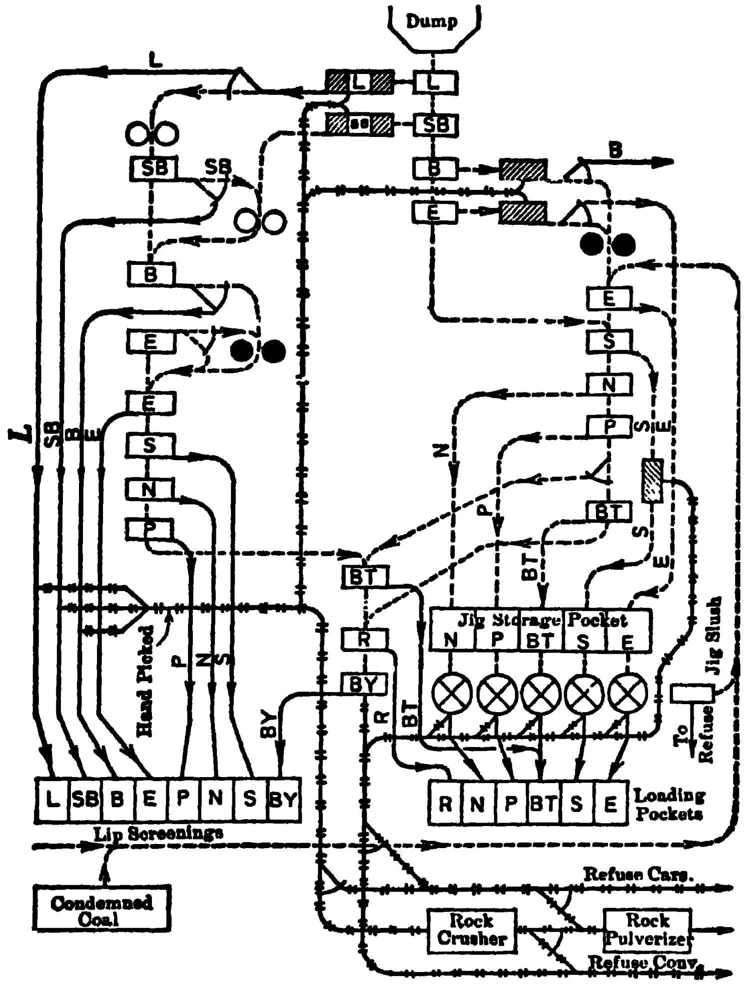

Fig 2. Flow-sheet of Dry and Wet Preparation

large degradation into steam sizes resulting from *crushing* (not breaking) large lumps direct into broken size.

When dry coal is not desired, nor practicable, the pure and mud-screen coals are mixed after cleaning. The mode of cleaning mud-screen coal is then similar to that of Class *A* breaker, respecting percentage of impurities in final mud-screen product, before mixing with pure coal and the number of mechanical cleaners for each size is entirely dependent on quality of run-of-mine.

6. CLASS C BREAKER

Details of preparation (Fig 3). This type provides for wet shipments of all sizes smaller than broken, since it is rarely practicable to produce the 3 larger sizes with arrangements to break down egg into stove and smaller. Run-of-mine is elevated to a hopper at head of breaker, from which it is fed mechanically or by hand into a bank of 4 screens, which size lump, steamboat, broken, and egg. Lump and steamboat are "skinned" on picking tables; that is, only a part of the rock is removed. After being broken down these sizes are mixed with the mud-screen coal and prepared with it. Pure lump and

steamboat are crushed to broken in rolls and flow to 2 screens, which size broken and egg. Broken coal gravitates to re-breaker rolls, and is reduced to egg or stove and smaller sizes, going thence to a central storage pocket. Egg coal gravitates direct to this pocket, or is mixed with the broken going to re-breaker rolls. Mud-screen broken and egg are usually run over preliminary mechanical cleaners, from which they are handled like the pure broken and egg, and mixed in the central storage pocket. Unsized mixture of pure and mud-screen coal is fed mechanically to a bank of screens, making all sizes, each gravitating to its respective JIG STORAGE pocket. This pocket is a reservoir for the jigs, accumulating coal during rush periods; it is necessary because jigs are operated at a fixed capacity. The jig removes enough impurity to make marketable coal, and from it each size flows

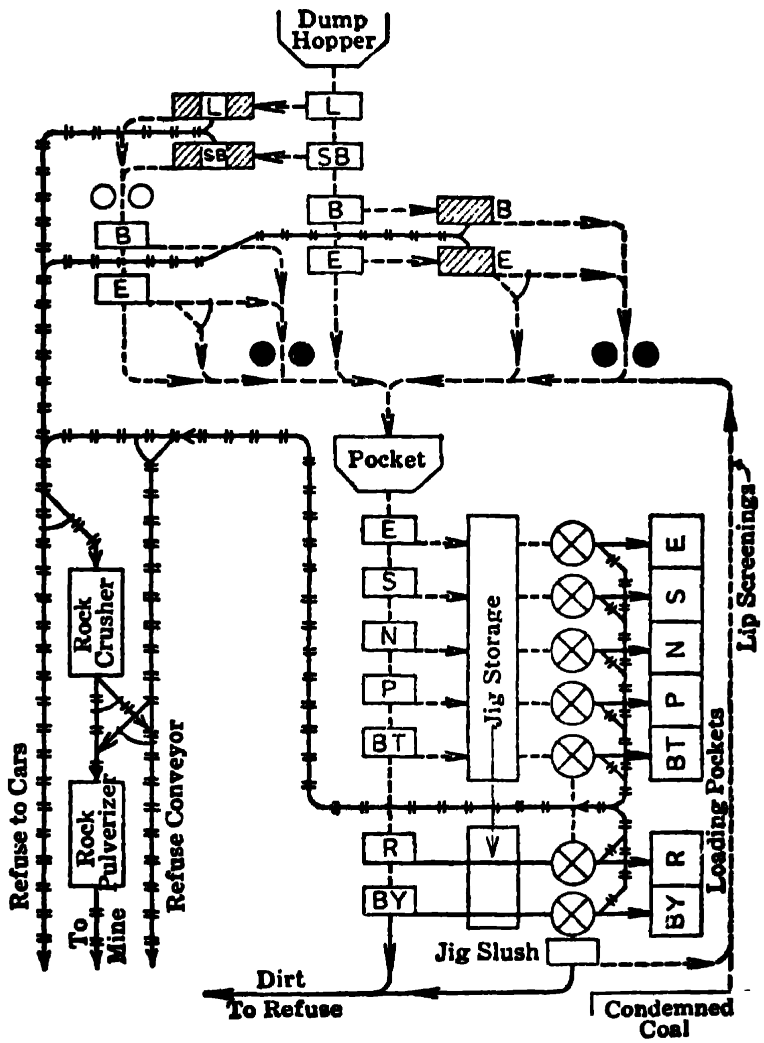

Fig 3. *Flow-sheet of Wet Preparation with Jigs*

to loading pockets. When the jig is emptied, the hutch product, containing nut coal and smaller, is washed over a JIG-SLUSH SCREEN, of a size to remove only the coal smaller than barley, oversize being re-elevated to the central storage pocket. Sized coal is loaded and inspected as in Class *A*; lip screenings and condemned coal are re-elevated with the jig-slush-screen product.

Percentage of bone coal in run-of-mine is usually small, and sized products will carry all the bone in a seam, if the rock is eliminated (Table 2). This treatment of bone is recommended above all others. When the bone percentage exceeds total allowable bone and slate, bone is handled separately, and the preparation here is identical with Class *A* or *B* breakers. A three-part separation is made of run-of-mine on picking tables: coal, bone and impurities. Re-breaker rolls reduce this material into egg or stove and smaller, the broken-down product being mixed with pure coal sizes in the proportions which each will carry. Prepared-coal mechanical cleaners also make a three-part separation; bone from egg and stove is broken into nut and smaller, or egg, stove, and nut into

pea and smaller; then screened and mixed with sized coal going to pockets. Modern methods usually disregard bone coal, and make no special provision to handle it, except to consider very poor or heavy bone as an impurity and hand pick it into refuse from the large sizes.

Flat coal, characteristic of certain seams, as compared with the more usual cubical pieces, when occurring in sufficient quantity in mud-screen prepared sizes, is removed by a flat-coal picker before going to mechanical cleaner, thus avoiding difficulty in removing impurities from a mixture of cubical and flat pieces. Flat coal flows to its own cleaner, and the clean product is mixed with cubical coal before going to pockets. The quantity of flat coal is often sufficient to spoil the appearance of prepared sizes, when loaded. If so, part of the flat coal is removed and broken smaller.

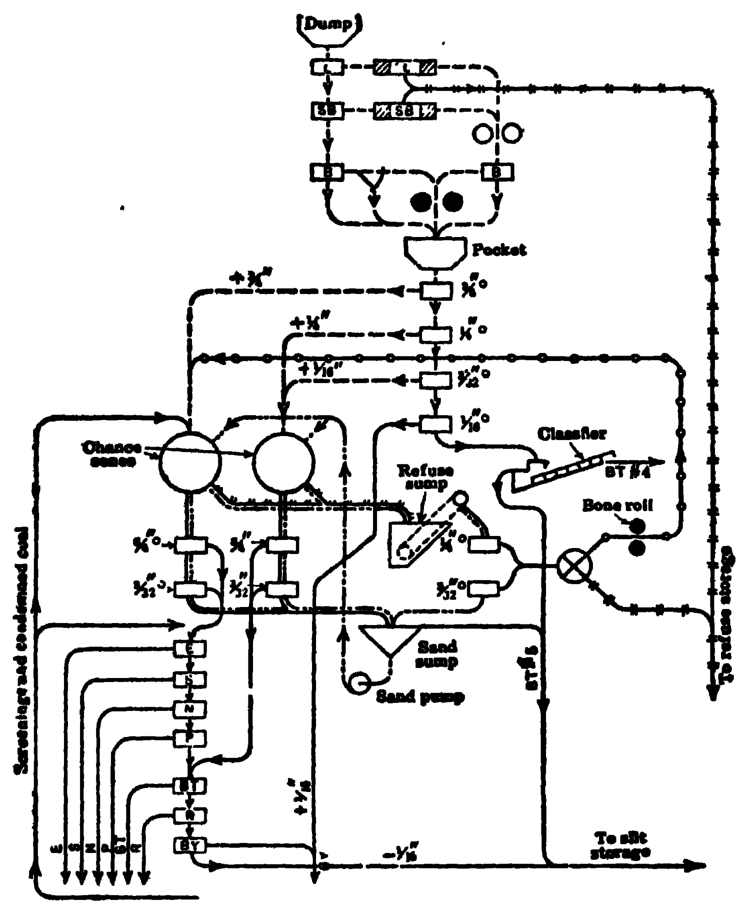

Fig 3a. Flow-sheet of Chance Preparation

Chance system (Fig 3a), for wet shipments of all sizes. Preliminary preparation above the storage pocket is the same as for Class *C* breaker. The unsized mixture is fed on a bank of 4 shakers, with $^3/_4$, $^1/_4$, $^3/_{32}$ and $^1/_{16}$-in round mesh; the particular object being to remove the minus $^3/_{32}$ in and silt, which when mixed with the sand and water in the cone would lower the gravity and cause loss of coal. Experience shows that 4 shakers are necessary for sufficient splitting of the product to permit thorough washing for removing the minus $^3/_{32}$ in.

The $^1/_{16}$-in shaker recovers the barley sized out of the mixture, and returns it to the barley passing through the cone. Two cones are required, 1 for the plus $^5/_{16}$ in and 1 for the minus $^5/_{16}$ in to plus $^3/_{32}$ in. A sp gr of about 1.75 is maintained in each; refuse of more than 1.75 sp gr sinks, while coal floats out through an overflow to a bank of 2 de-sanding shakers, of $^3/_4$ and $^3/_{32}$-in mesh respectively. The product is thoroughly washed, all flowing to the main sizing shakers, where all sizes, egg to buckwheat inclusive, are made and stored in pockets or loaded direct into cars. The minus $^3/_{32}$-in sand and silt through the de-sanding shakers flows to a sand sump, from which it is pumped back to the cones. The refuse that sinks in the cones is trapped out under hydraulic seal into a refuse sump, whence it is removed by a conveyer and delivered onto 2 de-sanding shakers with $^1/_4$ and $^3/_{32}$-in round mesh. Sand is washed out and flows to the sand sump. The plus $^1/_4$-in and larger refuse contains some coal of a sp gr greater than 1.75; also bone and half-and-half pieces. This should be treated mechanically, jigs being used at present. The minus $^3/_{32}$-in which has not passed through the cones may be partly cleaned by classifiers, as the very fines are usually high in ash and if removed produce a fairly low-ash silt (15 – 18%). Depending on character of the run-of-mine, fine-coal jigs, tables, or (preferably) Rheolaveur fine-coal plants (see below) may be used.

The sand sump is arranged as a settling tank or an upward current classifier; any fine silt in it will be carried to the overflow and run to a settling tank or basin, so that clear water may be drained off and reused.

The modern Chance breaker uses a circular cone for plus $^5/_{16}$-in material and a rectangular cone for minus $^5/_{16}$-in to $^3/_{32}$-in material. All sizes plus $^5/_{16}$-in from the first

cone are de-sanded over $^5/_{16}$-in mesh, undersize flowing to the second or minus $^5/_{16}$-in cone. A sp gr of about 1.75 is maintained in each cone, with a mixture of water and sand. The coal overflows from each cone and the minus 1.75 material is trapped out at bottom of each cone, the material de-sanded and refuse going to the refuse disposal plant, and the mixture of sand and water going to the sand sump, to be returned to No 1 cone. Sizes smaller than $^3/_{32}$-in are treated separately, either on tables or in a hydrotator. When this is done, the material is sized out before entering the cone. Some breakers of 8 000 ton per day output use a Chance system having individual cones for each size. This has the advantage that each cleaned size can be broken down to next smaller size, when required, and re-treated in the following cone, if necessary.

Rheolaveur process (Fig 3*b*), is for wet shipments of all sizes. Preliminary preparation above the storage pocket is the same as for the Chance process, Class *C*. The unsized mixture is fed into the upper end of a large-coal Rheolaveur sealed level washing trough, in which is a stream of running water, the material bedding itself according to its sp gr. Usually 2 mechanical discharge Rheo boxes are attached to this trough, the first or upper box traps refuse, which is elevated to a sealed level re-washing trough. The second Rheo box traps a middle or regulating product which is returned and mixed

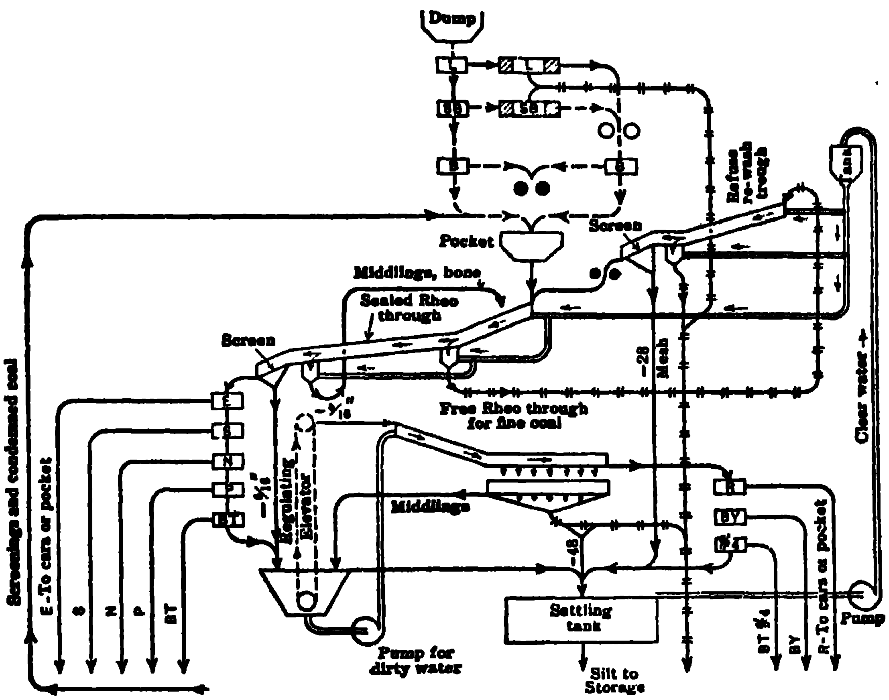

Fig 3*b*. Flow-sheet of Rheolaveur Preparation

with the feed. By varying the regulating product, the coal discharge at end of trough may be controlled.

The re-washing trough is fitted with 1 discharge Rheo box, which may be regulated to trap only pure slate, the mixture gravitating direct to refuse storage. The product discharged from the re-washing trough may be broken down and mixed with the run-of-mine feed to be retreated in the large-coal trough; or it may go to the main sizing shakers, to mix with the coal discharge from the large-coal trough, to be sized with it and be run to the pocket or cars. The large-coal trough cleans all sizes from plus $^5/_{16}$ to 3.5-in, the minus $^5/_{16}$-in being then treated in a "fine-coal free discharge plant," which cleans the fine sizes down to 50 mesh. All minus $^5/_{16}$-in material is collected in a regulating tank of about 50 tons capac, and elevated to the fine-coal plant, consisting of 1 or more troughs placed one over the other. A series of Rheo discharge boxes are placed in the bottom of each trough. A 3-part separation is made of clean coal, middlings or regulating product, and refuse. The coal is sized and delivered to pocket or cars; refuse gravitates to storage; regulating product returns to regulating tank, mixes with the feed, is elevated and re-treated. Controlling the regulating product by the valves on the Rheo boxes, quality of the cleaned coal may be varied at will. Sizes smaller than commercial fines are de-watered and stocked for shipment. (For further details, see Art 11.)

Menzies Cone Separator, Class C (Fig 3c). The principle of operation is a variable veloc of an upward current of water through a stratified mobile mass of coal and slate, within a conical separator.

Run-of-mine material, egg and smaller, enters top of cone and passes downward. In descending toward bottom of cone, the coal is washed upward over the top of cone into

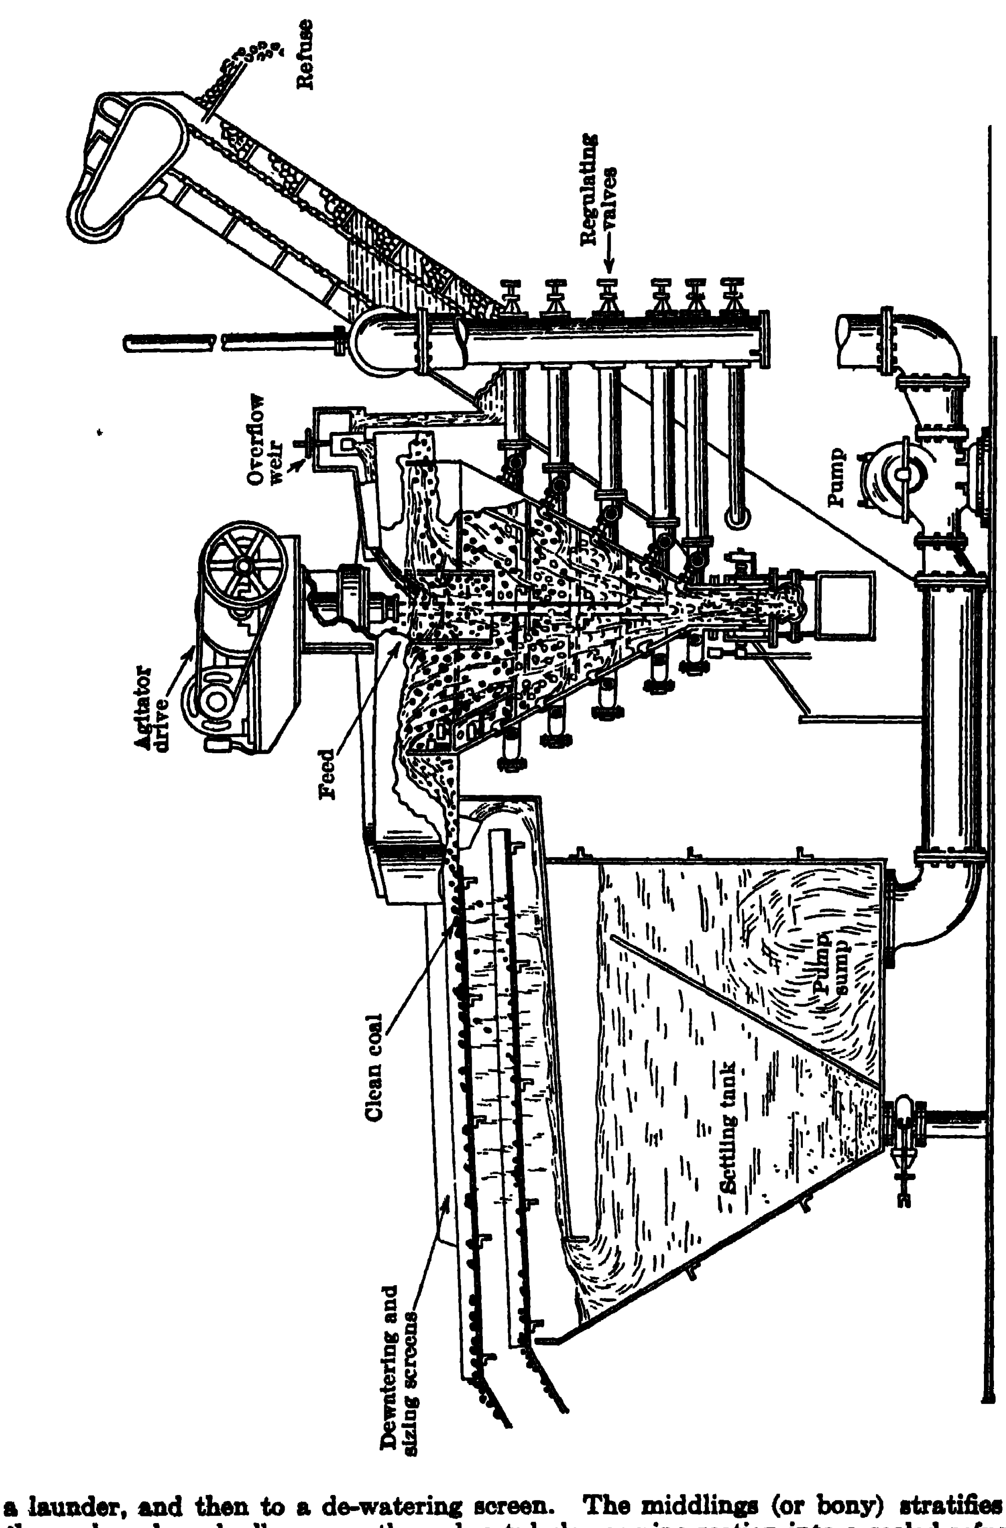

Fig 3c. Menzies Cone Separator

a launder, and then to a de-watering screen. The middlings (or bony) stratifies below the coal, and gradually passes through a tubular or pipe section into a sealed refuse conveyer, where it is discharged above the water level of the cone into refuse chute. The coal is held in suspension, or rather washed over top of cone, by a hydraulic current from a centrifugal pump, delivered to sides of the cone at fixed spaces. Each current of water

is controlled by a separate valve, to give the proper upward press. Coal leaving the cone goes over a de-watering shaker, which also acts as a sizing shaker, and then to the pocket, the water being returned by a sump to the re-circulating pump. Preliminary preparation above storage pocket is the same as for Class *C*. Two systems are in vogue in connection with the Menzies cones: (*a*) separate cones for each size to be cleaned; (*b*) mixed run-of-mine feed from egg to pea size, inclusive, in one cone, and buckwheat to barley size in the other.

Wilmot Hydrotator, Class C (Fig 3*d*). In this process, only material from chestnut and smaller are cleaned, each size going to its respective hydrotator. Preliminary preparation above the storage pocket is same as for Class *C*. Coal and refuse are fed and go into suspension in a cylindrical tank having a cone-shaped bottom. The coal rises to top and overflows onto a de-watering screen and then goes to the pocket, while the slate drops to bottom and into a sealed conveyer, being discharged above water level of the tank into the refuse chute. Water from the de-watering screen goes to the sump, and is re-circulated by a centrif pump providing the upward current. This water contains considerable undersize, consisting of coal and slate in sizes small enough to pass through the de-watering screen, this undersized material having a high spec gravity. The density thus produced causes the gravity separation. Variations in density produced by various quantities and qualities of feed, cause a fluctuating water level in the refuse conveyer, which in turn is controlled by an automatic valve admitting or shutting down the fresh water supply fed into the refuse conveyer. The re-circulating water is discharged into the hydrotator through a revolving agitator.

SIZE	A	B	C	D	E	F	G	H	I	J	J
5'0"	5'0"	2'9"	3'10"	4'9¼"	13'2½"	11'2½"	13'2"	25'10"	5'4¼"	7'4"	6"

7'0"	7'0"	2'10½"	3'10"	7'1½"	15'1"	13'0"	13'6"	27'9¼"	7'6"	9'4"	6"

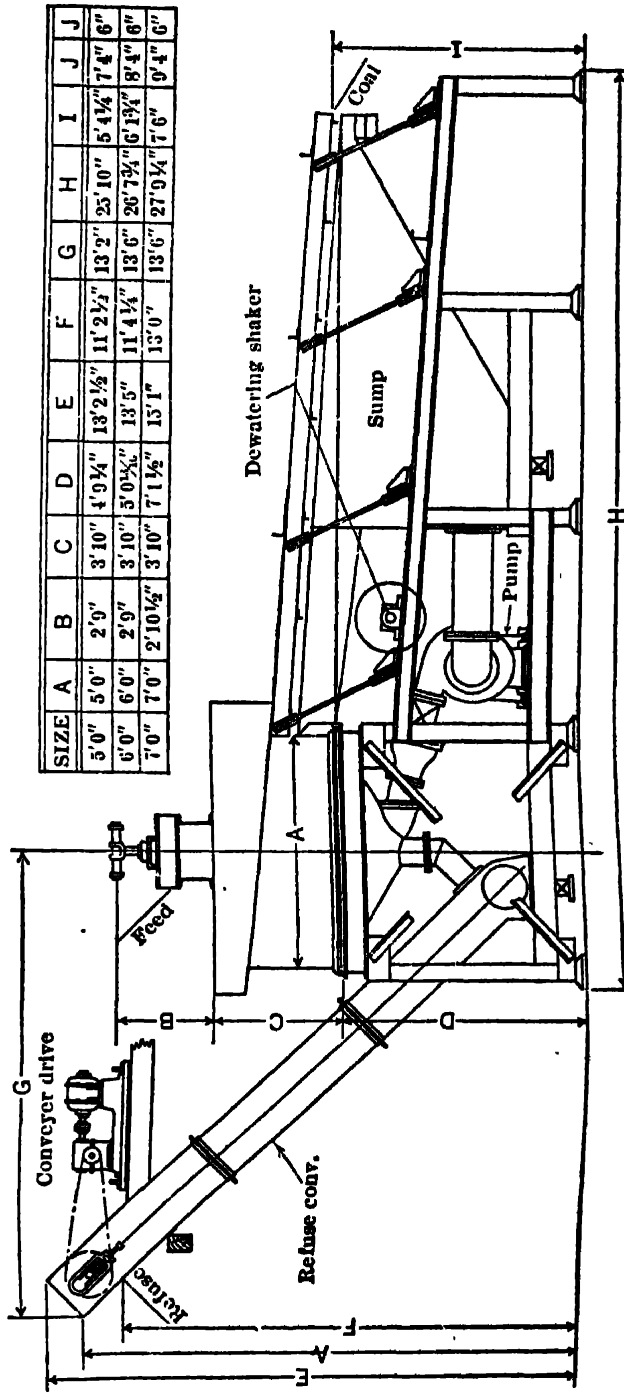

Fig 3*d*. Wilmot Hydrotator

E. I. DuPont de Nemours & Co have developed a straight gravity separation, using a "parting liquid" with gravities from 1.3 to 3.0. The process includes treatment of run-of-mine feed with "active agents," which immunise the solids against the parting liquid. The feed is treated with the active agent and enters a separator containing the parting liquid of pre-determined gravity. The "floats" are conveyed from the separator by one conveyer, while the "sinks" are re-claimed by a second conveyer. The two products are thoroughly washed to recover the parting liquid, which is collected and classified in a Dorr thickener, the excess water going to overflow, the "parting liquid" being re-claimed from the underflow and returned to the plant. This system will probably have a useful field for anthracite, but the first plant is yet to be built.

7. BREAKER STRUCTURES

Types: (*a*) all timber; (*b*) all structural steel; (*c*) all reinforced concrete; (*d*) steel base, timber superstructure; (*e*) reinforced-concrete base, timber superstructure; (*f*) reinforced-concrete base, steel superstructure. To determine best type, divide estimated cost by total estimated tonnage, and to quotient add estimated preparation cost plus yearly maintenance charges per ton of coal.

Depreciation. TIMBER STRUCTURES. For dry breakers, depreciation depends upon kind and quality of timber used, usually varying from 4% per year for yellow pine to 8% for hemlock For wet breakers, depreciation varies from 10 to 20% for yellow pine, when used for main or heavy timbers subjected to alternate wetting and drying. Hemlock should not be used in parts of structure which come in contact with water; if so used, depreciation is about 25%. White pine will outlast either yellow pine or hemlock, but is no longer available at reasonable cost. For STRUCTURAL STEEL OF REINFORCED CONCRETE, the depreciation for dry breakers is unknown, but is estimated at 1.25%. For structural-steel wet breaker, using acid mine water for washing, depreciation is estimated at $2\,^1/_2$%. Modern construction, with reasonably water-tight pockets, chutes, and $1\,^3/_4$-in tanks, should lengthen the life of such structures, depreciation being estimated at $1\,^1/_2$ to 2%. Reinforced concrete is not recommended in a wet breaker using acid mine water, because there is no certain mode of protecting concrete from its attack. In timber breakers, using wet methods, it is important that all chutes, pockets, and tanks be water-tight; such construction is more costly, but will reduce maintenance charges and lengthen the life considerably.

8. LOADING COAL FROM BREAKERS

Ideal loading pockets include following features: Chutes to lower coal into pockets with minimum breakage; sufficient storage in each pocket to hold not less than one car of coal; gates operated from loading platform; lip screens to remove undersize from lump, steamboat, and prepared sizes; loading chutes adjustable to varying heights of gondola cars, and arranged to load with minimum breakage on the center-line of the car and in the direction in which the car gravitates; special provision to load box cars, and when loading wet coal, provision to wash the sizes passing over lip screen.

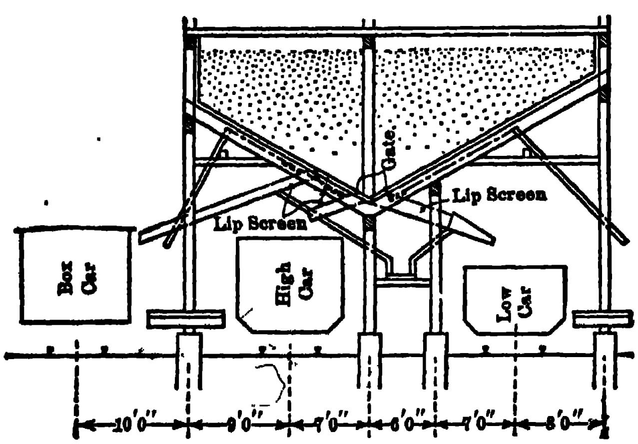

Fig 4. Direct Loading Pockets

Loading direct from storage pocket. Pockets are parallel with loading track (Fig 4). Good practice is to provide 2 tracks, for high and low cars, and a track for box cars. Such arrangement of tracks gives large loading capacity, simplifies mechanical arrangements required to handle all types of cars on one track, and permits simultaneous loading from adjacent pockets, even though less than a car-length apart.

Loading concentrated at one point. Pockets are usually placed at 90° to track (Fig 5), and coal is delivered by curved chutes to a belt conveyer parallel to pockets. Coal is discharged at tail of conveyer, over a lip screen adjustable for each size of coal. The tail of conveyer, together with lip screen, should be raised or lowered as a unit, by power, to suit different heights of car. Controls for gates, and operation and adjustment of belt, should be placed at loading point. Pockets may stand on the ground, and the conveyer be inclined to reach required height to load. Height of breaker is not much reduced by this construction, as increased pocket capac is required for storage because sizes must be loaded in sequence. Labor force is usually half that for other methods of loading, including maintenance. Rubber-covered conveying belts usually have the longest life, especially when handling wet coal; they should handle at least 2 million tons per 100 ft of conveyer. Speed of belt should vary from 250 ft per min for broken to 600 ft per min for wet rice and barley.

Loading direct from breaker chutes, with only enough chute capacity to provide storage while changing cars. General construction would be similar to that at bituminous tipples (Sec 35). Apparent advantages: no pocket breakage, no lip screens, reduced height and first cost of breaker. Disadvantages: at least 7 loading trucks are required, difficult car distribution, large loading force, and complicated arrangement to load box and gondola cars from same chute.

A recent loading plan is a combination of direct loading by chutes for egg, stove and chestnut sizes, and from storage pockets for all other sizes. This requires 4 tracks, 1

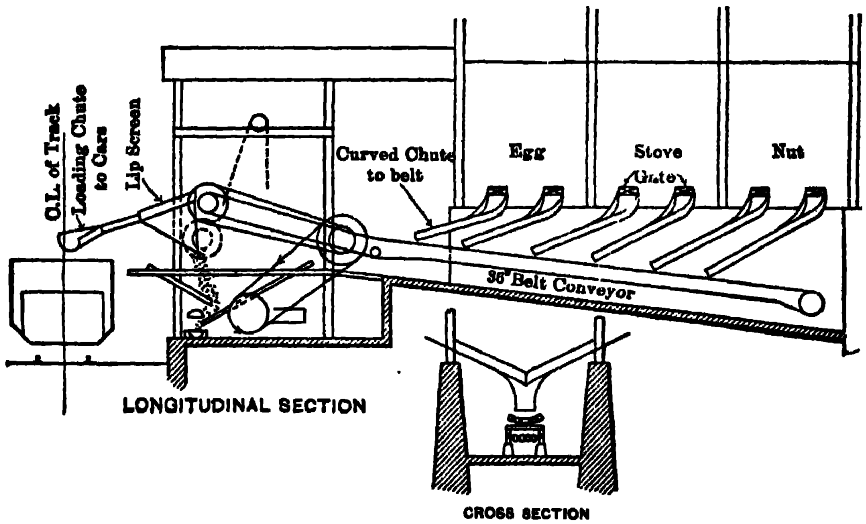

Fig 5. Concentrated Loading Pockets

each for egg, stove and chestnut, and 1 for smaller sizes. It is ideal in combination with a preparation plan in which final screening and sizing follows the cleaning machinery, so that clean and sized coal is loaded direct into cars, eliminating use of lip screens for prepared coal.

9. SIZING SCREENS (see also Sec 35)

Classification. Fixed or stationary: (*a*) adjustable bars; (*b*) finger or fixed bars; (*c*) punched plate or woven-wire segments. Movable: (*d*) cylinder or revolving screen; (*e*) "shaker" screen; (*f*) gyrating screen; (*g*) oscillating movable-bar screen; (*h*) revolving roller screen; (*i*) vibrating screen.

Stationary screens are usually built into a chute, at a pitch down which the coal will slide, while the undersize falls through the openings. They are not used when uniform sizing is required, but for preliminary separation of larger sizes from the smaller, before hand picking, and to remove dust and fine chippings made during preparation. Results are usually very unsatisfactory and they are used only for emergencies. Their only advantage is low first cost, which is more than offset by very low efficiency.

Adjustable bars are used only to size lumps out of run-of-mine, and are placed below the receiving hopper. Ratio of length of bars to width of opening varies from 8 or 10 : 1. The adjustment permits openings between bars to be increased or decreased in fixed increments, to vary percentage of material passing over them. Bar screens have low effic, considerable fines passing over with the larger pieces, so that the oversize is difficult to inspect and hand clean. Bars are T-shaped CI or round steel, 4 to 6 ft long. Their ends dovetail into fixed rests, which hold the bars parallel. Sides taper about 0.25 in in the depth, giving an inverted V-shaped opening between bars, which allows the coal to free itself. Lower end projects above the rests and passes any piece of coal which hangs between the bars. Opening between the bars is usually 5 to 6 in.

Finger or fixed bars are occasionally used to remove a portion of the undersize or dust from prepared sizes. They are made by placing in a chute equally-spaced round W I or C I bars, or angle iron with legs looking down at an angle of 45°. Opening between bars has a ratio of length to breadth ranging from 25 to 50 : 1. Specially constructed bars are used to remove pieces of flat slate or bone.

Punched-plate or woven-wire screens remove dust and chippings from prepared sizes, especially for lip screens at loading pockets; woven wire for dry, punched plate for

wet coal. When loading wet coal, a water jet is sometimes directed on the screen to remove fine material and wash the coal.

ADVANTAGES OF FIXED SCREENS: low first cost, no power required to operate, large capacity when used as lip screens. DISADVANTAGES: very poor sizing; being set on a pitch, they increase breaker height and cost; require constant attention, due to blinding; adjustable bars involve a drop at lower end, and increase breakage.

Cylinder or revolving screens, usually 6 to 8 ft diam by 12 to 24 ft long, were formerly used for all sizes of coal; they are now giving way to shaking screens. They may be single or double jacketed and the segments arranged to produce several sizes from one screen (Fig 6). Max peripheral speed should not exceed 200 ft per min. ADVANTAGES OF REVOLVING SCREENS: exact screening and sizing of coal; revolving at slow speed, they do not vibrate breaker structure; blinding of meshes is rare. DISADVANTAGES: high first cost and maintenance, as compared with shakers under similar conditions; small capacity, since coal is in contact with only about one-eighth of the screening surface at one time; require more space than shaking screens; greater breakage in the screen and in the enclosing hopper, due to high drop of coal; more difficult to inspect and repair than shakers; excessive weight as compared with shakers.

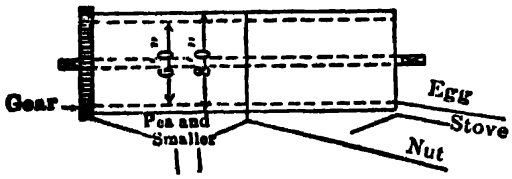

Fig 6. Revolving Screen, 6- to 8-ft diam

Shaker screen (see also Sec 35) is usually 4 to 8 ft wide by 9 to 21 ft long. Sides are of steel plate, angle iron or wood, connected by cross angles, to which the punched-plate segments are bolted. It is suspended by chains, rigid hangers with pin-connected end, or 1-in oak or hickory boards with fixed ends (Fig 6*a*).

Screen is driven by a pair of eccentrics connected to it by 3 by 6-in wooden eccentric arms with fixed ends, and reduced in section to 2 by 3 in at point of maximum bending,

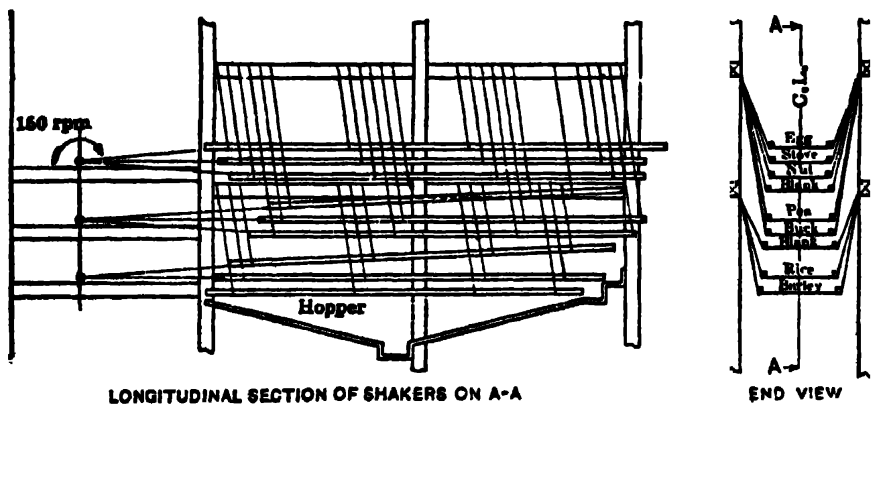

Fig 6*a*. Shaker Screen

or by forged crank arms, with metal connecting rods to a wrist pin on the screen. Usual throw is 3 in, speed 150 rev per min. Ratio of length of hanger to travel is, for rigid hangers, 3 to 6 : 1; for wood, 10 to 15 : 1. Hanger should be inclined toward back end of the screen, so that the vertical resultant acting on the coal at end of back stroke will lift the coal out of the mesh and prevent blinding; pitch of hanger varies from vertical to 3 in per ft, according to size of coal and length of hanger. Shaker screens may be built in 1, 2 or 3 decks, which should be hung in pairs, one over another, with their eccentrics on the same shaft, 180° apart, to balance vibrations. Absolute balance is impossible, due to: angularity of eccentric rods, and the fact that the screens work in different planes, with varying quantities of material on them. Resulting unbalanced load vibrates the breaker structure, which should be braced accordingly. (See Sec 35.) ADVANTAGES: exact sizing, low first cost, accessibility for repairs and inspection, simplicity of construction, reliability in operation, saving in breaker height, large capacity. DISADVANTAGE: vibration imparted to breaker structure.

Vibrating screens of various types have been experimented with on nearly all sizes of coal, but the results have not yet warranted their general adoption in place of shaker screens. Recent developments have perfected a vibrating screen particularly useful on the fine sizes, minus 5/16. The use of round mesh is specified for all sizes of anthracite, but the substitution of square wire mesh on vibrating screens in place of round punched plate requires more experimenting before its use becomes general.

Oscillating or movable-bar screens are seldom installed in new breakers; they are being superseded by shakers. Their field is limited to dump screens, for sizing lump from run-of-mine. ADVANTAGES: heavy construction, enabling them to handle large pieces of material; their action as feeders to the machinery following; saving in breaker height; slow speed; no vibration to structure. DISADVANTAGES: poor sizing; fixed space between bars, with no adjustment; high first cost; when not hand fed from a hopper, the mixed run-of-mine often rushes over onto picking table.

Table 6. Comparison of Shaker and Revolving Screens

(Sq ft of screen area required to screen one ton of coal in 10 hours. For sizes of openings, see Table 1.)

Size of coal	Shaking screen		Revolving screen	Size of coal	Shaking screen		Revolving screen
	Dry	Wet			Dry	Wet	
Steamboat	.....	1.50	......	Pea	0.20	0.69	1.75
Broken	0.60	1.20	0 75	Buckwheat	0.61	0.53	2.00
Egg	1.20	1.10	1.00	Rice	0.50	0.65	2.25
Stove	0.25	0.35	1.00	Barley	0.67	0.67	3.00
Chestnut	0 20	0.27	1.5				

Parallel revolving-roller screen consists of a number of parallel rollers equally spaced. Diam of rollers, 2 to 4 in and openings between them vary with size of coal handled, opening being varied by adjusting the roller centers. Screen is self-contained, and is usually installed in a chute at a pitch down which the coal will gravitate. Rollers revolve in same direction, and at speed of about 350 rev per min. This is not a sizing screen; it is used chiefly to remove flat coal or slate, and is often called a "slate-picker." It is occasionally used as a lip screen.

10. BREAKER ROLLS

Classification of rolls for breaking coal from a larger to a smaller size: CRUSHER or No 1 rolls (for breaking lump to steamboat or broken); MERCHANTS, or No 2 (steamboat to broken or egg); RE-BREAKERS, or No 3 (broken to egg or stove); BONEY or No 6 (egg bone to stove, stove bone to nut or pea, nut bone to pea). Rolls are also classified by their peripheral speed: high-speed (900 ft per min) and slow-speed (250 ft per min).

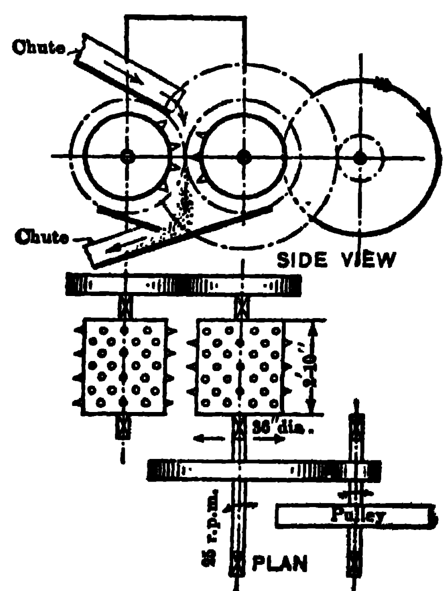

Fig 7. Toothed Slow-speed Rolls

Operation. Slow-speed rolls, with pointed teeth (Fig 7), give a higher percentage of prepared sizes than the high-speed, under same conditions. Coal should be broken by points of the teeth, and *not crushed* between roll bodies. Hence, jaw and gyratory crushers should not be used, as they crush rather than break the coal, thereby increasing degradation into steam sizes. According to design, rolls are divided into DRIVEN-TOOTH, and SEGMENT-TOOTH rolls. In the first, hardened-steel teeth are driven into drilled holes in the cast-iron roll body or drum; in the second, cast-iron or steel toothed segments are bolted to a drum or cast spiders. Pedestals supporting the driving rolls are fixed; the driven-roll pedestals are adjustable for varying the opening, which is limited by the length of gear teeth; for greater adjustment the gears are changed. Pedestals have cushion springs, which compress when hard foreign material falls into the rolls.

Table 7. Size of Rolls, Size and Spacing of Teeth, Generally Used for Breaking Coal

Roll name and number		Size of drum, in	Teeth			Size of teeth, in
			Number per row	Distance c to c	Number of rows to circumference	
Crusher	No 1	51 × 41	8	4.50	36	3 1/2× 1 3/4 sq
"	1	33 1/2× 46	8	5.50	19	"
"	1	35 × 34	6	5.25	33	4, 3 & 1.5 high
Merchant	2	30 × 36	10	3.75	26	2 3/4× 1 1/2 sq
"	2	35 × 34	8	3.50	33	2 1/2× 2 "
Re-breakers	3	30 × 36	14	2.42	39	2 × 1 1/4 "
"	3	35 × 34	13	2 3/16	55	1 3/8× 1 3/8 "
Bone	6	24 × 32	21	1.35	72	1 × 1 "
"	6	24 × 32	21	1.35	70	1 × 1 1/8 "

Table 8. Percentages of Prepared Sizes Usually Made by Breaking Down a Larger Size (See Fig 8)

Roll number	Size of drum, in	Peripheral speed, ft per min	Size of coal broken	Total percentage made of					% of prepared sizes
				Steamboat	Broken	Egg	Stove	Chestnut	
1	35×34	250	Lump	27	23.0	22.0	10.0	9.0	91.0

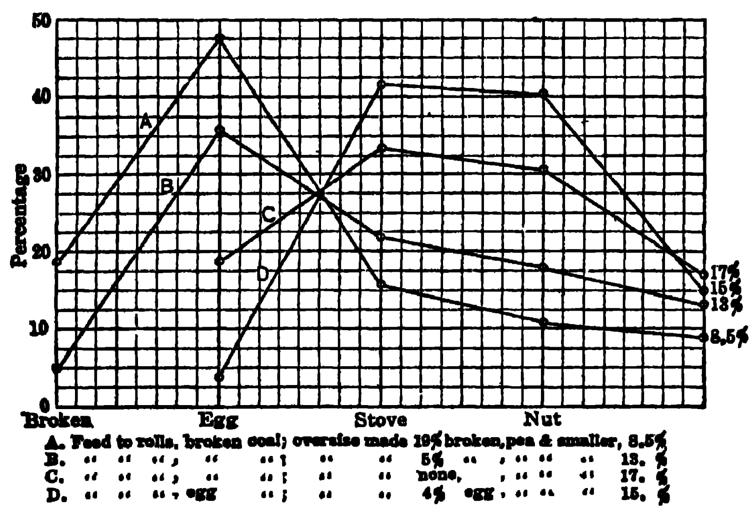

Fig 8. Percentages of Prepared Sizes made by 35- by 34-in Rolls, at 230 ft Peripheral Speed per Min

11. MECHANICAL CLEANERS

Classification. There are 3 groups, the operation of which depends on: (*a*) Difference in specific gravity; (*b*) difference in coefficient of friction; (*c*) difference in shape of fracture.

Plunger, pan, pulsator and upward-current jigs. There is no definite rule as to type of jig; personal preference seems to decide. Plunger and pan jigs give equally good results for all sizes. Upward-current and pulsator jigs are occasionally used for rice and barley coals. Combined plunger and upward-current jigs are also used. Overflow jigs cause less breakage than those with mechanical discharge. Pan jigs with mechanical discharge require less water than other types. Jigs will treat consistently a mixture high in impurities, yielding a marketable product, the refuse usually containing not over 4%

coal. Successful operation depends largely on the jig tender's skill; the coal end probably requiring some hand picking (see Table 9). So-called automatic jigs have not been entirely successful.

Broken-coal jigs for preliminary cleaning are advantageous, the jigged product being broken down to egg and smaller, and mixed with the run-of-mine for further jigging. Constant feed is essential for good results, and there should be a storage hopper back of

Table 9. Loss by Breakage in Jigs, due to Mode of Discharge, and Abrasion of Coal in Jig-tank

Size of coal	% loss into			Approx loss in value, ¢ per ton	Method of discharge
	Stove	Nut	Pea and smaller		
Broken	0.42	0.21	1.78	5.0	Overflow
Egg	0.40	0.22	1.68	5.0	"
Broken Egg	0.98	0.56	4.09	10.0	Flight conveyer
Broken Egg	0.10	0.42	3.18	8.0	Belt "
Stove		...	1.43	4.0	Flight "

each jig with 1 hr capac. Jigging of the coal refuse from the jigs improves total recovery. Jig capac varies, being dependent upon quantity of impurities in the feed. With a high percentage of impurities, the regulating gate is set low to allow more time for cleaning; conversely, with low percentage of impurities, the gate is raised.

Egg coal, containing 44% slate and 6% bone, in a 4-ft pan jig at 135 r p m, gave following results: coal discharge, 2.25% slate, 2.5% bone; slate discharge, 3.75% coal, 2.75% bone; clean coal, 6.3 ton per hr. The coal was hand picked before going to storage pockets.

Pulsator and upward-current jigs are occasionally used on rice and barley, but seldom reduce ash content below 15%. There are also special small coal jigs, but they generally produce about 15% ash coal, which seems to be the low limit practicable with jigs.

Concentrating tables are largely used. They differ from ore tables chiefly in size. The deck is approx 17 by 8.5 ft. The riffle cleats, instead of being parallel to discharge edge of table, are at an angle with it. A two-part separation is made of coal and refuse. With careful supervision, about 12% ash coal is obtainable. Constant feed and uniform water supply are important for best results. Aver.feed capac, 8–12 ton per hr, for buckwheat, rice and barley; for slush or buckwheat No 4, 4 ton. Water required is about twice the weight of coal; that is, 8-ton feed per hr requires 75 gal water per min.

Air washer or concentrator table is a specially designed table having riffle cleats mounted on a perforated metallic deck, with the usual driving mechanism; air forced through the deck agitates the feed. A 3-part separation takes place as on the wet concentrator. This table, designed for rice and barley coals, functions well on a feed containing less than 4% moisture; feed of higher moisture cannot be easily cleaned. As practically all fine coal is sized wet, the field for the air washer will be very limited, unless a cheap drying process can be devised.

Chance sand-flotation process (Fig 9). Coal is floated in a fluid mixture of sand and water, maintained at a predetermined fixed sp gr in a cone, in which slate and other refuse readily sinks. With sea or beach sand (2.6 sp gr) a fluid mixture up to 1.75 sp gr can be maintained, so that any material above that gravity will sink. Minus 30 and plus 80-mesh sand should be used. Coarse sand requires more agitation; finer sand is difficult to settle and is lost in the sand-sump overflow, unless extra large sand sumps are used.

The refuse in Table 9a carries 5.8% good coal at 1.75 gravity and 6.13% at 1.70. In run-of-mine coal there is usually merchantable coal up to about 1.90 gravity, which is not recovered directly by this process. When percentage of fine coal is high in the run-of-mine, comparatively little refuse is removed. Refuse should probably be treated by jigs to recover lost coal. Use of sand is an objection, in introducing material foreign to the coal, and, because of its excessive abrasive action on the machinery, maintenance cost is high. The cleaned coal usually looks well and is attractive to the trade. An expert attendant is necessary, who must be sure the gravity of the fluid mass is up to the desired point; otherwise, more coal will go to the refuse.

Run-of-mine coal (Fig 9) is broken to egg size and usually smaller. Silt is screened out and remaining product fed into the top of the fluid mass in the separation cone; the coal floats near the top, flows from the cone discharge with the fluid mass with which it

is mixed, passes over a de-sanding screen and then over sizing screens. Slate and other refuse sinks and is trapped out by alternate opening and closing of the two slate valves;

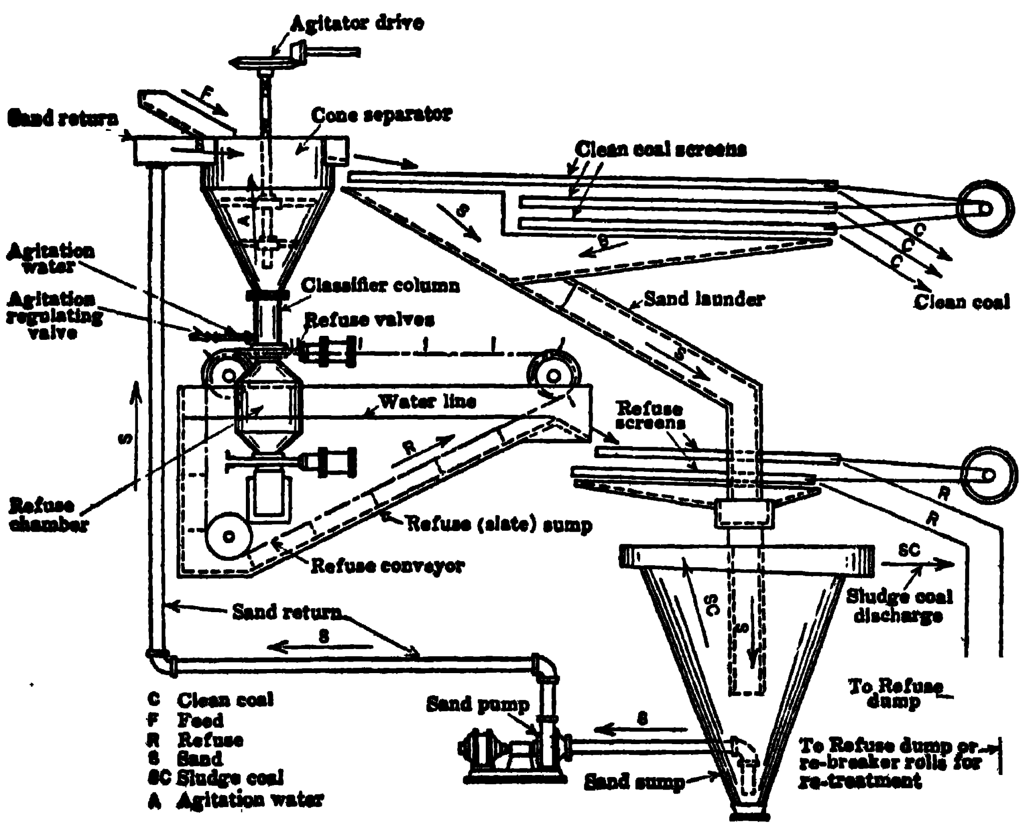

Fig 9. Chance Coal Cleaner, Sand-flotation Process

the slate falls into a sump and is elevated to a de-sanding screen. Sand and water from de-sanding screens flow to a sand sump, in which the sand settles and is pumped back

to the separator cone. Overflow, of clean water, flows to the circulating pump for reuse for agitation, shaker sprays, etc.

Rheolaveur process (Fig 10, 10*a*) is an application of the launder washer, for handling coal in size from 3.5 or 4-in to approx 48-mesh (see flow-sheet, Fig 3*a*). Invented and patented by Antoine France, Liége, Belgium; American rights owned by American Rheolaveur Corp'n.

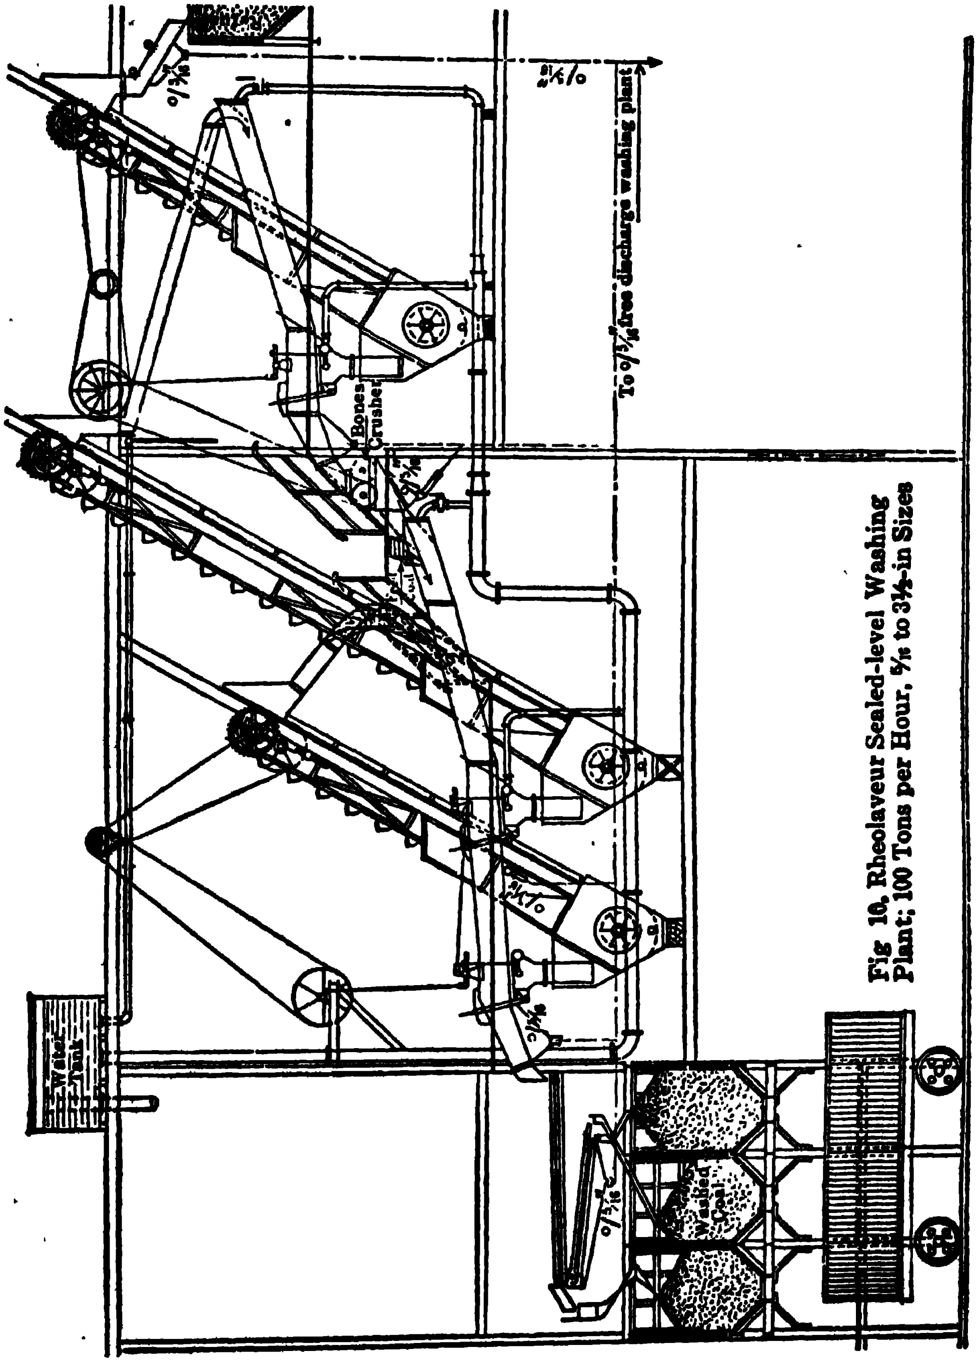

Fig 10, Rheolaveur Sealed-level Washing Plant; 100 Tons per Hour, $^5/_{16}$ to 3½-in Sizes

Classification is effected by horiz currents of water in an open launder, causing stratification of the material in proportion to its density, shape and coeff of friction. The lower layers are drawn off progressively by "Rheo" boxes; these are traps in which an ascending current prevents particles from passing to the discharge, unless their density causes them to sink. There are two types: closed or sealed (Fig 10), for the larger sizes of coal; open or free discharge (Fig 10*a*) for small sizes, usually from $^5/_{16}$-in to sludge.

Closed type. The Rheo boxes have an adjustable opening into the launder, large enough to pass the required size of coal and provided with a perforated oscillating flap to

prevent arching or clogging. A baffled water connection with a quick-acting valve admits water to create an upward current of known strength. The discharge from the boxes passes into a sealed elevator boot, maintaining the water at trough level and raising the material to a point above the water seal.

The feed enters the current at upper end of launder, which is quite steep for a distance that depends on character of feed. As the material passes rapidly down this steep grade,

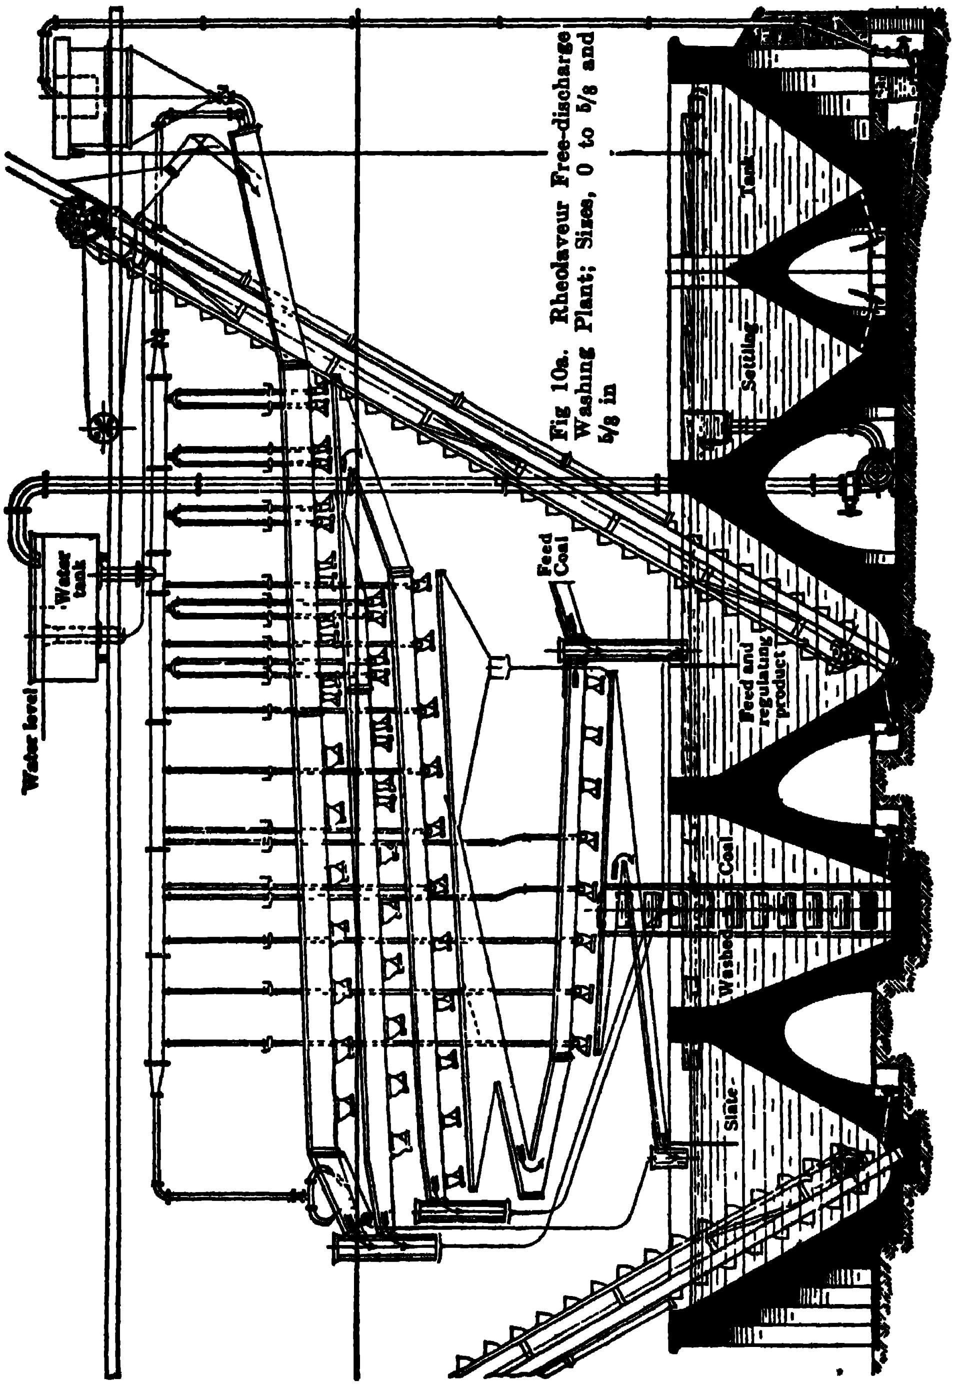

Fig 10a. Rheolaveur Free-discharge Washing Plant; Sizes, 0 to 5/8 and 5/8 in

A PRIMARY CLASSIFICATION is made, the light particles floating quickly to the discharge at end of launder. Heavier or slabby materials seek the bottom and are retarded, while those of intermediate density are classified between and move at varying speeds, according to their density and coeff of friction. From the classification end of the launder the grade flattens until it is nearly level, the heavier materials building a bed which travels very slowly along the bottom. Just beyond the beginning of the flat grade is the first Rheo box, which extracts the heaviest material. From this point the veloc of current decreases, and

stratification becomes more definite; so that, on reaching second Rheo box, particles of intermediate gravity constitute the bed on the trough bottom and are drawn off by the second box.

Materials from the first Rheo box are rewashed if they have any recoverable content, or pass directly to the refuse hopper. Those from the second box are returned to the head of the launder and mixed with the feed. Thus, the amount of intermediate material is greatly increased and builds a thick layer between the good coal and heaviest impurities. This re-circulation goes on until the intermediate material is properly classified. The results are controlled by the adjustable openings of the boxes and the upward currents.

Open or free-discharge type of launder operates as above, but the Rheo boxes are different. They are very simple, having one or more slots opening into the launder, a quick-opening regulating disk valve, and a baffled and regulated water connection for upward current when required. The launders are very long and have many boxes, which take the materials from the lowest part of the bed progressively as required for re-wash in the troughs below. There are usually 3 or 4 troughs, one above another in a "batterie cascade"; the first and second discharge the good coal, the product from the third and fourth being elevated to the head of the system for retreatment. For certain classes of coal the fourth trough may discharge bone, which, instead of going directly to the re-wash, is crushed and re-treated in a SLUDGE PLANT, for obtaining max recovery. The bottom trough evacuates the refuse. The operation is adjusted by the disk valves and upward currents of water. Fig 10, 10*a* show launders of both closed and open type, as would generally be used in a commercial plant.

The Rheolaveur process has proved very efficient in obtaining low ash and high recoveries in both anthracite and bituminous preparation. Its simplicity, low cost and upkeep, and economical operation have also made a very favorable impression abroad, where it is largely displacing other systems.

Fixed and movable cleaners (friction). FIXED type may be designed to make a 2-part (coal and slate) or 3-part (coal, bone, and slate) separation. They usually consist of a series of inclined planes, separated by adjustable cross slots. Mixed material gravitates from top to first slot, where the slow-sliding slate and bone (due to their greater coeff of fric and flatter shape) fall into the slot, the coal passing over; this is repeated until the coal is sufficiently cleaned. Slate and bone falling through the slots may be similarly treated in another cleaner: the first slot removing slate, the bone passing over. These cleaners are usually adjustable, as to slot opening and pitch of planes. They require constant attention, and hand pickers for the refuse, and are almost obsolete, as they work poorly on wet coal. SPIRAL CLEANER consists of a central column, with a series of spiral bands inclined toward center, down which coal slides. Coal maintains a helical path around the column so long as friction balances centrif force. As veloc and centrif force increase, friction is over-balanced, and coal jumps over outer edge of spiral and falls into a chute. Slate and bone adjust themselves on the spiral, according to coeff of friction, and at discharge end may be separated and run to their respective destinations. Spirals require some attention and adjustment, since a change in character or condition of run-of-mine (as from wet to dry) will vary the coeff of friction. Effic is affected also by dryness or dampness of atmosphere. MOVABLE CLEANER consists of a metallic moving band, adjusted to give a pitch in 2 directions, across the table and lengthwise, so that the band travels up the pitch. Impure mixture is fed at the high corner; coal slides obliquely across the table; slate, having greater coeff of friction, is carried up into the refuse chute.

The Anthracite Separator Co have recently developed a two-thread spiral for primary cleaning, especially for broken coal, which removes excess refuse from run-of-mine feed before final treatment of the product.

Fixed and movable cleaners (fracture). FIXED type consists of specially made bars, placed in a chute, forming long narrow slots over which cubical pieces of coal slide, while flat slate and coal fall through. Or, punched or slotted steel plates may be used, the flat pieces passing through the holes. This type is usually attached to discharge end of a shaking screen. Some forms will remove more flat slate than coal. MOVABLE type (see parallel revolving roller screen, Art 9). Slate from these cleaners usually goes by gravity to jigs or friction type of cleaner, for final preparation.

Comparison of mechanical cleaners. For high recovery, the designed capacity should not be exceeded, or a loss of coal in the refuse will result. JIGS produce clean coal, but, where the refuse in the feed exceeds 15–20%, double jigging is desirable; and if there is a high percentage of bone middlings, triple jigging may be introduced. The jig requires a trained operator, but, after it is once adjusted, neglect on his part will not seriously affect results. For high recovery, close sizing is desirable; when jigs are used, each size must have its separate machine. The larger sizes must be inspected and usually hand-picked. The CHANCE PROCESS produces clean coal; it has the advantage that, as pre-

sizing before cleaning is unnecessary, refuse is removed before sizing, with possible reduction of the screen areas. The labor force is less than that required for a jig plant. Recent installations show a preference for the Chance equipment over jigs, although more screens are required to remove the fines before entering the Chance cone, with de-sanding screens after the cone on coal and refuse.

The RHEOLAVEUR PROCESS has the advantage of handling mixed sizes, removing refuse before sizing; for high recovery, launders may be arranged in series for re-treating the refuse. CONCENTRATOR TABLES are adapted usually to fine coal, and adequate water supply, uniform feed and skilful operation are essential. The HYDROTATOR has shown good results on all sizes up to and including pea coal; but, as it will not handle mixed feeds, each size must have a separate machine.

12. CONVEYERS, CHUTES, FEEDERS, WATER SUPPLY, POWER

Conveyers are classified as: (*a*) single-strand flight; (*b*) double-strand flight (including scraping and carrying conveyers); (*c*) belt conveyers. FLIGHT conveyers with single strand may be used for all sizes of flights up to 24-in width; double strand for larger.

Sizes of flights: SINGLE-STRAND, 4 by 10 in, 6 by 12, 6 by 18, and 8 by 18; DOUBLE-STRAND: 10 by 30 in, 10 by 48 and 10 by 54. Speed 75–100 ft per min. Trough, steel or C I, the latter preferred for long life, especially in acid mine water. Breakage, 2–4%, is due to method of feeding; little breakage occurs in transit in smooth troughs. Belt conveyers are especially adapted to dry coal; when conveying mixed wet coal, they run at higher speed, to 500 ft per min, for throwing off wet fines which otherwise stick to the belt and are carried back on return belt. Breakage is probably higher than for a chain conveyer, due to drop at the discharge end at high veloc; partly overcome by using a discharge chute receiving the coal on a tangent.

Shaking chutes, replacing conveyers, have usually 3 by 8-in wood sides, with 2.5 by $^5/_{16}$-in cross angles, 3 ft long, at about 6 ft centers. The angles extend 6 in beyond the sides, and are bolted to 1 by 6-in hanger strips, 6 ft long. A pair of 3-in throw eccentrics, at 90–100 r p m, drive the chute, which is set on a pitch of about 0.5 in per ft. Width varies to suit capac, which is approx equal to area of chute × half the total travel per min, thus: area chute, 1 sq ft, 0.5-in pitch, 100 r p m, 6-in travel; 1 sq ft $\times \frac{100}{2} = 50$ cu ft per min.

Shaking chute is also used to replace inclined stationary coal and rock chutes, to reduce breakage, give uniform flow or feed, and reduce breaker height. Max safe length for a chute 24 in wide by 8 in deep is about 75 ft. For large capac, single chutes may be placed in series, the drive being in balance.

Elevators should be double-strand and of the gravity discharge type; their breakage at discharge end is less than for any other type. Loss in breakage is from 2 to 5%, according to method of feed and discharge.

Chains for elevators and conveyers working in acid water should be heavy and contain few parts, with safety factor of 6 to 10. Eye-bar links with riveted pins should not be used; rivetless chains having few parts are preferable, even if more power be required. To reduce extra stock of parts, all conveying or elevating chains at any one colliery should be of same type. (For details, see Sec 27.)

Inclined chutes for conveying coal by gravity, if badly constructed, cause a degradation loss exceeding all other losses combined. This loss is attributed to irregularities in chute bottom; striking of one piece of coal against another; drop at any point, especially at right-angle turns; and the blow which a piece of coal receives at such a turn on striking side of chute. PITCH on which coal will slide varies with quality of coal, and on chute

Table 10. Pitch and Width of Chute, for Coal Sliding on Steel Plates

Size of coal	Pitch, in per ft	Width of chute, in	Size of coal	Pitch, in per ft	Width of chute, in
Lump......	2 1/2 to 2 3/4	48	Pea..................	4 to 5	12 to 13
Steamboat..	2 1/4 to 3	36	Buckwheat..........	4 1/2 to 6	12
Broken.....	2 1/2 to 3	30	Rice................	5 1/2 to 7	12
Egg........	2 5/8 to 3 1/4	24	Barley..............	7 to 8	12
Stove......	2 3/4 to 3 1/2	18 to 24	Dirt................	8 and over	12
Chestnut...	3 to 4	18 to 24	Rock........	5 and over	18 to 60

Note.—Pitch for bottom of dump hopper, not less than 7 in per ft; for storage pockets, not less than 8 in per ft.

lining. Clean coal slides on flatter pitch than a mixture of coal and impurities. A sluggish section of inclined chute can often be remedied by replacing steel lining with bronze, if impracticable to increase pitch. Chutes for dry coal are of 2-in plank lined with sheet steel. For wet coal, use 2-in plank, lined with 2-ply smooth prepared roofing, covered with 1-in boards, and lined with sheet steel or bronze. Right-angle or 180° turns in chutes should be of laminated wood strips, $^1/_2$ by 2 in.

Vertical chutes, "telegraphs," may be designed merely for lowering coal, Fig 11, *a*, or for lowering and depositing to variable depth in a pocket, Fig 11, *b*. In the latter case,

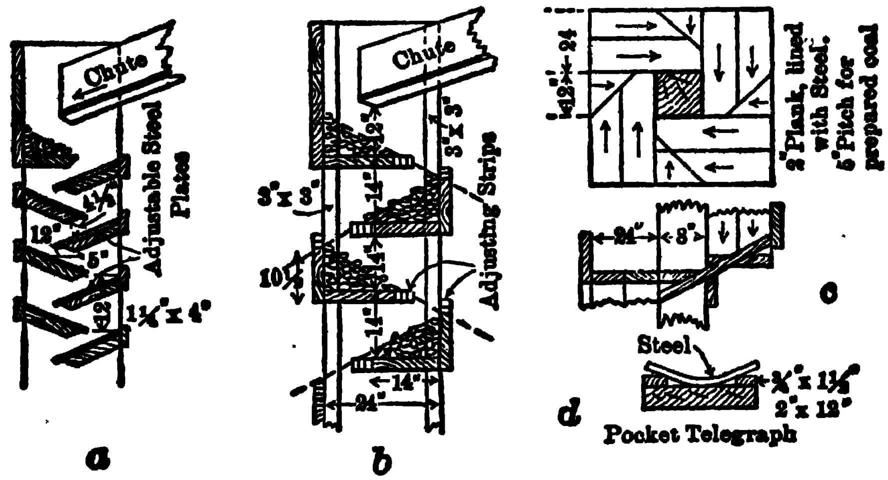

Fig 11. Vertical Chutes, or "Telegraphs"

when top of pile reaches and blocks lowermost opening, coal then issues from next higher opening and deposits on summit of pile; breakage due to subsequent avalanching down slope of pile is negligible.

Capac of a telegraph 24 in sq is 150 tons per hr; 48 in sq, 300 tons per hr; used for all sizes from egg down, and may be of any height up to 65 ft. Breakage in a well-built telegraph is only about 1%. Spiral telegraph is shown in Fig 11, *c*. Automatic control mechanism, Fig 12, is designed to keep telegraph full of coal, by discharging only as fast as fed, thus reducing breakage. Coal entering the top presses upward against pan *a*, thereby opening gate *b* at bottom.

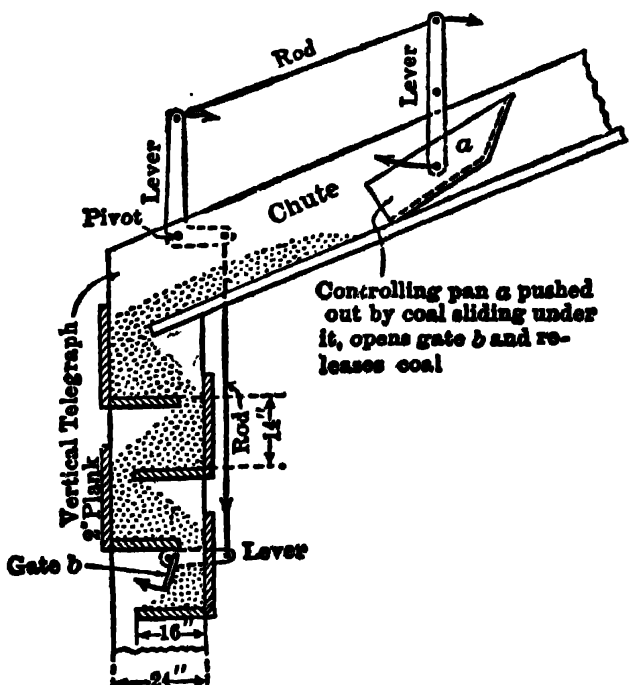

Fig 12. Automatic Control for "Telegraph"

Automatic feeders are installed between receiving hopper and lump-coal screens, and in front of rolls. Feeders may be omitted when automatically controlled chutes are used, since these serve the same purpose. Reciprocating feeder has advantage of simplicity and practically no breakage, as compared with other standard types.

Water is used in wet preparation to wash coal during sizing, on lip screens to remove fine screenings, and in jigs. The quantity required, in gal per min, is approx twice the tons shipped per day.

Gravity system gives best results, because of its constant head. It requires a storage tank in top of breaker, supplying a main feeder line, with branches to the various machines. C-I pipe is required when using acid water, and is of following sizes: shaker screens, of 60–90 sq ft, 2–2.5 in; jigs, 2 in; lip screens, of 12 to 15 sq ft, 1.5–2 in. A fan-tail spray

nozzle directs the stream onto shaker or lip screen, and against the flow of coal. Gate valves are placed at ends of all branch lines, plug valves at sprays on shaker, quick opening valves on lip screens, with spray line operated from the loading platform. All lines have blow-outs for cleaning.

Mine water is commonly used, as fresh water is seldom available. Aver acid content, 1% or less free H_2SO_4. Treatment of mine water saves largely in maintenance of pipes, chute lining and screen segments; saving soon pays for labor and material required to neutralize the water. Lime treatment is simplest; a small feeding and mixing machine is installed, and lime water fed into suction line or sump of the breaker supply pump. About 1 ton of lime per 8-hr is required for 2 000 gal per min of ordinary mine water.

Breaker drives. Both electricity and steam are used, local conditions governing choice. As between unit and combined drives, the latter is preferred. A breaker fed by conveyer should have its drive unified with the rest of the breaker machinery. Jigs should have individual drive, so they may operate during delays to other machinery or delivery of run-of-mine coal. The Chance separator should have separate unit drive, for, if stopped, the sand settles, causing delay in starting up. Belt or rope drives are used from line shaft to all power units. To avoid carrying many repair parts, all machinery should be standardized, with 48-in pulleys, 4 3/8-in shafts and 10-in belts; these sizes covering practically all conditions. Steam from a colliery boiler plant is usually cheaper than purchased electric power, but the convenience of motor drives with remote controls, as compared to steam plant, is unquestionable.

Table 11. Horse Power for Operating Breaker Machinery

	Approx h p	Speed per min
Revolving screens, 6–8 ft diam by 24 ft long	5	250 ft periph
Shaking screens, per 60 sq ft of area	2.5	150 r p m
No 1 crusher rolls, 36 by 36 in, compound	30 max	25 r p m

Size of flight and spacing, in	Weight per ft	Capac, ton per min	
6 by 12-in, at 12 in	10	0.75	For additional length, multiply by length, and divide by 100
8 " 18 " 18 "	19.7	1.5	
10 " 30 " 18 "	45	3.5	
10 " 48 " 36 "	54	5.5	

Table 12. Total Breaker Hp, with Number and Kind of Machines

Breaker capacity, tons	I hp		Machines, number and kind					
	Light	Loaded	Rolls	Shakers	Picking tables	Conveyers, no and length	Elevators, no and length	Jigs
1 500	216	280	7	33	3	2–185 ft	3–184 ft	....
2 000	342	512	4	34	....	2–135 "	4–210 "	32
2 500	354	471	4	35	....	3–225 "	4–240 "	....
1 800	274	336	3	36	1	3–220 "	1–80 "	30

13. BREAKER COSTS AND CAPACITIES. NUMBER OF EMPLOYES

While it is difficult to set a figure, the accompanying tabulation may be used for rough estimating. For structural steel frame, with metal sides and roof, and steel sash, as a basis (L.L.Y.P. construction) about 10% less.

Output, tons per day	Cost per ton per daily output
1 000	$150
2 000	137
3 000	120
4 000	120
5 000	120
6 000	115

There is a preference for high structures, so that the coal, during preparation, may flow by gravity from intake point at top of breaker, down to the storage pockets. Storage pockets, if used, practically determine ground area of breaker. Usual capac of pockets is 70–90 ton for each size, requiring 8 pockets for the 8 sizes usually made. When ample storage room is available for empty and loaded RR cars, pockets may be replaced by boom loading, with advantage of eliminating pocket degradation.

Cost of breakers is divided into about the following percentages for the classifications given: excavation, 0.37%; foundations, 6.23%; floors, 1.20%; structure, 34.60%; lumber, 8.25%; machinery, 33.40%; water piping, 8.60%; loading machy, 3.05%; misc and engineering, 4.30%; total, 100%.

Distribution of steel for a 1 500-ton Class *C* breaker. Volume of breaker, 640 000 cu ft; ground area, 8 700 sq ft; roof, 9 000 sq ft; sides and windows, 36 400 sq ft. Weight of steel, tons: columns, 125; beams, 186; bracing, 39; roof, 22; girts, 41; pocket stringers, 36; rivets and misc, 9; total, 458 tons.

Distribution of timber for 1 500-ton wooden Class *C* breaker. Volume of breaker, 870 000 cu ft. Feet, board measure: posts, 73 900; girts, 127 000; pocket bracing and supports, 140 000; roof, 41 900; siding, 75 000; machy supports, 13 100; jig tanks and supports, 67 700; bracing for chutes, walks and misc, 276 900; total, 815 500 bd ft. Erecting time, 124 days; total man-hours for construction, 67 369.

14. LOCATION AND REQUIREMENTS OF STORAGE PLANTS

Irregularities of market for all sizes of anthracite, which would interfere with continuous operation of the mines, have led to the erection of storage plants at convenient points. Due to better transport facilities from the mines, plants located on the seaboard have largely been abandoned. Local plants, in or near the anthracite region, still exist and are used to store sizes not absorbed by the market. They have the advantages of short haul from the mines; quick release of cars, which is important during a car shortage; low freight rate on coal stored; and convenience of shipping to any market. Interior plants on the Great Lakes are still in use, although the necessity for large storage is ques-

tionable, because of the loss of markets in the West and Northwest, formerly drawing their supply from this source.

Ideal storage plant should fulfil the following conditions: (*a*) production of minimum breakage in stocking and reloading; (*b*) separate storage of each size and in varying quantities; (*c*) rapid handling in storing and reloading; docks on the Great Lakes, receiving coal by steamers, should have large unloading and stocking capacity, as quick dispatch of boats is desirable; (*d*) screen house to resize all coal from storage; (*e*) separate storage for screenings and facilities for resizing them; (*f*) arrangements for reloading and screening more than one size at a time; (*g*) loading facilities for both box and gondola cars; (*h*) covered storage when in regions subject to extreme cold and heavy snows; (*i*) facilities to handle frozen coal, especially at plants receiving wet coal from the mines or at uncovered plants; (*j*) ample railroad classification yards; (*k*) ample trackage through plant, operated by a car-haulage system; (*l*) loaded and empty car scales; (*m*) minimum danger from fire; (*n*) design permitting enlargement; (*o*) low first cost per ton of capacity, and minimum operating cost.

Frozen coal is most efficiently thawed by hot water; steam jets are of little use. There should be ample provision to handle the drainage, which contains much fine dirt.

Operation of storage plants is very irregular. Night and day rushes, in unloading or reloading, are often followed by long periods of inactivity, with the plant either full or empty. Low operating cost, when the plant is working, may be offset by high fixed charges during idle periods.

15. CLASSIFICATION OF STORAGE PLANTS

Each of the two general classes, wholesale and retail, is sub-divided into non-mechanical and mechanical.

Non-mechanical	
A. Stocking on surface	Reloading by hand, yard reloaders, or steam shovel
B. Stocking on surface from trestle	Reloading by hand or yard reloaders
C. Stocking on surface from trestle	Reloading by tunnel, with cars or conveyers to a screen house, with or without yard scrapers
D. Stocking from trestle into bins	Reloading from bins into cars or wagons over lip screens
E. Stocking from trestle on hillside	Reloading by hand, dock scrapers or by hydraulicking
Mechanical	
F. Stocking by elevator and conveyers into bins	Reloading by tunnel as in *C*, or direct into cars or wagons, as in *D*
G. Stocking by cable railway and dump cars into bins or on surface	Reloading by hand, tunnel, or from bins, as in *C* and *D*
H. Dodge system. Stocking by truss trimmers in conical piles	Reloading by swing conveyers, or pivotal reloaders with inclined conveyers to screening towers
I. Stocking on hillside by traveling cantilever trimmer	Reloading by gravity and hydraulicking
J. Stocking on surface by traveling trimmer	Reloading by longitudinal and cross tunnel conveyers, fed by gravity and traveling reloaders, delivering to screen house
K. Stocking by surface cable cars, operating on traveling tramways	Reloading by tunnel conveyers to screen house
L. Stocking by grab buckets, operating on traveling or fixed tramways	Reloading by grab buckets and conveyers to screen house

16. APPLICATION OF THE DIFFERENT CLASSES OF STORAGE

A. Limited to temporary storage of steam sizes. Consists in forming a dump on a level surface, laying tracks on the accumulating stock, and raising and shifting these as the storage grows. Reloading with steam shovel or grab-bucket cranes, operated from edge of pile, or by hand. Only one size can be stocked, breakage of the prepared sizes is excessive, no screening is possible, and operating cost is almost prohibitory.

B. Commonly used for small retail yards, when first cost is the chief consideration. Consists of a trestle, the height of proposed pile, from which loaded cars are dumped. Sizes are separated by partitions. Reloading by hand or yard reloaders into wagons. Only hand screening is possible. All sizes may be stored, but breakage is excessive, due to high drops in stocking.

C. Occasionally used for large storage, where conditions do not warrant a more expensive plant. Stocking is done by trestle, as in *B*, with a reloading tunnel under the storage pile. Reloading gates in tunnel deliver into cars, or to a belt or scraping conveyer, which transfers the coal to a central loading point or screen house. Lip screens at loading gates give only a partial screening when loading cars. Screenings are collected in dust boxes and afterwards transferred by hand to a screening storage. All sizes may be stored. Approximately 60% may be reclaimed by gravity, the remainder being handled by hand or yard scrapers, with a partial screening when loading cars. Breakage is excessive, due to high drops in stocking and drawing coal under pressure in reloading. High first cost and imperfect sizing are the disadvantages of this type.

D. For large retail storage plants, for wholesale storage at seaboard, or for interior plants loading boats or steamers. Consists of bins traversed by railroad tracks, from which each size is dumped into its respective bin. Reloading is direct into cars or wagons, which pass under or alongside of bins. Loading gates in each bin feed the coal over lip screens to remove the screenings, which may be collected in dust boxes under the screens, and removed by hand or conveyers to screenings storage. ADVANTAGES: all sizes stored in varying quantities, and reloaded by gravity; can unload or reload more than one size at the same time; partial screening. DISADVANTAGES: excessive breakage, due to high drops in stocking and drawing coal under pressure when reloading; imperfect sizing.

E. For large storage, of pea coal and smaller. Consists of a hill with a side slope of 25° to 30°, at least 300 ft wide, with an abrupt change at the foot from this slope to a level surface for tracks; reasonable railroad grades to the top of the storage hill and down again. Coal is stocked from a high trestle at top of hill, and avalanches down the hillside until arrested by a retaining wall or by a level space at bottom. Reloading is through gates in the wall, but only the layer retained by the wall and lying above the angle of repose will flow by gravity to reloading gates. It is usual to reload the remainder by hand, dock scrapers, swing conveyers, or by hydraulicking, using hot water in winter. Fixed screens in front of loading gates remove screenings during reloading, which may be conveyed by cars or conveyers, or hydraulicked, to a screen house. Lip screens not used on sizes smaller than pea coal. The different sizes are separated by partitions, made movable to vary their storage capacities. Entire hillside should be covered by planking or concrete to avoid admixture of dirt.

F. For small retail storage, where location prohibits RR approach to top of bins on an easy grade. May be developed for large storage plants. Stocking is done by dumping RR cars into a receiving hopper, which feeds into an elevating and scraping or carrying conveyer, transferring coal to storage bins. Reloading is direct into cars or wagons, through gates with lip screens in the delivery chutes, the screenings collecting in a box underneath. Lowering chutes or telegraphs in each pocket reduce high drops when stocking. Stocking conveyer may encircle storage building, the lip screenings gravitating from the storage box to the lower run of the conveyer; then re-elevated and discharged into a screening bin. The space between under side of pockets and the surface may be used for storage by stocking through a gate in bin bottom. This stock coal is chuted to the lower run of the conveyer and returned to pockets.

G. For large storage plants or retail yards; especially to transfer water-shipped coal to storage or direct to screen house. Consists of a cable or gravity return car, traversing bins or a trestle over a surface storage floor, and dumping at the desired points. Reloading is by hand, or tunnel, with conveyer. Method of screening is similar to that of *C* and *F*, or, when well-sized coal is desired, it may be re-screened in a separate screen house, as with *K*. Low in first cost and operation, readily adaptable to extension and for covered storage. Breakage, into pea and smaller, may be as low as 8%, but is generally higher.

H. Dodge system, used for large storage, consists of storing on the surface in 2 conical piles by a trimmer truss supporting a flight conveyer. A unit has 2 trimmer trusses with track hopper, one central reloader, and a screening tower, with loading tracks and scales. Loaded cars are dumped into a receiving hopper and fed into the trimmer conveyer, which is built on a catenary curve from under the hopper to meet the incline of trimmer truss. Coal is discharged at apex of the growing pile, through bottom of conveyer trough. Bottom of trough is a flexible steel ribbon, which is pulled up to vary the discharge point as height of pile increases. Reloading is by a pivotal reloader (placed between the two conical piles), which carries a flight conveyer on its edge. Reloader travels on a curved track, and is drawn against the edge of the pile by wire cables winding on drums placed on the reloader. Coal is drawn to the pivotal point of reloader, where the conveyer is inclined, and is carried to screening tower. Shaking screens in this tower size the coal and deliver it direct into cars. Screenings are collected in a hopper and transferred to a screen house for sizing. Driving engines or motors are located near reloading tower. The plant is readily enlarged by adding additional piles. BREAKAGE in the prepared sizes varies from approximately 6% for egg to 2.5% for nut.

This type requires large area in proportion to its capacity. A 120 000-ton plant covers 250 000 sq ft, as compared with 105 000 sq ft for a MODIFIED DODGE PLANT, not including tracks. Practically all the coal is reclaimed by machinery. The modified plant usually has fixed trimmers in a storage building, with bulkheads between piles. Reloading is by a tunnel conveyer under each pile, delivering each size to its respective screen house, and thence to a storage pocket to be loaded into cars.

I. For large storage plants, especially for steam sizes. Consists of a side slope, as described under *E*, and single-track trestle with continuous bin chutes of sufficient height to permit feeding into a traveling cantilever trimmer, by which the coal is elevated and discharged onto storage floor. The trimmer comprises a platform mounted on trucks, traveling on a broad-gage track, parallel to dumping trestle. It carries a cantilever truss, and a scraping conveyer with a movable trough bottom, which permits discharge at any desired point. To increase capacity and prevent stored coal from flowing back on trimmer track, a bulkhead may be erected between storage floor and track. Reloading as in *E*. When surface contour will not permit an approach to the dumping trestle on easy grades, a loaded car plane can be installed. This delivers cars on the dump trestle, over which they should be operated by gravity to the apex of an empty car plane, down which the cars are lowered to the empty stand track. A steel barney, disappearing at the bottom into a pit, should be used on each plane. Plant should have ample receiving storage tracks and loaded-car stand tracks, operated by gravity, with loading scales for receiving and shipping. Hot water should be supplied for hydraulicking during winter reloading. Breakage is small when handling steam sizes.

J is a modified Dodge plant, consisting of a single-track trestle, with continuous bin chutes, on which cars are handled by a rope haulage system, spotted and dumped as desired. Hand-controlled gates feed coal from bins into an inclined trimmer conveyer, supported on a traveling truss. This traverses the length of storage floor, building up a wedge-shaped pile with rounded ends. A trimmer truss is carried on a bridge spanning the storage floor, the ends being supported on movable towers electrically operated. Reloading is by tunnel conveyer, placed under the storage floor and parallel to the trestle. A transverse conveyer receives coal from the reloading conveyer and conveys and elevates it into a screen house, where it is re-sized and loaded. Nearly 60% of stocked coal is tributary by gravity to reloading conveyers, which are fed by gates in tunnel roof; remainder is delivered to the gates by a traversing reloader. This consists of a steel truss, mounted on wheels and carrying on its edge an encircling conveyer. It is drawn against the face of storage pile by steel cables, anchored to each end of storage floor and passing around propelling sheaves mounted on reloader. Electric power, used for operating trimmer and propelling trimmer truss, is supplied by feeder rails, parallel to storage floor, and through collectors on the truss to the motors. Flexible cable supplies power to reloader from plug stations on storage floor. Tunnel conveyers and screen house are operated preferably by electricity. Plant should include extensive RR yards for receiving and shipping. Breakage is about the same as for type *H*.

K. For large storage plants and occasionally for retail yards. Stocking is by fixed or traveling tramways, spanning storage floor, traversed by cable railways. This type is readily adapted to plants receiving coal by steamers or barges, especially when storage floor is at a distance from unloading point or dock. Steeple unloading towers, at dock front, equipped with grab buckets, elevate coal to a receiving hopper. under which cable cars pass, automatically releasing a gate in the hopper which allows a fixed amount of coal to be discharged into passing car. Cars traverse a trestle to tramway and pass over it, automatically stocking the coal at any desired point, as the car door latch engages with a tripper. Reloading may be done by tunnel conveyers, transferring product to a screen house.

Quantity of coal reclaimed by gravity depends on number and location of tunnels; the remainder may be handled by dock scrapers. Cable tracks should be arranged for transferring coal direct from unloading towers to screen house. Screenings go to screenings storage, in cable cars operating in connection with an elevator. This type permits stocking of separate sizes in varying quantities by use of movable bulkheads between sizes, or by leaving valleys between them, but at a sacrifice of storage capacity. Increase in speed of stocking is accomplished by the addition of cable cars. The plant is especially adapted to irregular areas, using fixed trestles for the cable way, and for covered storage. Degradation in prepared sizes varies from 8 to 15%, due to high drops in stocking.

L. For large storage, especially at interior plants located on the Great Lakes, which receive coal by water. Grab buckets operating on traveling bridges are used for stocking. Storage floor parallels the dock front and is spanned by one or more bridges, which may be propelled along on the supporting tracks from one end of floor to the other. Bucket is suspended from a trolley, which operates across the bridge on a track hung from the

lower chord; a hinged boom, with tracks matching those on the bridge, extends over the vessel so that the bucket may unload direct from boat into storage. Reloading may be done by tunnel conveyers, or a conveyer may be placed at rear of storage floor, to receive coal from the grab bucket, either direct from vessel or picked up from stock. This conveyer transfers the coal to a screen house. For COVERED STORAGE, this type may be modified by placing fixed trolley tracks in the storage building, which match tracks on a traveling unloading tower, so that one tower may serve several tracks. Traversing trolley carrying the bucket may be operated by two methods, known as "rope" or "man-trolley." In the former, the bucket-hoisting and trolley-operating engine or motor is built into the bridge and connected to the bucket and trolley by wire cables. The operator controls the bucket and trolley. Two controlling stations are often installed, one overlooking the boat, for unloading, and the other arranged for best supervision of reloading. In the electrically-operated man-trolley, the hoisting and traversing motors are mounted on the trolley, with the controlling levers in a cab suspended from it. Usual bucket capacities are 1.5 to 3 tons for the former, and 5 to 7.5 tons for the latter. Rope trolley is cheaper in first cost, due to light construction required as compared with man-trolley; but is higher in breakage, since the man-trolley operator is always in view of his work, and can better lower the bucket onto storage pile when stocking, thus decreasing the drop and degradation. It also saves by unloading and reloading in large units. Fixed bridges may be arranged to span the screen house, thus eliminating reloading conveyers; but these are limited to small plants and require a bridge and screen house for each size stored.

This type is adapted to stocking separate sizes in varying quantities, with or without bulkheads, as under *K*, but does not lend itself to enlargement. It is usually rapid in stocking, the speed depending upon skill of operator; but speed of reloading is limited by the screen house capacity. Hoisting speed is about 500 ft per min; trolley speed, up to 1 500 ft per min. Degradation is approx 10%.

17. IDEAL SCREEN HOUSE

Essential elements. 1. Screens to remove undersize from each size reloaded.

2. Storage pockets for each size handled, to hold all the undersize made from the size being reloaded, unless sales orders can be arranged to permit loading undersize as made; otherwise, undersize must return to storage when its shipping pocket is filled.

3. Lip screens to remove pocket breakage.

4. Separate screenings storage floor, with transfer conveyers from screen house to storage, with arrangements to return them to the screens for re-sizing.

5. Arrangements to load either gondola or box cars.

6. Minimum breakage.

7. Minimum force of men, and low operating and first cost.

Design should include a receiving hopper, with feeder to shaker screens, one for each size handled, arranged one above the other and directly over the pockets. Each size of coal should gravitate directly from its shaker to its pocket, using telegraphs for reducing breakage. Loading into cars may be done as at mines, with preference for belt conveyer system (Art 8). All sizes above pea should pass over lip screens, the screenings being transferred to storage. Local and interior plants receiving box cars should be equipped with mechanical BOX CAR LOADERS. Where large tonnage is handled in reloading, the TILTING OR GRAVITY LOADER is superior to others. The first cost, approximating $50 000 complete, is warranted only where large capac is required. MOVABLE BOX-CAR LOADERS give excellent results when capac is small; cost, about $7 500 installed.

18. MISCELLANY

Mechanical car unloaders for gondola cars are generally used at shipping points at seaboard or on the Great Lakes, where large capacity is required. Car dumpers operate by elevating the car to a height from which the coal will gravitate into the vessel, at which point the car is turned over, allowing coal to run out. Box car unloaders or dumpers may be constructed like the box car tilting loader. Average rate for unloading box cars by hand is one car per hr per man.

Breakage of coal. This always occurs in handling anthracite, varying from 5 to 25%, according to method of handling. Causes are: dropping of coal, drawing coal under pressure from storage piles or pockets, poorly constructed chutes, and handling by conveyers, elevators and grab buckets. BREAKAGE FROM DROPPING varies with different classes of coal. Though it is impossible to avoid it entirely, it may be reduced by sliding

the coal in chutes or on itself; tests show that when sized coal is delivered on a pile it seeks its angle of repose by avalanching in large masses, with little breakage. DRAWING

Table 16. Breakage of Coal Due to Drop *D*, ft (R. V. Norris)

Size	Breakage into smaller prepared sizes	Breakage into small (steam) sizes	Total breakage
Broken	3% + 0.43 *D*	2% + 0.17 *D*	5% + 0.6 *D*
Egg	4% + 0.43 *D*	2% + 0.17 *D*	6% + 0.6 *D*
Stove	2% + 0.33 *D*	2% + 0.27 *D*	4% + 0.6 *D*
Nut	....	4% + 0.4 *D*	4% + 0.4 *D*
Pea	....	2% + 0.5 *D*	2% + 0.5 *D*
Buckwheat	....	1% + 0.25 *D*	1% + 0.25 *D*

COAL UNDER PRESSURE from deep bins or storage piles is a serious cause of breakage, though often neglected. When reloading from a gate under pressure, breakage is reduced by opening first those gates under the "run" or edge of the pile. CHUTES, poorly constructed, cause large breakage, and should be constructed in same manner as in breakers (Art 12). ELEVATORS and SCRAPING CONVEYERS cause breakage of from 2 to 5% for the former, and 2 to 4% for the latter. BELT CONVEYERS cause no breakage during transit, but the drop at discharge is often high unless discharge chute receives the coal at a tangent. GRAB BUCKETS cause some breakage, the percentage being in direct proportion to the length of their cutting edge per unit of coal handled; hence the greater the cubic capacity of the bucket the less the degradation.

HOWARD N. EAVENSON, MINING ENGINEER

Note.—Numbers in parentheses in text refer to Bibliography at end of this Section.

PREPARATION AND COKING OF BITUMINOUS COAL

1. GENERAL CONSIDERATIONS

Purpose of COAL PREPARATION is to increase the value of fuel by making it more suitable for uses of the consumer (1). This is done by: (*a*) screening or sizing; (*b*) mixing or blending; (*c*) cleaning. By combining any 2 or all of these methods, coal can be prepared to standard specifications. A preparation plant should produce clean coal, and refuse free of saleable coal.

Screening or sizing was the first method of increasing the value of coal as a fuel; mixing or blending is important in preparing coal for steam, metallurgical, and gas-making purposes. For steam coals, controlling the proportions of coarse and fine increases boiler effic, control of ash and fusion, and of rate of fuel feed. For metallurgical coals, mixing and blending permit control of ash, sulphur, phosphorus, ash-fusion temperature, and volatile matter; and for gas coals are often used to control size consist and analyses. Table 1 shows distribution of $-^3/_8$-in size in raw slack and after mixing.

Table 1. Distribution of $-^3/_8$-in Size in $1\ ^1/_8$-in Slack (4)

	Raw mine slack	Prepared and mixed slack
Number of cars	113	100
Aver % of $-^3/_8$-in	50.7	47
Percent of $-^3/_8$-in	Cars, %	Cars, %
Under 35	9	5
35–40	6	11
40–45	17	17
45–50	17	38
50–55	19	18
55–60	15	9
60–70	12	2
70 and over	5	0

2. MARKET STANDARDS AND USES OF BITUMINOUS COAL (1)

Definite standards for bituminous are lacking with which to compare results; anthracite is accepted or rejected on visual inspection (Sec 34). Table 1a shows factors considered for acceptance of bituminous coal; complete list in Bib (3). Visual inspection is not always sufficiently accurate for control, due to the variety of uses, as follows (3): stationary steam generation, colloidal; pulverised coal, hydrogenation; gas and coke making; domestic; ceramic products and cement burning; briquetting; locomotive fuel, bunker; metallurgical; cargo.

Table 1a

Type of Coal	Metallurgical	Steam	Gas	Domestic
Ash	x	x	x	–
Sulphur	x	–	x	–
Phosphorus	x	–	–	–
Fusion	x	x	x	–
Moisture	x	x	–	–
Proximate analysis	–	x	–	–
Size	–	x	x	x
Visible impurities	–	–	–	x
Dustiness	–	–	–	x
Uniformity	x	–	x	–
Volatile matter	x	–	x	x
Btu	–	x	x	–

3. HAND-PICKING

Hand-picking (1) is still widely practiced on sizes above 1 in. Tests on a large scale at a commercial plant show the accompanying percentages of extraneous matter (above 1.60 sp gr) remaining in the coal. Table 2 shows amount of waste removed per picker in the same tests.

Sizes, round hole, in	Sink at 1.60 sp gr (Art 8) in cleaned product, %	
	Limits	Aver
2 to 4	0.7–4.5	2.2
1 to 2	1.2–7.1	3.2

Table 2. Tons Waste per Hour per Hand-picker

Size, round hole, in	Limits	Aver
Over 4	0.8 -2.5	1.9
Over 2	0.05–0.4	0.3
2 to 4	0.15–0.3	0.24

Compared with hand-picking, figures in Table 2a indicate the elimination obtainable on various sizes by modern preparation plants (1).

Ash in the 1.60 sp gr sink material (Art 8) in hand-picked coal usually averages between 45 and 50%; that from mechanical preparation, 35–40% ash. Loss IN REFUSE from hand-picking, which generally contains 50–60% coal, is a real loss. The value of good coal in the pickings, if recovered, is often more than the cost of picking labor. Table 3 gives data on hand-picking at 9 plants; costs adjusted to equal labor scale of 1937.

Table 2a. Results of Mechanical Cleaning

Size, round hole, in	Percent sink at 1.60 sp gr	
	Steam coal	Metallurgical coal
2 to 4	0.5	0.2
1 to 2	1.0	0.5
3/8 to 1	2.0	1.0
−3/8	2.0	1.0

Table 3. Data and Costs on Hand-picking

Size of coal picked, in	A +4	B +4	C +2	D +4	E +4	F +3	G +2	H +2.5	I 2 to 4
Percent of raw coal rejected	10.6	23.5	2.5	10.4	10.0	3.7	3.4	13.3	1.9
Number of pickers	12	4.5	12	6	6	3	16	11	8
Tons per man:									
per elapsed hr	1.9	1.6	0.4	1.1	0.8	1.0	0.05	0.86	0.24
per operating hr	1.9	2.6	0.6	1.4	1.0	...	....	1.14	....
Cost per ton of rejected material	$0.38	$0.45	$1.86	$0.67	$0.88	$0.72	$4.28	$0.83 (a)	$2.97 (b)

(a) Contained 60% of coal in addition. (b) Less than half of total impurity (4.1%) removed by picking.

Hand-picking is done on conveying or shaking tables, in chutes, or in RR cars as material is loaded. The Marcus screen is also used as a picking-table.

Conveying picking-tables are belts or apron-pan conveyers, either flat-top or with skirt boards to guard the side links and chain. Flat-top table is preferable, as pickers can work faster by sliding off large pieces instead of lifting them over the skirt boards. Belts are used as combination picking-table and loading boom. Speed of 50 ft per min on conveyer picking-tables is preferred; max, 60 ft. Width should not be over 60 in.

Shaking picking-tables have greater capac, since pieces too large to lift can be guided off the table. The material spreads evenly at one particle depth, if not retarded by perforated plates.

Tables have steel or wood frames with steel decks 3/16–3/8 in thick, supported on inclined stilts of wood or steel, pivoted or fixed at both ends; tables should not be over 60 in wide; lengths, 10–30 ft, depending on number of pickers. Top of table not over 32 in above pickers' platform; slope, 5°–8°; speed and stroke adjusted for a speed of 50 ft per min of the material passing over the table; stroke, usually 4.5 in; speed, 150–155 rpm. Drive is by crank or eccentric, with flywheel.

4. FEEDERS

Feeders give steady flow of material. Storage bins or hoppers, above the feeders have sufficient capac to provide continuous flow at a rate obviating undue delays. Feeders are adjustable, for handling dry or wet materials at a uniform rate for a given setting. Following are types of feeders.

Fan-shaped plate, sloping 10°–18°. Coal is dumped on the narrow end; the wide end usually delivering to a screen, has adjustable convex curvature for spreading the coal evenly. It is inexpensive, has no moving parts, and causes little or no degradation.

Adjustable vertical gate, for free-flowing fine materials, is placed in a bin or hopper with a bottom inclined 45°, and set for the proper opening, or raised and lowered by connecting to a power-driven eccentric.

Swing-hammer regulator. When delivering lump material from hoppers, bridging is prevented by using large openings, the regulator keeping the material in check. Heavy hammers hang in front of the opening above the feeder, limiting flow to the depth established by height of the hammers above the feeder. When a large lump appears, one or more hammers rise to let it pass.

Belt feeders are well adapted for fine, dry material under 2.5 in, at capacities to 150 tons per hr; widths are to 42 in, lengths to suit conditions; min length depends on angle of repose of material at the height of feeder opening. Belts run at 20–60 ft per min. To increase the life of a belt handling abrasive materials, steel armor strips are riveted to the carrying side, with countersunk heads on the pulley side.

Apron feeder, for large capac and large lumps, provides regularity of flow with small power consumption and little headroom. Storage bin over the feeder should be designed to relieve as much weight as possible from the feeder pan and chain.

This feeder consists of a series of overlapping steel pans, to form a continuous conveyer carried between heavy roller chains and attached rigidly to the inner links. The conveyer moves between 2 fixed skirt boards, permitting large capac. The chain runs on an angle-iron or rail track; where it undergoes undue stress, a roller-track feeder may be used; the load on feeder and wt of the chains and pans are carried, through the chain bars, on larger rollers Speeds of apron feeders vary from 5 to 50 ft per min; widths, 24–60 in; lengths, 3–10 ft between sprocket centers. Capac depends on depth of material, which, with a regulating gate, should be twice the size of lump.

Roll feeder can proportion very accurately and has a relatively large capac; headroom is greater than for some other feeders. It is not adapted for materials over 6-in diam, but for conditions within its range its simplicity and accuracy are advantages. Peripheral speed, 5–20 ft per min.

Vane feeder resembles the roll, but the rotor has 4 or more vanes. It may be used as a measuring device, giving a continuous, uniform feed, and is adjustable for predetermined deliveries. It is not adapted to wet sticky material, as the vanes soon become packed. Like the roll feeder, it may be placed at bottom of a bin or at end of a chute; the material is deposited directly or carried farther by chute. Speed, 10–20 rpm; capac, 650–3 250 cu ft per hr at 15 rpm; size, 12–24 in diam, 15–18 in wide.

Reciprocating feeder, especially useful for lump coal, is a reciprocating steel plate forming the bottom of a hopper. It is supported on rollers and driven by an eccentric or crank. On forward stroke, the material is carried away from the hopper; on the reverse, the plate slides back, thus unloading a certain amount at end of the plate. Rate of feed is varied by changing speed of the eccentric or crank, or size of opening. This feeder is simple in construction and operation, accurate in delivering specified amounts of material at a uniform rate; and requires little headroom and power. The plate is subject to considerable wear, and the rollers, unless rotating freely, develop flat spots. Feeders are 15–60 in wide and 5–12 ft long; stroke, 3–8 in; speed, 10–50 rpm; power, 0.5–15 hp. A flywheel on the drive shaft is desirable.

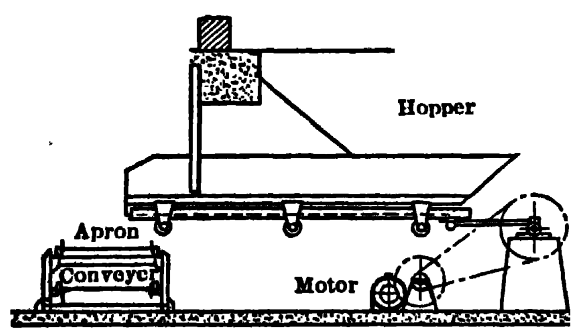

Fig 1. Reciprocating Feeder

This feeder may be supported on wheels (Fig 1), or suspended from pivoted hanger rods, or by a combination of both; feeder plate may be horiz or slope downward. It is not self-cleaning unless run at high speed. The hopper is best made with 45° sides and a vert end at least 12 in high (or a slope not less than 45°). It should take as much weight as possible from the feeder plate, which can then run faster, with less power and wear. When feeding a belt conveyer or screen with mixed sizes, the feeder ends should have extended fingers, of grizzly bars or rails, to deposit the fines on the belt as a cushion for coarse lumps.

Disk feeder. Bottom edge of the hopper is slightly elevated above the disk, to allow material to flow and assume its angle of repose within the plate's circumference. The hopper throat may be adjustable, and one or more plows set to discharge from the rotating plate. An agitator attached to the plate may extend up into the hopper to prevent clogging or bridging; this adapts the feeder to damp materials. The drive is by constant-, variable-, or multiple-speed motors, through open gear, chain drive, or gear reducers.

5. SIZING AND CRUSHING

Fixed-bar grizzly consists of screen bars set at an angle to allow the material to flow over them by gravity (2). The bars are usually of tapered or diamond-headed sections, set with the thicker edge at the top. Screens are 3–6 ft wide, 8–12 ft long; suitable for scalping large sizes when material is not sticky; used oftenest over bins or in chutes to relieve the crusher of small sizes; are the simplest and cheapest to install and operate; have practically unlimited capac, require no power and little attendance, and withstand rough work. Principal objections: (*a*) headroom required; (*b*) difficulty of changing size of product; (*c*) trouble due to changes in coeff of friction between screen and material; (*d*) low eff in exact sizing; (*e*) incomplete screening; (*f*) breakage of product.

Revolving or disk grizzly consists of a series of parallel shafts carrying disks, the spacing and diam of which leave square openings of the size desired. The shafts all revolve in same direction, but at different speeds; the first, at the receiving end of the grizzly, revolving slowest, succeeding ones slightly faster; slope, 15–20°. The openings are 1.25–4 in with 5–8-in shafts; disks, 9.5–18-in diam; screen surfaces, 24 by 68 in to 48 by 81-in; capac, 100–200 ton per hr for scalping; 75–150 ton for sizing; power, 5–7.5 hp. Space required, 73 by 56 in by 32 in high, to 84 by 78 in by 42 in high.

Revolving screen (2) is rare, due to excessive breakage; may be used as a combination breaker and screen (Bradford breaker), and a modification for breaking laminated material in the coarse refuse from a wet cleaning plant, screening out the fines and re-treating them. Max size of material, about 3 in. Screens may be 24–72 in diam, and 6–24 ft long, in 2 or more sections; they are supported on through shafts, or trunnions. Since only 1/6 of the perimeter is covered at one time, the screen has a low capac per unit area; more space is required for a given capac than other types. For damp coal, increase screen area 50% Screens are set on a slope of 5°–7.5°; peripheral speed, 225–250 ft per min; above 275 ft per min, effic decreases rapidly. Power for a screen revolving on a shaft; hp = tons per hr ÷ 10; or diam screen (ft) × length (ft) ÷ 9. Two or more screens are often set concentrically on same shaft; innermost is the coarsest, the others making additional separation. This reduces the space needed for a given plant.

Diam hole, in	Tons per hr per sq ft area
1	0.33–0.25
1.5	0.50–0.25
2	0.67–0.50

Shaking screens are advantageous in that the entire area is utilized; hence, greater capac for a given space. They require less headroom, can be used for damp coal and for dewatering, and are well adapted to sprays. The coal slides over the surface with little breakage. Disadvantage is the vibration set up in the structure. Shaking screens are widely used in tipples for sizing dry run-of-mine coal over 0.5 in and not under 0.25 in, incidentally serving as conveyers for loading on several tracks.

The frame is of steel plate and structural shapes; may have wooden sides. The screen may be used not only for sizing but also as a shaking conveying chute, by blanking off part of it with plates. Primary or run-of-mine screens are heavy, to withstand hard service. Drive and support should be well braced, to prevent flexure and shear of rivets and bolts. Lighter steel, or wood and steel, frames are suitable for secondary screening of small sizes. Light screens are run at higher speeds and with shorter strokes than for run-of-mine. Their inclination is less, permitting more exact sizing without reducing capac. Shaking screens may be up to 12-ft width; usually, 5–8 ft. Width should be figured to give a thin bed, without excessive speed of flow; aver flow, 50 ft per min; max, 75 ft; length must satisfy the tolerance of undersize in the oversize; the longer the screen, the greater the degradation.

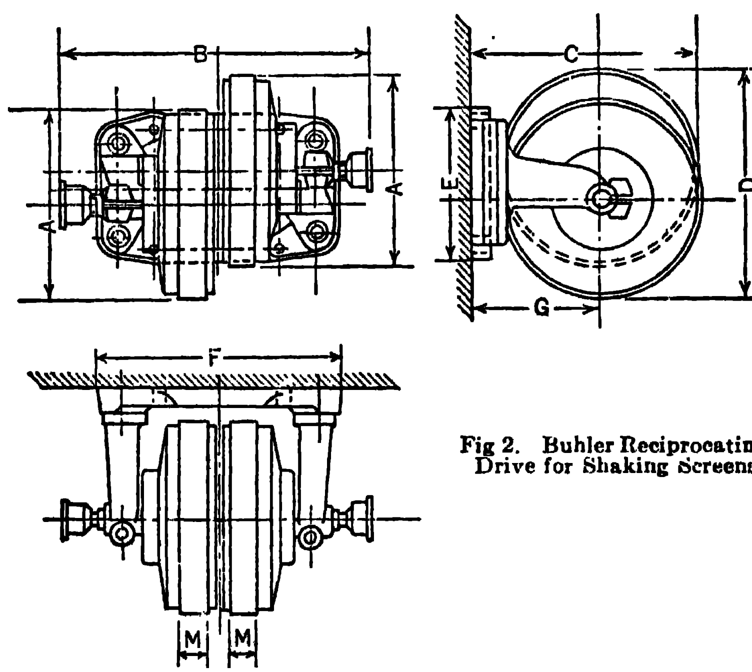

Fig 2. Buhler Reciprocating Drive for Shaking Screens

A shaking screen may have one frame, or 2 or 3 superimposed frames with one drive; or, the frames may be tandem, one drive to each 2 frames. When superimposed, the plates with larger holes are on the top deck; in tandem arrangement, the fine-hole screens are at the feed end, the others at discharge end. Superimposed frames are spaced to

allow room between decks for changing and removing the screen plates. Bottom deck may be blanked with plate, for use as a shaking conveyer. Chutes are attached to bottom or side for discharging the products at desired points. Screens are hung by rods, wire rope, wood-bound hangers, or set on wooden or steel stilts, fixed or pivoted at each end. The drive is usually an eccentric or crank. A recent application is the BUHLER RECIPROCATING DRIVE (Fig 2); its dimensions with flywheel follow:

Rpm	Dimensions, in								Weight, lb	
	A	B	C	D	E	F	G	M	Without load	Max added load
460	13 3/4	12 1/2	16 1/8	15 3/4	9 3/16	13 5/8	8 15/16	1 1/2	90	40
460	12 1/2	12 1/2	14 1/8	14 1/2	7 7/8	11 1/2	8 3/4	1 1/4	75	31

540	8	12 3/4	9 1/4	9 3/8	5 1/4	10	6 1/4	1 1/4	34	8

Table 4. Data on Run-of-mine Screens
(All with 4-in holes, except as noted)

	Tons per hr per sq ft of perforated area			Loaded product
	Feed	Through	Over	Moisture at 105° C
A	7.63	5.58	2.06	2.9
B	3.22	2.34	0.88	3.3
C (a)	2.33	1.30 (a)	1.03	2.5
D	3.71	3.18	0.53	2.0
E	5.16	4.36	0.80	2.0
F (b)	6.22	4.98	1.24	......
G	2.49	0.79 (c)	1.70	1.4 (d)

(a) Marcus screen; through product 2–4 in. (b) 3 3/8-in holes. (c) Through product 3 3/8–4 in. (d) Moisture at 85° C.

The 3 variables of slope, speed, and throw are interdependent, and the right combination must be ascertained for rapid and complete screening. Run-of-mine shaking screens average 100 rpm, with a throw of 6 in, there being less variation in these adjustments than in the slope, which averages 3.5 in per ft, or 16° 55′. Light fine-coal screens run at 130–160 rpm, with 3 to 5.5-in stroke. The less the slope the higher the speed and longer the stroke for a given capac. Table 4 gives capac of dry screens at 7 large installations; for other examples, see Table 9.

Parrish screen has wide applications for bituminous coal. It usually has wooden sides, is suspended on flexible wooden hangers, and driven by wooden arms, with spring pieces to provide flexibility. It is cheap and light in weight. Sides of frame are usually 3 or 4 in by 6-in oak or yellow pine, sometimes 6-in angles or a plate and angles; cross members, 2.5- or 3-in angles. Punched plate, of ordinary steel, Monel metal, bronze, or stainless steel, is flanged and bolted to sides. Wire mesh, sometimes used for fine sizes, tends to blind at coarser sizes. Screens are 4–7 ft wide and 12–70 ft long; complete deck weighs 1 000–6 000 lb. Slope, 0.5–1.5 in per ft; the steeper slope increases conveying capac at expense of effic; on a low slope, lump coal travels faster than fine; aver travel with 5-in stroke and 160 rpm is 60 ft per min.

Frames are commonly supported from above by oak, hickory, or ash boards, 1 by 8 in, rigidly fastened to screen and to the overhead structural member; flexibility of the boards allows sufficient movement of screen. Hanger boards often slope backward 1.5 in per 12 in, so that screen rises on forward stroke and accelerates movement of coal. Steel hangers or chains may be used instead of boards, and screens are sometimes supported from below on flexible legs. Single or superimposed groups of 2 or 3 screens are oscillated from cranks or eccentrics through wooden arms, rigidly bolted to each screen, with a part reduced in cross-sec to provide flexibility; steel arms with wrist-pin connection to screen frame are also used. Eccentrics are commonest on driving shafts, but cranks have advantages. If more than 1 screen is driven from same shaft, eccentrics or cranks are at angle of 180° (for 2) or 120° (for 3) to neutralize structural vibrations; power, 3–10 hp per screen. Usual adjustments: for lump coal, speed 100–150 rpm, throw 6–4.5 in; for prepared sizes, speed 125–160 rpm, throw 5–4 in; for steam sizes, speed 150–200 rpm, throw 4.5–3 in.

A new type of drive for shaker screens (Link-Belt Co) is shown in Fig 3. The motor and eccentric shaft are mounted on a counterweighted base, suspended by links from the main structure. The thrust to oscillate the screen is absorbed by the suspended base, thus eliminating vibration in the machine.

Vibrating screens. The impulses are imparted mechanically or through electromagnets; the movement may be circular, elliptical, or straight-line. The whole frame may vibrate, or the vibrating mechanism be attached to the screen cloth on the longit center at 1 or 2 points. Screens may be horiz, or, for moisture reduction, inclined 2°

upward towards the discharge end. They are 1-, 2-, or 3-deck; 2-6 ft wide and 3-20 ft long; usually supported on a fixed base, through an anti-vibrating medium of springs, rubber, cork or wood. The frame is fixed or adjustable as to inclination; suspended by wire ropes or rods, with springs and turnbuckle vert adjustment. For capacities, see Table 9.

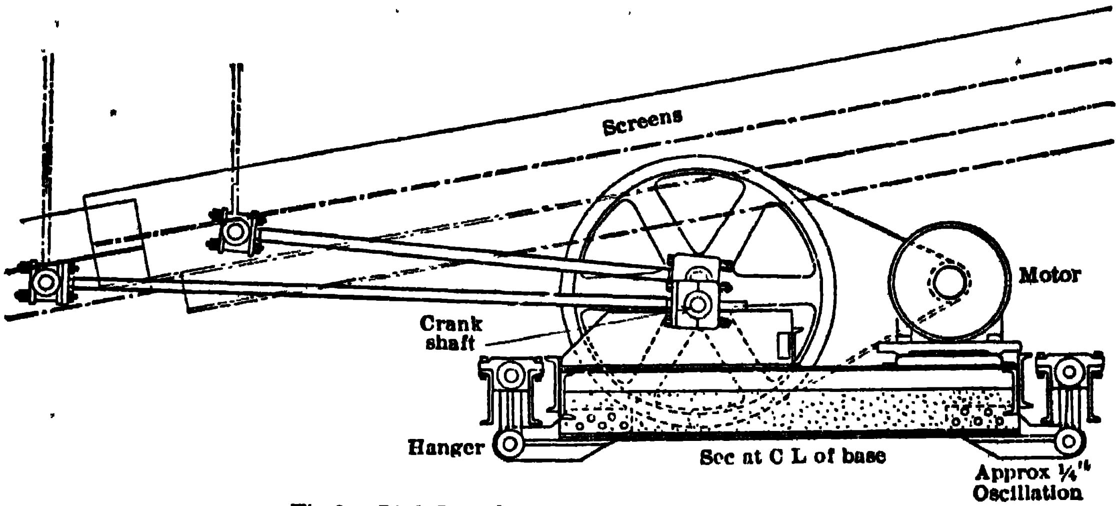

Fig 3. Link-Belt Co's Drive for Shaking Screens

Re-screening. Limited space and trackage may require loading of 2 or more coal sizes on same track; the main shaker, also, may be too short to make all the sizes. Such conditions involve re-screening of minus 2-in or 1-in slack or smaller, which may be elevated to screens set over the tracks at suitable distances from loading points, to give room for shifting RR cars. The re-screens are set over 2 or more bins, depending on number of sizes. Sized coal (except slack or fines) is deposited in the bins by spirals (see Sec 34) or lowering chutes, to avoid breakage. Vibrating screens are preferred, due to their larger capac for a given height and space.

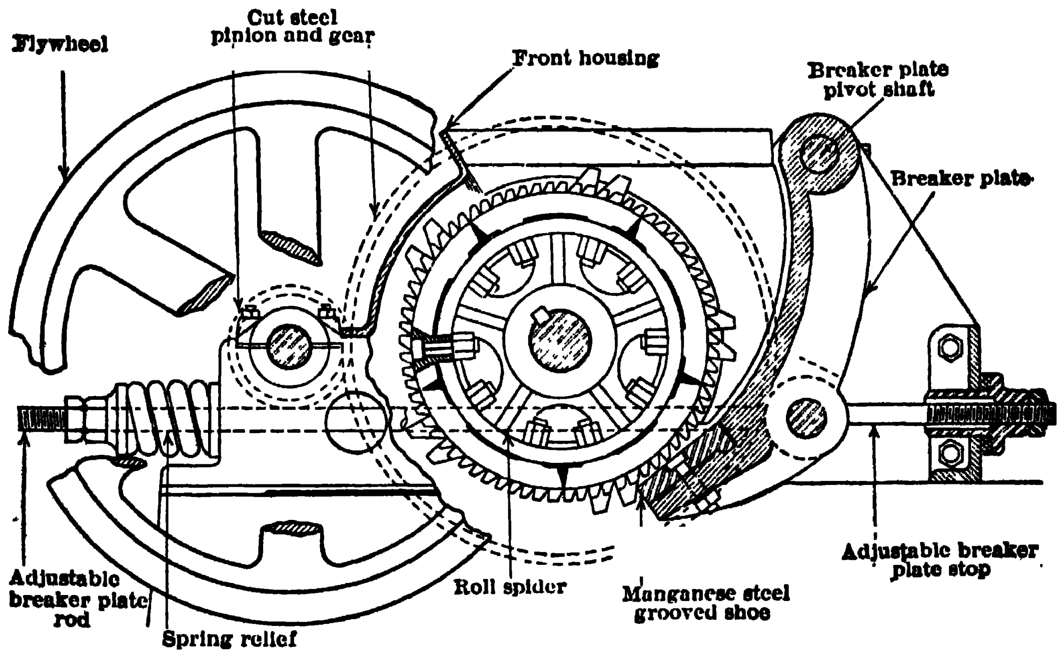

Fig 4. Single-roll Crusher

Crushers. By proper selection of equipment, the yield of coarse sizes is greater than when rough mining and handling are permitted; crushed products have more cubical pieces. Crushing may also be applied in connection with washing, to free attached particles of rock; or to raw coal prior to washing, or to refuse before re-washing. Crushers should have uniform feed, with provision for removing undersize product by by-passing. For rolls, the feed is adjusted to flow across their full face to prevent uneven wear; they should have a spring relief (Fig 4), to allow hard substances, as tramp iron, sulphur balls, or wood to pass through without breaking parts or bending a shaft.

Single-roll crusher has 2 side frames connected by cross members, on which are carried a revolving roll and a breaking plate held stationary by spring action. The drive, through gears, gives a peripheral speed of 400–600 ft per min. The roll has crushing teeth about $^7/_8$ in high and slugging teeth 1.5–4 in high, depending on size of feed. Size of product is adjusted by moving the crushing plate towards or from the revolving roll.

Double-roll crusher has smaller capac than the single roll, but is more effic, and produces larger yield of a desired size. There are several makes. One type has its 2 rolls connected by a chain drive, and has wide latitude of adjustment for different sizes of feed and product. The double-roll type requires less power, as there is less friction than against a stationary plate. Crushing is more uniform because the absence of backlash in the drive permits the teeth to mesh properly. At peripheral speed of 300–600 ft per min, rolls produce more coarse sizes than at higher speed. For large capac, oversize rolls are desirable. Rolls may be solid with inserted teeth, or in segments bolted to a C–I or steel spider; segments have integral-cast teeth, and may be of chilled C I, manganese steel, or heat-treated alloy steel, the latter being favored.

Power depends mainly upon hardness of the coal. Soft coal requires $^1/_8$ hp per ton per hr (crushing to 4-in aver cube) to $^1/_4$ hp (crushing to $^5/_8$-in). For hard coal, power per ton per hr is about doubled for corresponding sizes. Worn teeth diminish capac and increase power required.

Pick breaker pierces the coal by rows of vert picks, making stove, furnace, and egg sizes. The coal, carried on a plate conveyer, is stationary while the picks descend, and is moved forward when the picks rise. The steel frame supports a plate conveyer carried on a chain. There are 2 sets of picks, for preliminary breaking and final sizing, mounted in plates bolted to an oscillating frame.

Hammer breaker is chiefly for producing fines under 0.5-in for coking, but is applicable also to many other purposes. It is designed for products from $-^1/_8$-in to -2-in; also to break preliminary to washing, or to crush a middlings product, of laminated coal and rock, prior to re-treatment.

Bradford breaker is a slowly revolving cylindrical screen, within which the coal is raised by internal shelves, and dropped repeatedly until broken small enough to pass through the screen. Speed, 15.5–17 rpm, according to size. Maintenance cost is low; capac, 25–600 tons per hr.

Table 5 shows operating factors of several types of crushers (*Coll Eng*, Oct, 1931).

Table 5. Crusher Operating Features

Type of machine	Max feed, in	Size of product, in	Output, tons per hr	Hp per ton per hr
Vert pick..	run-of-mine	8–2	45–250	0.09–0.25
Horiz pick...	"	6–2	20–40	0.25–0.35

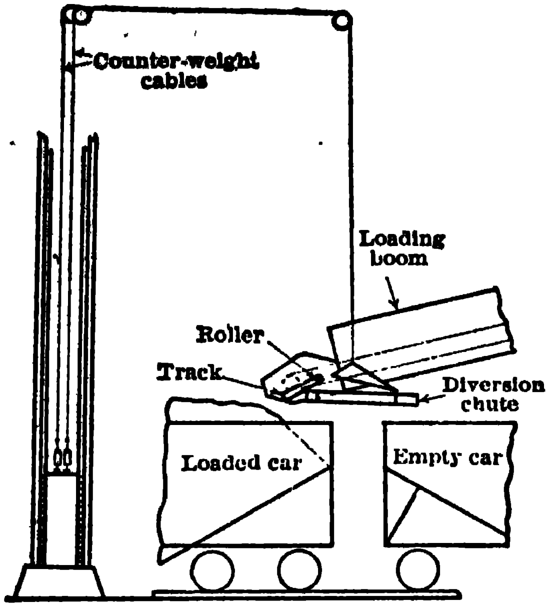
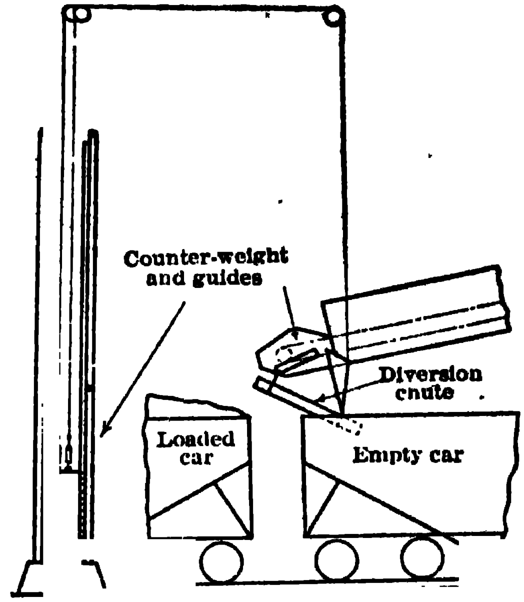
6. LOADING BOOMS AND MIXING (see also Sec 27)

These may consist of an apron or belt conveyer, shaking pan, or a low-flight, double-stranded chain conveyer with steel bottom; the conveyer is not over 60 in wide, for discharging into RR car. The boom is usually on the center line of a track and discharges down-grade, the car traveling away from it while loading; the boom may also be swiveled for discharging into a box-car loader between the tracks. For other details, see Sec 27. Speed of conveyer is from 50 ft per min on combination picking table and boom, to 100 ft per min on belt-loading booms. Capac, tons per hr = 1.55 SWT, where S = speed, ft per min; W and T = aver width and depth of material, ft. Power, depending on length of boom, capac and slope, is 5–60 hp; for boom hoists, 3–10 hp. Fig 5 shows use of an automatic loading chute at end of boom.

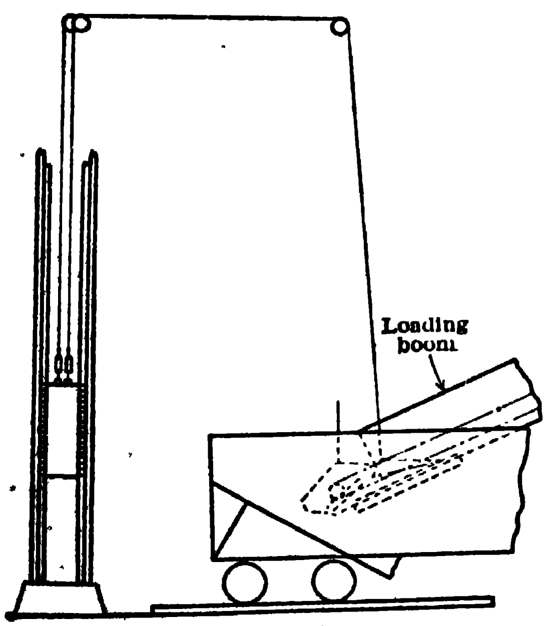
Simplest form of mixing conveyer straddles all the loading tracks and is arranged so that as many booms as desired may be raised to discharge into the conveyer on one or both of its strands, the mixed coal then being spouted to any one track. For large tonnages, the screens may discharge the different sizes onto band-conveyers running across the tracks and delivering to the horiz sections of the several booms or spouts above the tracks; each cross-conveyer has gates to discharge part or all of its load onto any boom or chute. For blending, the various sizes may be conveyed, elevated, or stored in bins having spiral lowering chutes (Sec 34) and withdrawal chutes. The coal may be drawn from bins by variable-speed feeders, and passed over degradation screens and anti-breakage spouts to mixing conveyers, loading booms, or telescopic loading chutes.



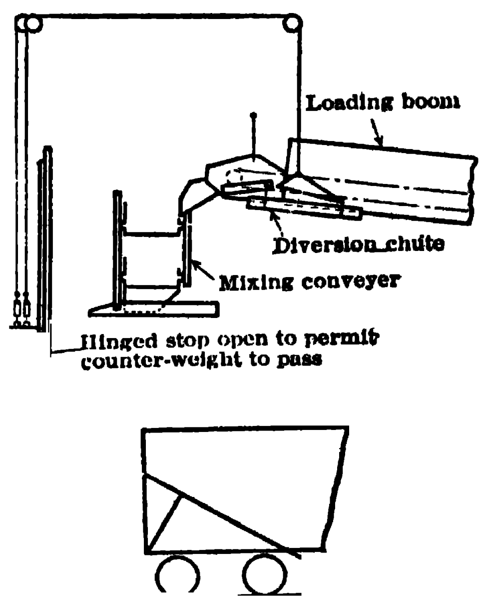
Position No. 1
Topping out car. Counter-weight at rest., to release chute upon upward movement of boom



Position No. 2
Boom raised, for chute to divert coal into oncoming car. Cables slack



Position No. 3
Empty car in loading position. Boom, dropped into car, bringing counter-weight into play and moving diversion chute under boom



Position No. 4
When mixing conveyer is used at outer end of boom, an intermediate hinged stop is required for the counter-weight. Counter-weight rests on this stop for positions 1, 2 and 3, and passes through it when boom is loading into conveyer

Fig 5. Automatic Coal-loading Chute

7. CONVEYERS. CHUTES AND LAUNDERS (see also Sec 27)

Conveyance includes: handling of raw coal; collecting for selective loading; delivery of lump and egg to rolls; re-screening operations and delivery of their products to pockets and thence to cars; delivery of coal to cleaning units, and sized products from screens to cars; disposal of refuse. Commonest types of conveyer: (*a*) inclined or horiz longit shaking; (*b*) inclined side-shaking; (*c*) flight; (*d*) belt; (*e*) pan; also, screw and bulk conveyers, chutes and launders.

Longitudinal shaking conveyers are for small tonnages of prepared sizes. They are inexpensive but noisy, and, unless designed to convey only one layer deep, cause coal breakage.

Moisture, temp, and shape of broken coal affect speed of travel; in general, to convey 100 tons per hr, a width of 30 in, slope of 6°–7°, and 150 6-in strokes per min is correct practice. Wooden hangers, with min length of 5 ft (aver 8 ft; max 12 ft), spaced 5–7 ft apart, are 8–10 in wide and 0.75–1 in thick. By inclining them forward in direction of travel, the conveyer slope may be decreased (compare shaking screens, Art 5). A conveyer with 10-ft hangers, inclined 3 in, and oscillated at 150 strokes per min, may be set horiz; speed of travel for prepared sizes, about 60 ft per min.

Side-shaking conveyers are rare. For the same service they must be steeper than the longitudinal type, and corners should be rounded to avoid breakage.

Flight conveyers (see also Sec 27), applicable to all tonnages, are especially suitable for distributing and mixing at several discharge points. They have the advantage of carrying a load on both runs, if desired.

The flights are 6–15 in deep and 12–60 in wide, of $^3/_{16}$–$^3/_8$-in plate, dished or reinforced with structural angles. Flights 16 in wide or less are carried by a single strand; wider ones by double strand of roller, strap, bar-link, or drop-forged chain. Speed for roller chain is usually 100–150 ft per min; bar-link and forged chains, 50–150 ft, 80 ft per min preferred. Roller chain is adapted to dry coal, has less frictional resistance, but weighs more per ft for a given strength than forged or bar-link; latter 2 chains are better for wet coal or to operate in water; for refuse, the bar-link is recommended. Flights 3 in high serve well for conveyers that are horiz or inclined up to the angle of repose of sized material.

Materials used in flight conveyers handling wet, corrosive, or abrasive coal or refuse: chains should be of corrosion-resisting steels; heat-treating increases strength and resistant properties; sprockets are of cast steel, for strength and to permit welding of teeth on worn sprockets; conveyer bottoms are of $^3/_{16}$–$^3/_8$-in mild steel, or of abrasion- or corrosion-resisting plates; flights of spring steel take polish and wear longer than mild steel.

Belt conveyers are for comparatively long distances and dry coal; widths, 12–60 in; speed, 200–400 ft per min; inclination, up to 18° or 20°, depending on size of coal. They are adapted to all sizes, including run-of-mine, and for capac to 1 500 tons per hr.

Pan conveyers are best for large tonnages, short distances, and inclinations to 30°. They are usually of $^3/_{16}$- or $^1/_4$-in plate, in double-headed flights, and carried on strap-roller chain at 9-, 12-, 18-, or 24-in pitch, depending on capac. Rollers travel on angle-iron or 20- to 30-lb T-rail track; speed, 75-100 ft per min.

Costs. Of the mechanical conveyers, the pan is most and belt conveyer least expensive in first cost. Operating cost and upkeep are about the same for all inclined conveyers, which are normally lower in first cost, operating, and upkeep, for same vert lift, than gravity-discharge elevators.

Chutes are conveyers only in a limited sense, their normal function being to lower coal without breakage. They have rectangular, rounded or semicircular cross-sec. Chutes that change direction should be of spiral form or with warped or triangular plates, so that coal will slide freely (Sec 34); as they wear considerably, especially in handling wet coal and refuse, bottom and sides should be made of, or lined with, abrasion- and corrosion-resisting metals. Slopes vary with moisture, temperature, shape and size of coal, and nature of chute bottom. When steeper slopes than those required for flow are unavoidable, retarding devices are placed in chutes, such as weighted chain, loops of wire rope, belting, or other baffles. Wooden chutes are lined with steel plate. To prevent blocking, width of chute is about 3 times the size of largest lump.

Storage bins, for raw coal and for sized coal intended for blending, require LOWERING CHUTES OR TELEGRAPHS (Sec 34) to reduce breakage.

Launders convey products by aid of water on flat slopes. Very little if any breakage of coal occurs in well designed launders. Capac depends on the pitch and amount of water rather than on the width. (For sand-conveying launders, see Sec 10, Art 92.) Launders may be of concrete, steel, or wood-lined; cross-sec, rectangular or semi-circular.

8. TESTING FOR METHOD

General. Design of a preparation plant should begin with careful examination of the coal to be treated. Investigation may start with samples from boreholes, to be followed, as mine development advances, by channel samples from working faces, and finally by bulk samples representing aver yield expected from the mine, and depending as much on mining method as on nature of seam. Essential factors: (*a*) distribution of sizes in run-of-mine output, ascertained by screen analysis; (*b*) distribution of impurities, all heavier than coal, among the several sizes, and their total amount in the mine output, both of which features are determined by float-and-sink analysis (see below). Correlation of screen and density analyses will then indicate: (1) whether a coal meeting the specifications of the expected market can be prepared; (2) whether a reject can be discarded (also, its amount) sufficiently free from coal to be not worth re-treating; (3) amounts of material of intermediate grade to be re-crushed and treated, if not salable as an inferior fuel; (4) at what sizes and densities separations should be made for max profit. To supply a specialized market, separations must sometimes be made at sizes or densities not favorable to the coal in question, entailing added cost for construction and operation, and increased losses in refuse.

Sampling. Methods of sampling in a mine are described in Bib (11); those for bulk or cargo lots, in Bib (12). Following data refer mainly to sampling for plant control, for examination of raw coal as to its washability, or in general, where a flowing stream of

(*a*) Gross wt of sample is increased if any of it is to be removed, as "head" sample, for other tests. (*b*) For a sized refuse, wts to be taken are those specified for corresponding sizes of coal, plus 50%. (*c*) Total wt may not be less than sum of wts specified for individual sizes composing the gross sample; either number of increments or their individual wts may be increased to yield this total.

coal can be cut for sampling. The material taken at one cut to represent the cross sec of the flow is called an "increment"; sum of these constitutes the gross sample. The number and weight of individual increments required to yield an authentic sample depend upon: (*a*) max and min size of fragments; (*b*) tonnage represented by the sample; (*c*) nature of test to be applied to the sample, whether a screen analysis, a float-and-sink test (below) with or without previous sizing, or a chemical analysis.

Adherence to a fixed sampling schedule is desirable for comparability of results. A schedule adopted by the Pittsburgh Coal Co is given in Table 6; recommendations by 2 authorities as to min wt of samples proper for float-and-sink analyses, in Table 7. Tendency towards segregation of sizes in a flowing stream demands attention (9); wherever possible, sample should be taken at a point immediately following some mixing operation. Unaccounted losses of moisture must be avoided. Samples may be reduced in bulk by "alternate shovel" or "long pile" methods, if above 3/8-in size; smaller sizes, on mechanical riffles cutting out at least 10% of gross sample (see Sec 29). Samples for sizing tests must be handled cautiously to avoid breakage. For satisfactory size-weight ratios in samples for washability tests (rarely permitting a reduction in size before dividing the sample), see Bib (8).

Screen analysis. In modern plants, hand-picking gives place to mechanical cleaning at about 6-in size. When testing a run-of-mine sample, the sizes usually adopted are: +6-in; 6–4 in; 4–3 in; 3–2 in; 2–1.5 in; 1.5–1 in; 1–0.75 in; 0.75–3/8 in (all round-hole screens); 3/8 in–4 mesh; 4–8; 8–14; 14–28; 28–48; 48–100; 100–200; −200 mesh (Tyler std or equivalent square-hole screens) (see Sec 31). Each sized product, down to 48-mesh, may be separately tested by the float-and-sink method (below) at densities graduated systematically from 1.3 to 2.0; material finer than 48-mesh is usually considered clean coal.

Float-and-sink testing. Since all wet-cleaning processes (except flotation) depend upon differences in sp gr between coal and its impurities, determination of amount and distribution of impurities (as to size) is a valuable guide in designing a process. Run-of-mine may contain constituents ranging from pure coal (sp gr, 1.25) to clean slate (2.8) and pyrite (5.0); "bony" coal, an indefinite mixture of carbonaceous and finely divided inert matter, is very troublesome due to its intermediate density. Impurities are often in thin laminations, but separable on further crushing into light and heavy components.

Test is conducted by immersing the sample, preferably sized between 2 consecutive screens (see Screen analysis) and free from dust, in a series of heavy solutions (see below) graduated as to density, usually beginning with the less dense. Float material is removed, washed (if necessary), dried, and weighed; that which sinks is re-treated in the next heavier solution. This procedure may be reversed if the impurities disintegrate in the solution; starting with the densest solution (usually 1.70 sp gr), the heaviest (sink) components can be eliminated at the outset. For a complete test, solutions range from 1.30 to 1.70 sp gr, in steps of 0.05; for routine testing, customary densities are 1.4 and 1.6, yielding 3 products. When all sized products from the original sample (usually excluding that finer than 48-mesh) have been examined, and a composite calculated, it is possible to determine what proportion of the raw coal can be: (*a*) sold to specifications, (*b*) discarded as refuse, (*c*) improved by further crushing and repeated washing. Each item has direct bearing on design and operation of the plant.

Table 8. Composition and Density of Heavy Solutions for Float-and-sink Testing (13)

Density at ord temp	Anhydrous salt, gm per 100 cc solution		Percent by volume

1.25	26	26	51.2	48.8
1.30	31	31	58.0	42.0
1.35	35	35	64.8	35.2
1.40	39	40	71.5	28.5
1.45	42	..	78.1	21.9
1.50	46	..	85.1	14.9
1.55	49	..	91.9	8.1
1.60	52	..	....	....
1.65	55	..	....	....
1.70	58	..	....	....
1.74	60	..	....	....

Heavy solutions for coal testing are: (*a*) aqueous solutions of $ZnCl_2$ or $CaCl_2$; (*b*) organic liquids, as carbon tetrachloride (sp gr, 1.584), or bromoform (2.904), diluted with benzol or toluene. Latter group, though more expensive, has advantages of wetting dry coal freely, and evaporating from the samples at end of test, without washing. Solutions of

the metallic salts, especially at higher densities, are viscous (hence, not recommended for samples finer than $^3/_8$ in), and must be thoroughly washed from the products to avoid errors in weighing and analysis. With precautions as to washing, the chloride solutions may be used on samples down to 48-mesh. For routine and large-scale testing, $ZnCl_2$ solutions are widely used (Table 8) (13). With commercial grades of $ZnCl_2$ or $CaCl_2$, allowance must be made for their H_2O contents; sp gr of solution is tested by hydrometer. For testing at densities above 1.70, methyl iodide (2.278) and bromoform (2.904), diluted with benzol, are available. For details of float-and-sink procedure, see Bib (5, 7, 14, 15), also 2nd edn of this book, p 2009.

Float-and-sink apparatus. Small-scale tests, with lumps to 1-in size, can be made with a spoon and a beaker about $^3/_4$ full of solution at desired density. Coal sample is stirred in, a little at a time; floating material is spooned out, replaced by more sample, and operation repeated, allowing sink to accumulate. Before last removal of float, the sink is stirred to liberate entangled

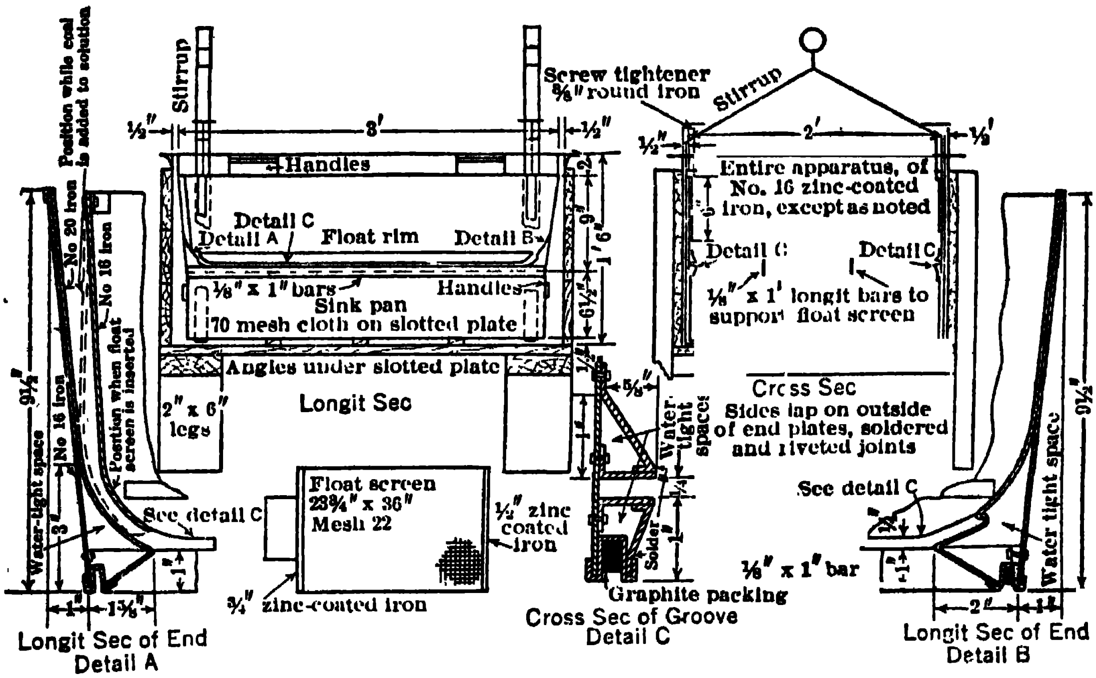

Fig 6. Details of Float-and-sink Testing Apparatus for Coarse Coal (5, 14)

light particles. For larger-scale testing, specially designed (but simple) equipment is desirable. Fig 6 shows a device used by McMillan and Bird in 1924 (5, 14). It has a flexible screen, inserted from above and outside the tank, to close the bottom of the float pan before lifting it off the sink pan and out of the tank.

9. PLANT DESIGN

Capacity of plant (1) influences design chiefly as to provision for re-treatment. In a given plant, it may not be economical to install re-treatment units; while such omission inevitably reduces effic, cost of re-treatment often exceeds the gain therefrom. In large plants, effic of cleaning is most important; inefficiency is inexcusable, except when the percentage of refuse is very low. Experience in ore concentration has shown how rarely a clean finished product and a clean refuse can be made in a single unit. Re-treatment is necessary for producing clean coal of uniform quality and a refuse reasonably free from recoverable coal; it also serves to adjust variations in quality of feed, in operating the primary units, and maintaining uniformity in both cleaned coal and refuse. **Delivery** of raw coal to the cleaning plant is a variable item in the layout, and methods show wide differences. Some cases require nothing more than a conveyer or elevator from tipple to plant. If raw coal is first stored in bins, with provision for mixing to maintain uniform feed, this may become a large first-cost item.

Screening equipment varies widely with size of raw coal and number of sizes of product; it also makes a difference whether the treated coal is slack, loaded unsized, as for coking. Sizing screens may also be used for dewatering (see sludge recovery, Art 14). Table 9 gives data on screens (see also Table 4).

Loading and mixing depends upon mixing facilities and whether sized coal is handled on booms. Number of sizes loaded at one time determines the number of tracks, also possible necessity for storage bins for certain fine sizes. Desired mixing and blending determine the bin and conveyer system.

Refuse may be conveyed to a bin outside of the washer and loaded into RR cars; or by larry cars, aerial tram, or truck to the dump. If distance is not too great, and water abundant, refuse may be flumed to dump; when previously stored in bins, it should be partially de-watered in elevators or drainage conveyers, or, for sludge, on filters. In one installation, refuse over 3/8 in was crushed to minus 3/8 in by swing-hammer or ring-crusher, mixed with water, and pumped to dump (20). Dumps should be so situated that fumes from fires in them will not cause a public nuisance.

Costs. Analysis of OPERATING COSTS should be correlated to indicate sources of inefficiency. Table 10 compares costs at 4 types of plant; *A* is a wet plant preparing steam coal; *B*, for metallurgical coal; *C*, a dry plant for steam coal; *D*, a combination wet and dry plant for metallurgical coal. The proportionate expense for cleaning coal is shown to be approx the same, regardless of type of equipment. Relative costs of screening and picking, and of loading and mixing, vary with size of coal, numbers of pickers, and amount of sizing, blending and mixing. Table 11 itemizes CONSTRUCTION COSTS for a complete wet-process preparation plant, calculated as percentage of total cost.

Table 10. Operating Cost (Labor and Supplies Only) at Four Typical Cleaning Plants

	A	B	C	D	Aver

10. WET-CLEANING UNITS: JIGS AND LAUNDERS

In American practice, the following cleaning units are widely employed.

Baum jig. Fig 7 shows a longit and transverse sec of a 2-cell, 5-compt jig. Compressed air is the pulsating medium, thereby avoiding back suction. The jig is divided longit into 2 parts, and transversely into smaller compts, generally 3–6, according to the coal treated. The shell and dividers are of steel plates, welded or bolted to prevent weaving or "breathing."

The screens, 5–8 ft wide and supported on a steel frame, are on one side of the longit wall. The air valve is adjustable to give any desired upward veloc during any portion of the pulsation period; settling period is similarly under control. Water supply is adjustable after valves W1, W2, etc. are set. Pulsation air is admitted at valves C1 to C5, set for such quantity of air as will maintain mobility in the bed and permit rock to separate from coal by gravity. Rock settling on the screen moves out through adjustable gate *G* and rotary valve *H* to elevator. Fine refuse passing through screens reaches elevators via screw conveyers *L* and *S*. Withdrawal of refuse is continuous, as fast as it accumulates on the screen; rate is controlled automatically by a float *F* actuating an ejector drive mechanism; so long as the depth of refuse remains fixed, the ejector speed is constant. Valves *H* and *P* are controlled automatically by patented devices, both electrical and mechanical.

Table 12 gives data on a test of a Baum jig, operating as follows (17): rated capac, 80 tons feed per hr; actual feed, 100 tons; size of feed, minus 3-in round hole. First cell, 4.5 ft long, 5 5 ft wide; second cell, 10 ft long, 6.5 ft wide. Depth at overflow, 16 in. Water circulated, 1 700 gal per min, or 4.8 tons water per ton feed. Pulsations, 56 per min; amplitude of pulsations in washing compt, 12 in. Power, 0.35 hp per ton per hr.

Battelle launder is a fine-coal washer, developed by the Battelle Memorial Institute (16), and embodying features of the old trough washer. It is a single trough, with refuse

draw pockets so closely spaced that they constitute essentially a draw along the entire bottom; space between pockets is only sufficient to house the drawing mechanism.

The pockets have wedge-shaped channels through which the refuse passes. The approach to the pocket is formed by perforated plates, the bottom plate being set at an angle of 20°–40°, depend-

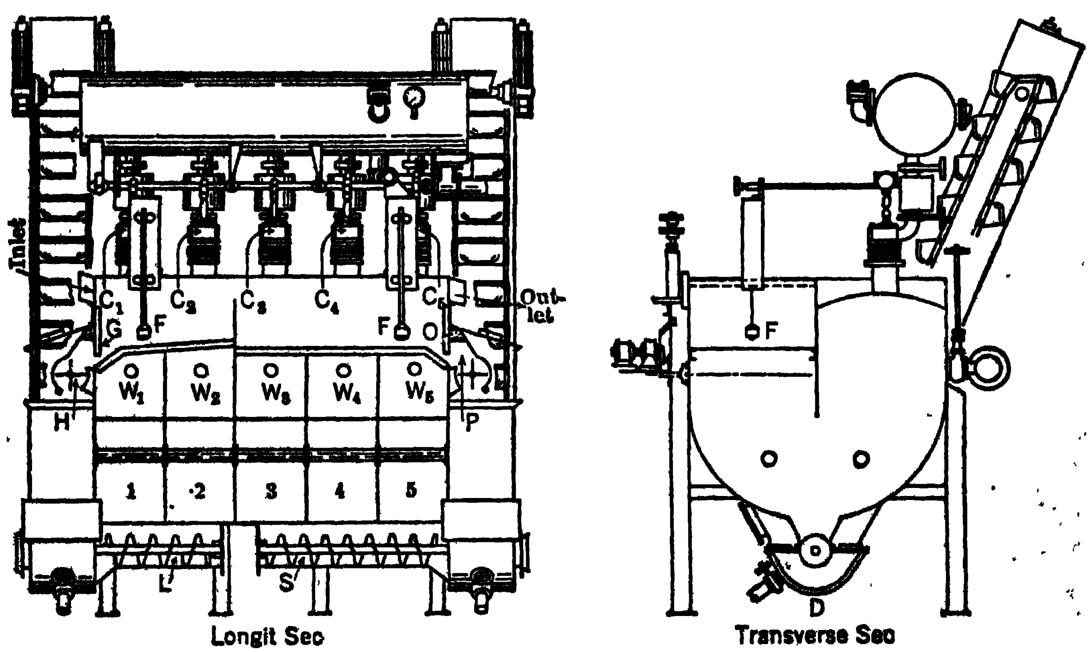

Fig 7. Baum Jig

ing upon the materials being separated. The compts below the screens have water pipes with valves and gages to regulate the water supplied to the various sections of the bed. A plant to treat [illegible] tons per hr of material under 5/16 in occupies a space 6 by 24 ft by 6 ft high; the launder being

14 in wide by 20 ft long. Refuse discharges into a sealed chamber, from which it is removed by screw conveyer or bucket elevator.

Hydro-separator (Fig 8) separates coal from heavy impurities by a rising current of water. Raw coal enters hopper *A* and passes into the separating compt *C*; here a rising current carries the coal over weir *D*, onto dead plate *E* and de-watering screen *F*, and thence into the second cell *G*, where the action is repeated. Clean coal and water pass over weir *H* into launder *J* and to a set of de-watering screens. Heavy materials in compt *C* settle in a loose mass on perforated plate *K*, and pass through gate *M* and spout *L* into conveyer *N*, which raises them above water level and discharges them as de-watered refuse. Heavy material settling in cell *G* moves similarly into bucket elevator *P*, which returns this product, if so desired, mixed with raw coal to be recirculated. Middlings may also be diverted to refuse, or saved as a saleable product. Water from the de-watering

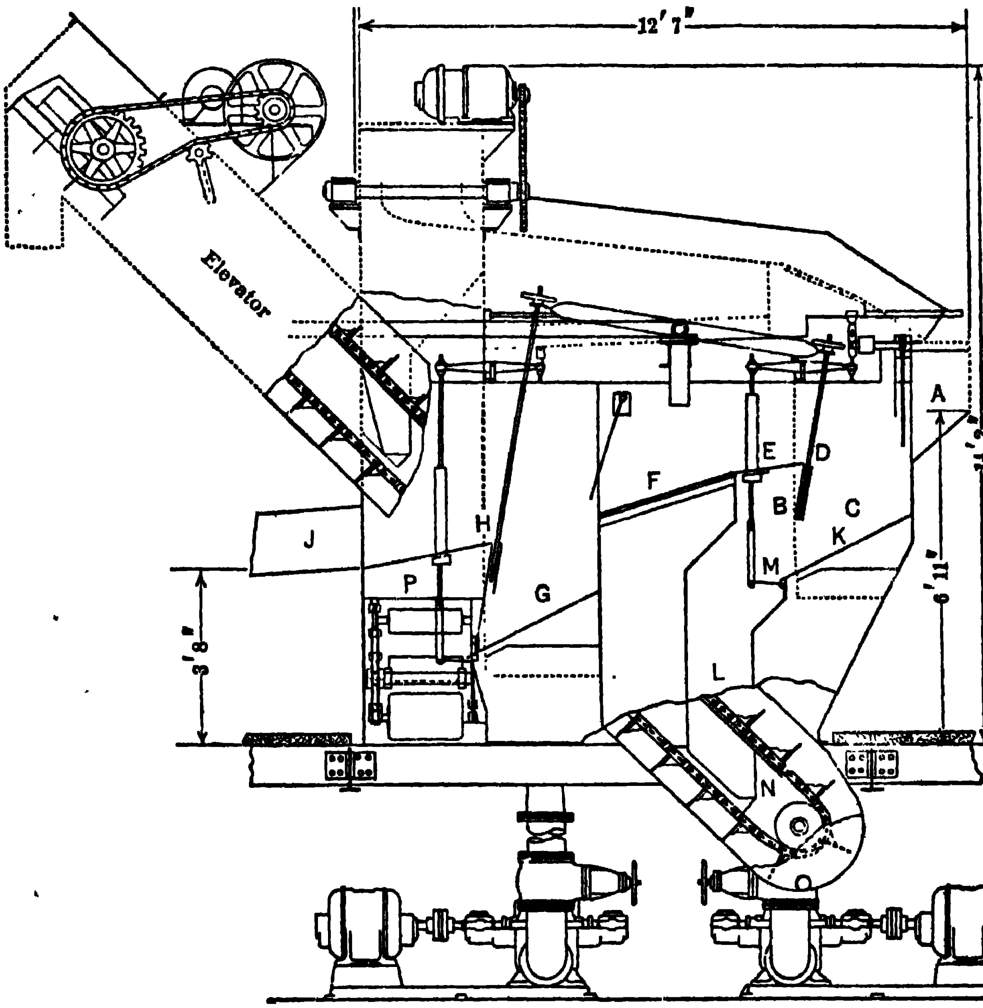

Fig 8. Hydro-separator

screens and screen *F* collects in a settling tank, from which the slurry is conveyed and the clarified water returned to the separator.

This washer is small, compact, easy to operate and control, and its initial and maintenance costs are low. It has a capac of 2–2.5 tons per in of width, and is in widths of 30–48 in, in single- and double-cell types. Feed is usually 3/8-in to max 5-in round hole. For effic operation, the size ratio in feed should not exceed 4–1. Water consumption, 6 tons per ton of feed.

Menzies coal separator. Operation is based on a variable veloc of water rising through a stratified, mobile mass of materials within a conical-shaped separator, in which the feed passes downward. Cleaned coal passes over the separator into a launder, then to a de-watering shaker screen. Material of intermediate sp gr stratifies below the coal in a loose mass, gradually increasing in density; the heavy rock descends through it into a conveyer. Quality of feed and desired product govern capac, which for aver conditions

is about 2 tons of feed per hr per sq ft of top area of separator. Feed sizes, 1.25–4 in; advisable size ratio of feed, 2–1. Water circulation, 11 tons per ton of coal. Power, 0.8–1 hp per ton of feed per hr (Table 13).

Table 13. Data on Standard Sizes of Menzies Separator

Diam cone, ft	Sq ft surface	Feed, tons per hr	Hp to drive	Hp for refuse conveyers	Hp for pump	Total hp	Hp per ton	Pump, gal per min

Rheolaveur method (21) utilizes the classifying action of a horiz current of water in a launder of a length, shape, and slope to afford the desired stratification (for design and operation, see Sec 34, Art 6, 11). CAPAC depends on width of launder, and size and character of raw coal; widths are standardized, for combining to treat any desired tonnages; launders of coarse-coal plants are 20–56 in wide; capac, 150 to over 400 tons per hr in a main launder. Fine-coal plants have capac of 15–150 tons per hr in a single or multiple unit; individual launders of 14-, 10-, and 8-in widths are assembled to provide for this range. Table 14 gives data on water requirements of 3 plants. This washer has low initial cost per ton-hr, low power requirements, is of simple construction, has large capac, and can be varied in design to suit the type of coal.

Table 14. Water Requirements of Rheolaveur Washers (21)

	Three-box plant		Four-box plant		Five-box plant	
	Primary	Rewash	Primary	Rewash	Primary	Rewash
Water, gal per min	1 800 (*a*)	500	3 600	1 300	2 500 (*b*)	1 000
Feed, tons per hr	225	55	650	120	450	110
Gal per ton	460	550	330	650	600	550
Size of coal, in	$^3/_8$–3 $^3/_8$	$^3/_8$–3 $^3/_8$	0–4 $^1/_2$	0–4 $^1/_2$	0–4 $^1/_2$	0–2
Refuse in feed, %	3–8	17–20	8–10	40–50	8–10	40–50
Tons total water per ton feed	1.92		1.90		1.95	

(*a*) Includes the 500 gal per min overflowing the rewash. (*b*) Includes 1 600 gal per min added directly at head of primary launders, and 900 gal per min overflowing the primary rewash launder.

Belknap chloride washer uses a $CaCl_2$ solution, to which a slight rising veloc is imparted by impellers. Use of the heavier liquid increases the difference in falling veloc between coal and impurities. The slow current, rising through a slot, permits refuse to fall, while the coal moves on to its conveyer. Incoming water and chloride solution are proportioned by float-controlled valves to maintain a constant density in the tank. The washer is adapted to standard sizes of $^3/_8$–6 in; preferred size ratio is 2–1, although a range of 4–1 has been treated. CAPAC, 1 ton per hr per in of width, for coal of 1.5–3 in; 25% less for 3–6 in. The washer is made in 30-, 36-, 42-, 48-, and up to 150-in widths. POWER, 0.1 kw per ton-hr. WATER, 5 gal per ton of coal.

Sand flotation, Chance process (for design and operation, see Sec 34, Art 11). Properly operated, this separator closely approaches results of the float-and-sink test. As sp gr is the only physical property utilized, particles of any size larger than the sand can be treated. Hp for plant of 2 10-ft cones with combined capac of 300 tons per hr, sized 1–4.5 and $^3/_8$ to 1 in, is: agitators, refuse conveyer, and de-sanding screen, 75; de-sanding screens for clean coal, 30; two 6-in sand pumps, 50; 10-in circulating water pump, 50; refuse pump, 20; make-up sand and water, 15; total, 240 hp, equivalent to 0.8 hp per ton per hr of feed. WATER CIRCULATED, 4–6 tons per ton of coal depending on size and quality of feed. SAND LOSS varies with size and quality of coal; aver, 2–3 lb per ton washed coal.

Wuensch "Differential Density" process utilizes a heavy medium composed of water and the slimes (fine coal and its impurities) settled out of the circulating wash water. Middlings accumulate in a conical separating chamber and form a column, of which the density increases from top to bottom.

This "differential density" feature allows the finer refuse to settle rapidly through the less dense medium at top, while the denser medium at bottom prevents loss of good coal. The column is a sealed chamber, from which the refuse passes by gravity to an elevator discharging above the liquid level. The refuse column is kept filled with heavy medium to a level slightly above that in the cone. Most of the medium is drained from the cleaned coal on dewatering screens and returned to the separator; the remainder, washed out by sprays, is settled to a heavy density in thickeners, and then re-introduced through the refuse column at bottom of the separator.

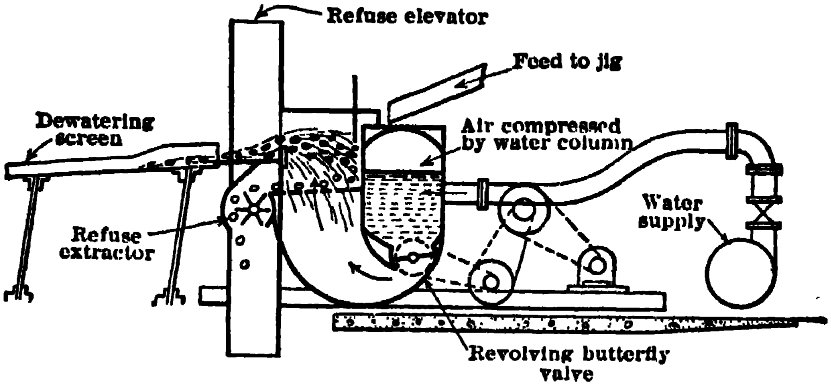

Fig 9. Vissac Pulsator Jig

Vissac pulsator jig (Fig 9) operates on same principle as the Richards ore jig; it is used on sized products (22). Refuse is removed through a gate and star valve at discharge end of the jig screen. In the nut-size jig, rotation of the valve is controlled by a float resting on the refuse bed; in the egg-size jig, by a mechanism actuated by variations in resistance offered by the bed to the upward flow of water.

Table 15. Specific Gravity Analyses of Products from Test of Vissac Jigs (18)

Table 15 gives results of a test on Vissac jigs treating egg coal (3-in round to 1.25-in sq hole) and nut coal (1.25–0.25-in sq hole). Additional data (18): air chamber, 3 by 4.5 ft; washing compt, 3.5 ft long by 4.5 ft wide; head of water, 18 ft; feed, 60 tons per hr; power, 0.1 hp per ton feed per hr; water, 1 850 gal per min, or 7.7 tons per ton coal; pulsations, 40 per min, at 4.25-in stroke for egg, and 2-in for nut coal; jig bed, 26 in deep for egg, 24.5 in for nut jig.

Koppers Llewellyn washer has a single box 6.5 ft long; or 2 boxes in tandem, comprising a sludge recovery unit, and primary and secondary washing cells. Middlings can be re-circulated, with or without crushing. The plunger, hinged at one end, produces a max activity at the feed end of the box, gradually diminishing towards discharge. Suction is eliminated by a valve in the plunger, which pumps water under the jig boxes from the overflow launder of the settling tank, thus making a circulating pump unnecessary. The refuse discharge is automatic. Cell width, 4 ft; sizes cleaned, 0.5–5 in; preferred ratio of size, 1–2; capac, 60–70 tons per hr; stroke, 4–6 in; speed, 40–30 rpm; power, 10 hp for double, 5 hp for single cell.

Prins multi-flow washer, a combined jig and launder, is small and compact. A jig with a rated capac of 135 tons raw coal per hr has a trough 18 in wide, and jig box 23 in wide. The feed moves down a central launder, where it is partially stratified, the heavier material dropping through openings into the jigging compt.

The jig basket is adjustable in length and speed of stroke; its bottom curves upwards from feed to discharge end. Water entering at different points keeps the bed fluid, floating the lighter particles to discharge end. Refuse drops through an opening in the basket into a well, from which it is conveyed for disposal. Capac, 75 tons per hr per ft of width. Re-circulation water, 10–20 gal per min per ton of coal per hr, or 2.5–5.0 tons water per ton coal treated. Power, $^1/_3$–$^1/_2$ hp per ton coal per hr.

11. COAL-WASHING TABLES

Among various types of tables, the main differences are in shape or contour of the deck and in the head motion. Decks are covered with linoleum or rubber, smooth or corrugated, with hard-wood or rubber riffles.

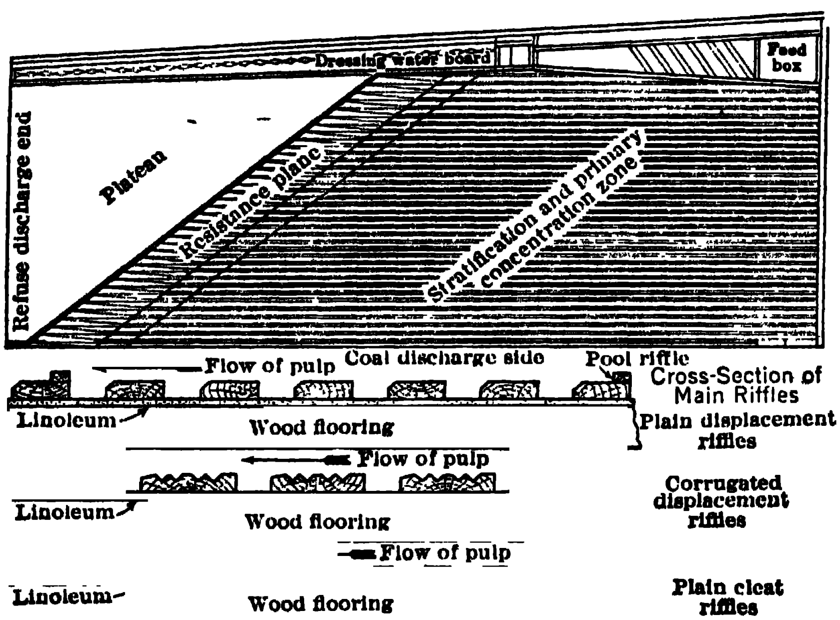

Fig 10. Plat-O Coal-washing Table

Plat-O table (Fig 10) is like that for ore, except for 55% greater deck area and heavier head motion. It cleans unsized coal, $^5/_8$-in and finer, as fed from a box attached to the table deck. The feed box itself acts as a small deck, concentrating and immediately discharging the coarsest and heaviest refuse, leaving the finer and lighter impurities to be removed on the main deck. Capac, 6–10 tons per hr. Water, 350 gal (1.5 ton) per ton of raw coal, plus a little final wash water. Running load, 0.75–1 hp; a 3-hp motor with high starting torque is usual. Speed, 255–300 rpm; stroke, $^5/_8$–1 $^5/_8$ in; usual feed contains 45–50% solids.

Deck surface of this table lies in 2 or more parallel horis planes. In the 2-plane type, universal for bituminous coal, the lower plane forms the larger part of the deck, and is the "stratification and primary concentrating" zone. The plateau or dressing zone extends back from the discharge, and joins the primary concentration zone along a diagonal line. Its height above the lower plane is about $^3/_8$ in. Between the plateau and the lower deck is a narrow, diagonal, upward-sloping "resistance plane." The main riffles end approx along the upper edge of this slope, their ends being tapered on the underside, leaving the upper edges horis. Table 16 gives data for coal sized between $^3/_{16}$ in and 48-mesh, at 6.2 tons per hr. Speed, 275 $^{15}/_{16}$-in strokes per min; transverse slope, 0.25 in per ft; longit slope (upward to discharge end) $^3/_8$ in for 12 ft; rise to upper plateau, 0.75 in.

Massco table has a linoleum-covered, riffled deck, adjustable as to transverse slope. Head motion is differential, to accelerate travel of the material with minimum agitation. The deck reciprocates endwise and horizontally, riffles being adjusted to discharge throughout its length. Capac, 4-7 tons per hr on coal passing 0.25-in round hole. Speed, about 220 rpm, requiring 1 hp.

Table 16. Coal Washing on Plat-O Table

	Wt, %	Sink at 1.60, %
Feed	100.0	6.8
Clean coal	88.9	1.1
Middlings	5.8	20.5
Refuse	5.3	91.0

Overstrom Universal table. Driving mechanism consists of an unbalanced loose pulley, on a shaft rigidly attached to the table frame; momentum of this revolving weight reciprocates the deck, which is supported by flexible hickory legs. A differential motion is produced and adjusted by a cushioned stop at forward end of stroke and coil springs on other end. Neither cams nor toggles are employed. The supporting legs slope slightly back towards the head motion, causing the table to rise in a circular arc on its forward stroke. Length of stroke varies automatically with the load. Speed, 240-280 strokes per min. Riffles curve upwards to the high side of table.

Deister-Overstrom diagonal-deck table. All riffles are parallel to direction of motion and at an angle to the discharge. This gives the advantage of deflected riffles without the whipping action, and allows the stratified refuse a free path towards the refuse edge. These tables may also have double decks, driven by same head motion, but separately asjustable as to slope and length of stroke. Speed, 250-300 strokes per min; stroke, $^5/_{16}$-1 $^3/_8$ in. Power under load, 1.5 hp. Size of feed, 2-in max. Capac, 4-8 tons per hr, varying with size and character of coal.

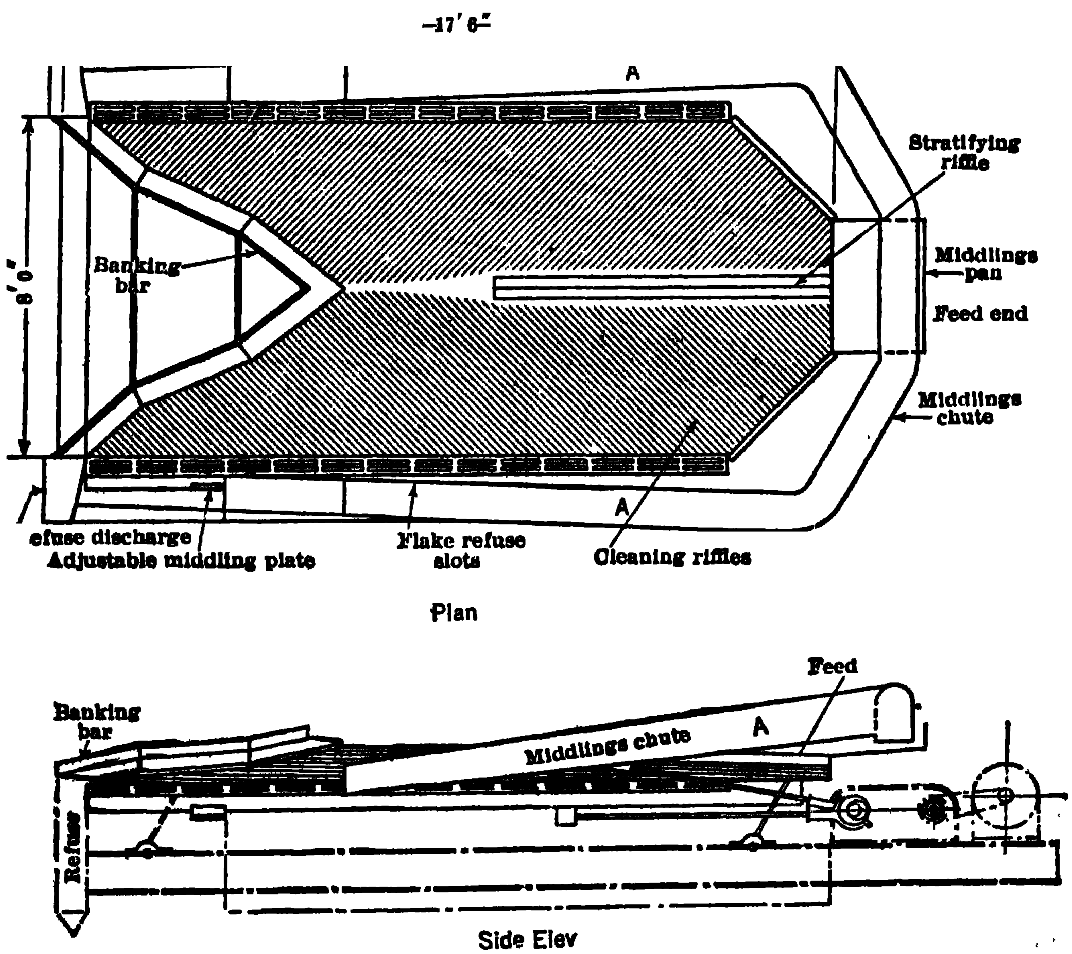

Fig 11. American Pneumatic Separator

12. DRY CLEANING

American pneumatic separator (Fig 11) utilizes its entire surface for cleaning. It ordinarily discharges 2 final products, clean coal and refuse; middlings may be made, to be

recirculated, re-treated separately or with refuse on other units, or discharged as a second-grade fuel. For re-circulation, middlings return to the feed on the deck via the anti-gravity chute A, or are conveyed back to the initial feed.

Distribution of air under different sections of the deck is adjusted by external controls: rapidity of stroke by variable-speed drive; longit slope of deck, by jack screws with lock wheels. Transverse slope of deck is fixed by construction. Proportions of the several products are varied by sliding cutter plates. The R-72-144 table requires 11 000 cu ft of air per min, at 2-in water gage, when treating minus 1/4-in feed, to 44 000 cu ft per min at 4-in gage for minus 3-in. Motor on blower fan ranges from 15 to 60 hp for minus 3-in feed; motor on separator, 5 hp.

Stump air-flow separator. The cleaning unit (Fig 12) is an air-tight metal box A, covered by a pervious deck on which rests a layer B of clay marbles of sizes depending on size of coal treated. This distributes air without requiring shutters and air ducts. Since the unit is stationary, it can be enclosed with dust-tight hoods. The layer of marbles is covered with a bronze or stainless-steel perforated deck, in which size of holes and percent of open area depends on size of coal treated. The unit is well adapted to coal of minus 3/8-in. Its initial and maintenance costs are low, and it occupies small space. Capac, 0.5–1 ton per hr per in of width, depending on size and quality of feed. Widths, 30–72 in. Air required, 250–500 cu ft per min per sq ft of deck area, at press of 2–5 in water gage under the deck, depending on size of coal.

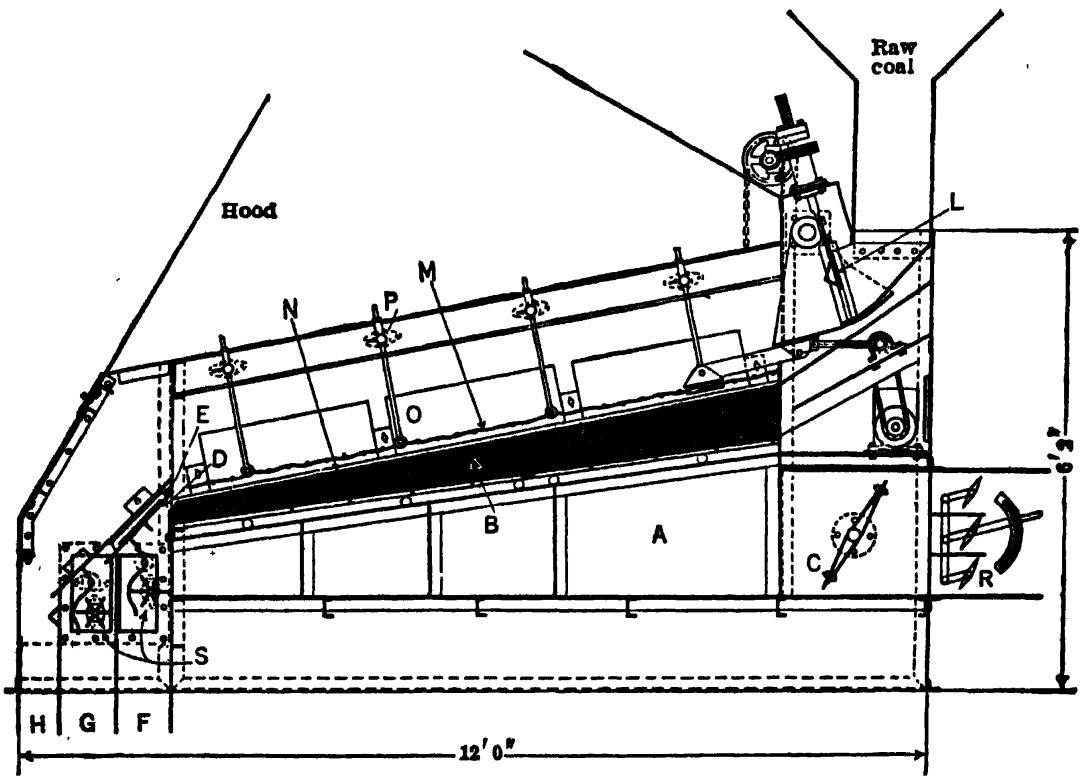

Fig 12. Stump Air-flow Separator

Table 17 gives results at a Stump plant treating minus 5/16-in coal at rate of 0.76 ton per hr per inch width of primary units.

Air-sand process utilizes a body of dry sand maintained in a mobile condition by an uprising stream of air. By regulation of air flow, the sand is maintained at such density that coal will float near surface, while refuse sinks through the sand.

The separator consists of 2 boxes in series, built into a trough-like unit, with dams and adjustable refuse gates to form 2 sand pools. The floor is a pervious deck. The draw-off box under each section receives air, through regulating gates, from a manifold on each side. The machine is inclined lengthwise at 5°; a continuous flow of sand passes over each compt, being fed to the upper

one at a regulated rate from a storage hopper. Washed silica sand, 20–100-mesh, is best; it is circulated at rate of 2.5 tons per ton of coal; make-up sand to replace losses, 1–2 lb per ton of coal.

(a) Includes primary clean coal, secondary clean coal, and dust collector products

Air is supplied by a positive displacement blower at 20–30 cu ft per min per sq ft of pervious plate; pressure, 12–14 in water gage. Capac, 1.7 ton coal per hr per in of width. Sizes treated: min, 0.25 in; max, 4 in; limiting size ratio in feed, 3 to 1. Power for a 6-ft unit treating 120 tons per hr (excluding dust collection) is 0.25 hp per ton-hr, distributed as follows: separator and refuse de-sanding screens and shaking chute, 5; de-sanding screens for clean coal, 7.5; sand lift, 10; blower, 7.5; total, 30 hp.

13. DEWATERING AND DRYING

Dewatering washed coal, and reducing its free moisture to acceptable limits, are difficult problems. Fine coal may be flumed from a washing unit over an inclined FIXED SCREEN, which removes most of the water and passes the coal onward to other and more effic dewatering devices. Slope and area of this screen are adjusted so that the minimum amount of water is required to carry the coal forward without choking or spilling. "WEDGE-WIRE" screen, often used for dewatering on both stationary and shaking screens, consists of parallel wires of wedge-shaped cross-sec, supported with their wide faces uppermost on cross-bars spaced according to size of wire. The long slots thus formed have little tendency to blind; the openings are 2 to 1/16 mm, corresponding to 8- and 200-mesh (Tyler std).

Flight conveyers for drainage differ from those for dry materials (Sec 27) only in having perforated bottoms, often of wedge-wire screen. Table 18 gives data on 5 drag-flight installations, all receiving cleaned, wet coal from shaking dewatering screens.

Table 18. Data on Drainage Flight-conveyers

Coal size, in, rd-hole	Tons per hr	Size flight, in	Length dewatering section, ft	Speed, ft per min	Wedge-wire No pcs	Width and length, in	Size opening	Total area, sq ft	Free H_2O as loaded, %
3/8–4	275	7 by 45	164	47	10	48 by 36	0.5 mm	120	3.0
2–4	250	2 1/2 by 32	54	100	5	34 by 36	3/16 in	42	2.3–1.5
1–2	120	2 1/2 by 32	68	100	6	34 by 36	3/16 in	50.5	3.1
3/8–1	125	6 by 32	80	90	5	34 by 36	1/8 in	42	4.5
3/8–1	60	6 by 32	150	49	9	33 by 36	0.5 mm	74	3.8

Drainage band conveyer is inclined, with deep, troughed pans, each holding 1–2 tons, attached to a double-strand, long-pitch chain moving 1–2 ft per min. The bottom plates are perforated and slightly curved; when passing over the rollers, they squeeze the coal somewhat, and water drips into a sump. Conveyers are 60–80 ft long, holding about 40 tons in transit, and allowing 30–60 min for drainage. Discharged product, with minus 0.5-in coal, averages about 22% moisture.

Shaking dewatering screens, for coarse clean coal often have wedge-wire with 1 1/5-mm slots, usually parallel to flow of the coal. Trays with steel or wood sides are hung or supported on hickory strips, and reciprocated like dry shaking screens (Art 5); usual speed, 300 rpm, with 1 to 1.5-in throw. In recent practice, wet coal of 0.25 or 3/8 to 1-in size may pass from the shaking screen to one or more horiz vibrating screens, set on 2° up-slope towards the discharge. Table 19 gives data on several installations; all of hanger-board Parrish type except the last, which is a horiz vibrating screen.

Dewatering elevators. Fig 13 shows the commonest method of dewatering fine coal, received in a sump of wood, steel, or concrete, and cone or pyramid shaped, with an overflow around its periphery and a loading well suspended near its center. Perforated buckets allow partial drainage, the water returning to sump through the tight bottom of the elevator casing; speed, 30–50 ft per min; buckets, 16–48 in wide.

Centrifugal dryers extract moisture from minus 0.5-in coal more completely than any other mechanical type. Carpenter and Elmore dryers are used extensively in U S for coal of that size.

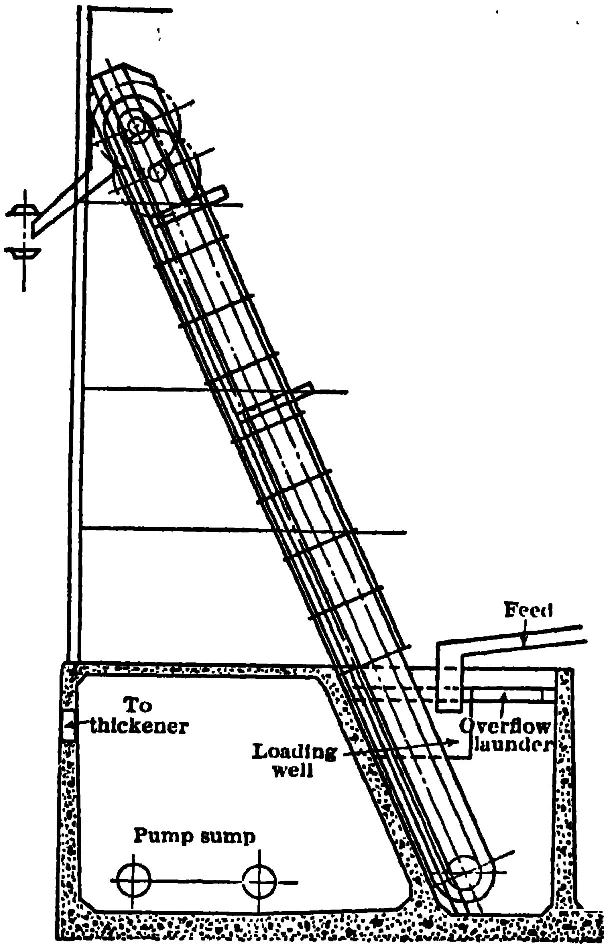

Fig 13. Dewatering Elevator

Carpenter dryer consists principally of a screen basket, in form of a stepped, truncated cone, carried on a vert shaft, with its smaller diam at top, and rotated through spiral bevel gears by V-belt from a motor mounted on a base cast integrally with the housing. Wet coal, fed into a hopper, falls on a horiz disk attached to the rotor shaft. Centrifugal force throws the coal upon the top row of screens attached to the basket; the opening between disk and screens is adjustable. The partly dried coal, on reaching the bottom of the first screens, passes over a lip and is redistributed on the second row, where extraction is continued. After passing 3 or 4 screens, the coal is gathered from the lip of the last into a hopper for final disposal. Table 20 compares 4 Carpenter dryers in one installation.

14. WATER CLARIFICATION AND SLUDGE RECOVERY

In a wet washery, regardless of size, coal characteristics, or method of processing, circulating water becomes polluted by sludge. Unless abundant water is available, it must be recovered in usable condition, and, unless the sludge is wasted, its coal must be recovered. These results are obtained by: elevator boot, rectangular sludge tank, cone, thickener, settling pond, and vacuum filter. In the first 4 methods, the sludge is flumed into the unit, passing into a baffled feed well, deflecting the stream towards the bottom, where it settles; water collects in an overflow launder around the edge, and goes to a sump. Effic of the unit depends on the ratio between the top settling area and amount of solids in the mixture, the volume, and the screen analysis of the solids. Table 21 gives data on settling at boot of elevator in 5 installations.

Table 21. Sludge Settling at Elevator Boots

Unit	Gal per min		Percent solids		% of +48 -mesh in overflow	Volume of tank, cu ft		Horiz area, sq ft at water level	Length of weir, ft	Elevator speed, ft per min	Elevator aver cap, tons, solids per hr

Rectangular sludge tank, of wood, steel, or concrete, or a combination, may have sloping or vert sides. Sludge is usually flumed to one end through a feed well. A chain and flight conveyer is installed in the tank; flights are 6 in high, of wood protected by steel angles, or of angles or channels, depending on width of tank. The discharge end is extended (sometimes bottomed with wedge-wire screen) on about a 30° slope to drain the recovered solids. The chain should be barstrap or rivetless. The bottom run is carried on wearing bars or small rails; top run, on flat bars, rollers, or sprocket idlers. The conveyer, running at 10–20 ft per min, gives the material time to drain. An overflow launder along each side, starting beyond the zone of turbulence from the feed well, runs to a sump from which the clarified water is pumped for re-use. The tanks have drains for cleaning and washing. Table 22 gives data on 2 installations.

Cone settling tank (Fig 14). Washery water recovered from sump is pumped into the cone through pipe *A*, which delivers inside of a cylindrical curtain *F*. Clear water is removed through pipe *B*; *D* is an outlet to prevent water from overflowing rim of tank. Connection *E* is for cleaning by flushing the slurry pipe *C*. Valves at base of cone control discharge.

Dorr traction thickener (see Sec 33). Table 23 gives data on 4 installations for coal. Where space is available and water plentiful, SETTLING PONDS are used for sludge disposal; or the whole mixture is flumed to the pond and discarded, or allowed to settle and the residue recovered. Usually, little water is recovered from such ponds.

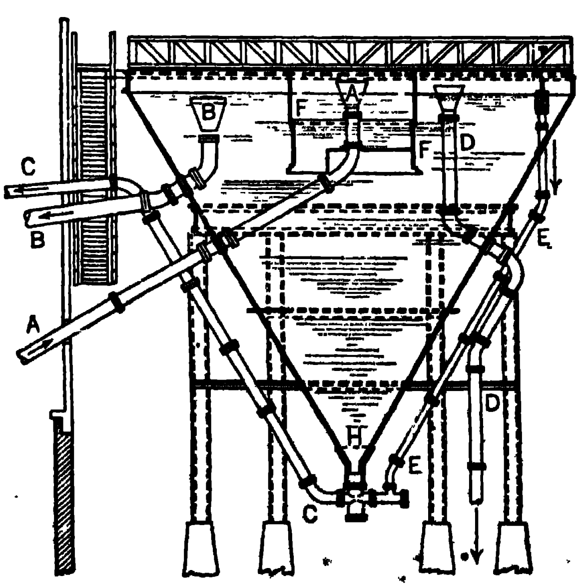

Fig 14. Cone Settler for Water Clarification

Filters. Common types are: (*a*) mechanical; (*b*) cord; (*c*) vacuum. The Bird filter is essentially a centrifuge; sludge fed into the machine passes through a high-speed impeller, which separates water and solids centrifugally. The CORD FILTER consists of endless cords mounted on 2 drums. On passing through a bath, the cords pick up the solids; water is drawn out by vacuum and the coal removed from the cords. Wright filter is an example.

In the older VACUUM type, a sectionalised cloth-covered drum rotates, with the lower part submerged in a bath. Suction collects a cake of solids on the cloth and dewaters it after rising from the bath. Just above the level at which the cake is discharged, comp air blows the cake loose and deposits it in a suitable conveyance. The DORRCO filter (Sec 33) reverses this procedure by admitting and distributing pulp to the inside of the drum, which is lined with filter-cloth. As a segment of the drum reaches the top of its travel, its load of sludge-cake drops off (assisted by press of air behind it) and falls onto the belt conveyer for disposal.

15. DEDUSTING AND DUST-COLLECTION

Installation of dedusting equipment involves many factors (19). Both ash and sulphur contents of coal often increase with diminishing size. When coal containing soft powdery fusain is wet-washed, the porous fusain fines remain in the small coal or in the

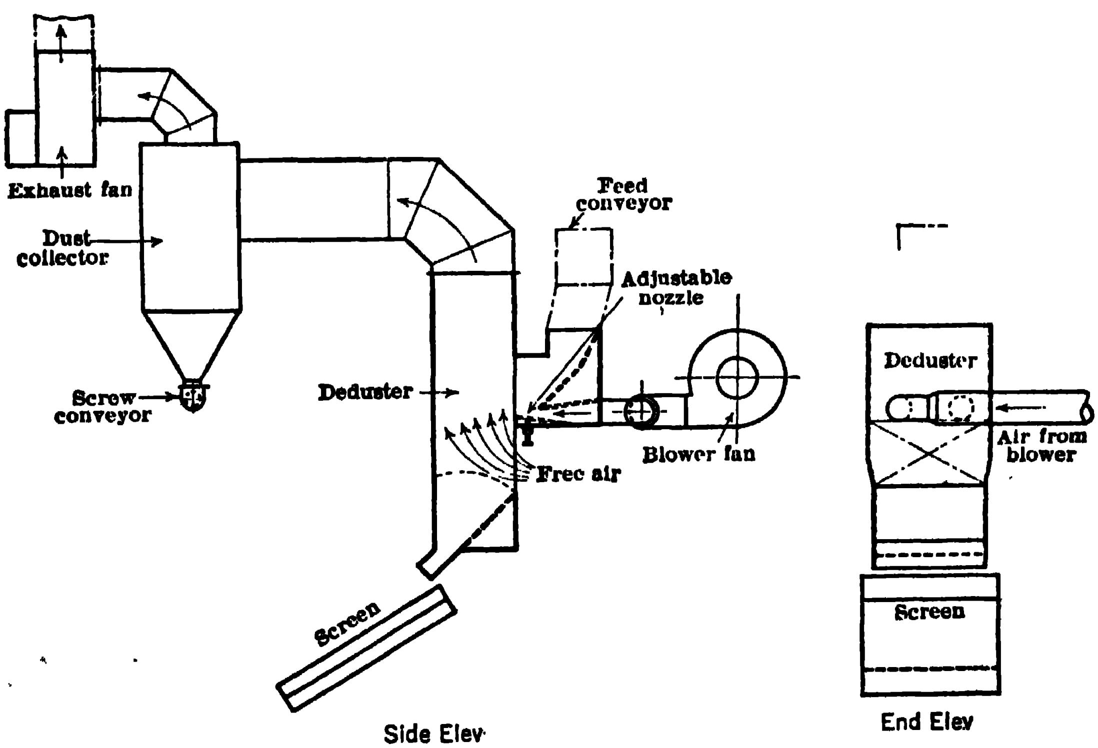

Fig 15. Koppers-Birtley Deduster

wash water, and obstruct dewatering of the coal and clarification of water. If, after investigating a specific coal, dedusting is found desirable, a problem arises as to disposal of the dust, for which a screen analysis of the coal with determination of ash contents of each size should be made. Dust is usually removed by screening or aspiration, or both.

Blaw-Knox apparatus directs 2 adjustable streams of air against falling curtains of crushed coal; dust is drawn off by 2 suction fans and delivered to collectors; air used, about 200 cu ft per min per ton-hr.

Algar deduster provides both screening and aspiration. Raw coal is fed through an air-lock onto a double-deck, circular, vibratory screen, the upper deck having the larger openings; mesh of both screens is adapted to the particular coal. Coarse material, falling in a circular curtain, is cut by rising air, which then passes through a set of conical louvres to the dust collector.

Koppers-Birtley system (Fig 15) depends on suction of a fan drawing air through an adjustable inlet, which lifts the coal off a stationary plate; a secondary inlet is provided, as shown. The modified American adaptation of the system supplies primary air by a blower and secondary air by suction fan. Coarser dust, after being lifted over a baffle, separates from the finer and is deposited in a hopper emptying automatically when enough material has accumulated to overcome a gravity-controlled sealing door. Fine dust continues through the fan to a collector. Normal air consumption, 100–200 cu ft per min per ton-hr of coal; power, about 0.18 hp per ton-hr. Table 24 shows effect of dedusting in a commercial installation.

Table 24. Screen Analysis of Dedusted Minus $^3/_8$-in Coal

Mesh	Percent by weight		
	Feed	Discharge	Dust

	100.0	100 0	100 0

Dust-collectors: (*a*) Cyclone, Multiclone, Polyclone, American Metallic; (*b*) Roto-Clone; (*c*) Bag collector. In group (*a*), coal particles are thrown centrifugally by an air current and collected in hoppers (19). CYCLONES are 1–4 ft diam, and consist of a cylindrical upper section above a conical bottom sloping 60°. MULTICLONE has a multiplicity of 6 or 9-in tubes, wherein high velocities are maintained; they operate under either press or suction. Units vary in size from 3 to 30 tubes; air requirements, 620 cu ft per min at 2-in water gage, to 14 640 cu ft per min at 4-in gage. Their effic is high. POLYCLONES resemble multiclones in principle, but are in units of 2 tubes in parallel. The cylindrical shells are 16–96 in diam and use 1 800–64 900 cu ft air per min at 2-in gage. The polyclone is less effic than the multiclone, but when used as a preliminary collector ahead of a multiclone, high effic is obtainable. Neither has any moving parts, nor requires much maintenance. AMERICAN METALLIC is similar in type to the Multiclone, and has been used for collecting dust from air-table cleaning. ROTO-CLONE acts as exhauster and dust separator combined. A housed impeller draws in the dust-laden air. Units require 0.75–15 hp, at capac of 400–7 810 cu ft per min at 2-in water gage, and up to 14 000 cu ft per min at 3-in gage, with 18.8 hp.

Bag collectors. The air stream passes through a fabric mounted as tubes or on frames, thus filtering out the dust; these are the most effic of all collectors. The BLAW-KNOX standard unit consists of cloth bags stretched over steel separating and beating frames. Dust-laden air enters through a duct in which it loses veloc and drops the heavier particles into a hopper, while the lighter are caught by the bags. Capacities are calculated on basis of 2.2–5 cu ft of air per min per sq ft of bag area, depending upon loading, temp and humidity of air, and moisture, size, and characteristics of the dust.

It is sometimes advantageous to operate under press rather than suction. When air is heavily loaded, it is best to install Cyclones ahead of the bag collectors. PANGBORN collector is similar to the Blaw-Knox in design, but differs in size of bags. KOPPER-WARING collector combines cyclone for coarse dust and bag filter for fine. The filter tubes are suspended above the cyclone from a frame to which they are attached by weights and springs for shaking the bags.

16. COAL DRYING

Types of apparatus: (*a*) slow-moving conveyer in a bath of warm or hot air; (*b*) screens mounted in heated and ventilated housings; (*c*) kiln-type rotary dryer.

Conveyer is usually housed by 10-gage plates. It may consist of chains and flights, flat pans and chains, or an integral-pan conveyer. Highest effic occurs when the bed of material is relatively thin. In some types, warm or hot air is blown in and exhausted by separate fans; in others, the bed is stirred by the carrier. Flue-gases are sometimes used for drying, as in the Dwight-Lloyd-Oliver dryer.

Drying screens are balanced, tandem shakers like the dewatering screen. Their tops have distributing hoods to spread hot gases over the screens. The under sides of the shakers usually have suction ducts to draw the gases through the coal. Hot furnace gases

are either blown or sucked through the screen. Some designs use a pulsating air current, synchronized with the screen motion to take advantage of the periodically loosened bed.

Rotary kiln dryer is usually a horiz drum with closed ends. The hot gases are either passed through a duct in the center, sweeping over the coal bed on its return, or pass

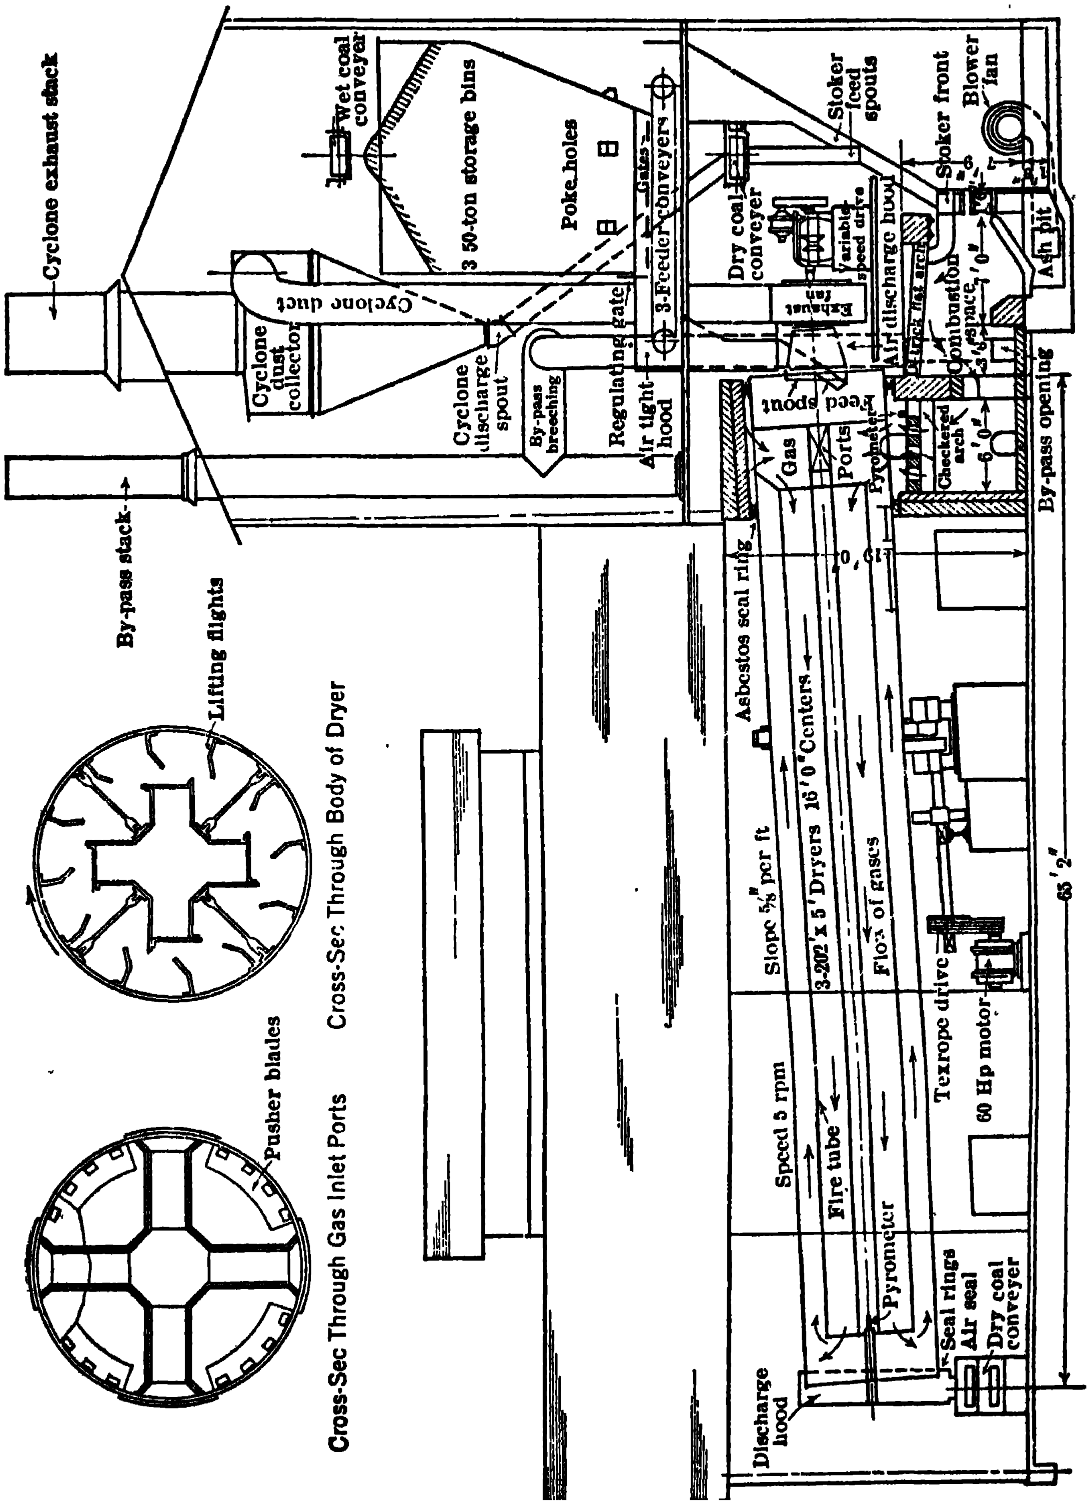

Fig 16. Christie Coal Dryer

between an inner and outer shell, coming into contact with the coal through openings. Feed end of the drum has a seal to prevent escape of coal and air. In most designs, some form of baffle stirs the coal as it rides up the sides and falls back. Dryers are set at a slope to cause the coal to travel through the drum. Fig 16 shows elev and cross-sections

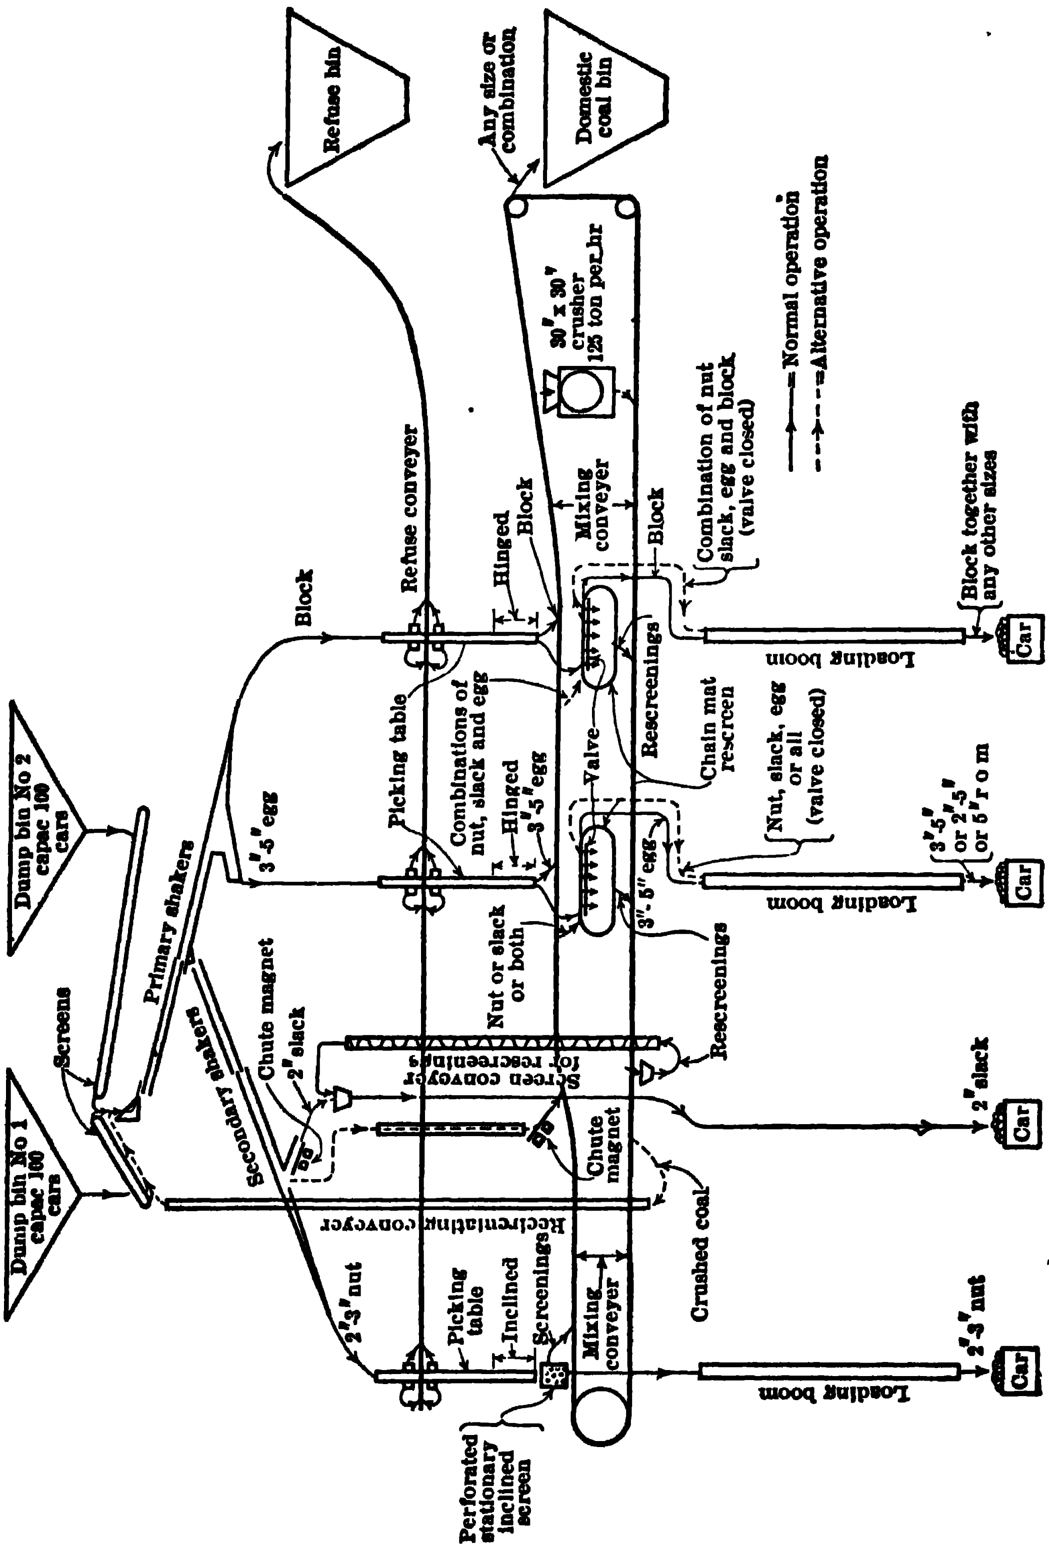

Fig 17. Tipple with Hand Picking (*Coal Age*, Jan, 1937)

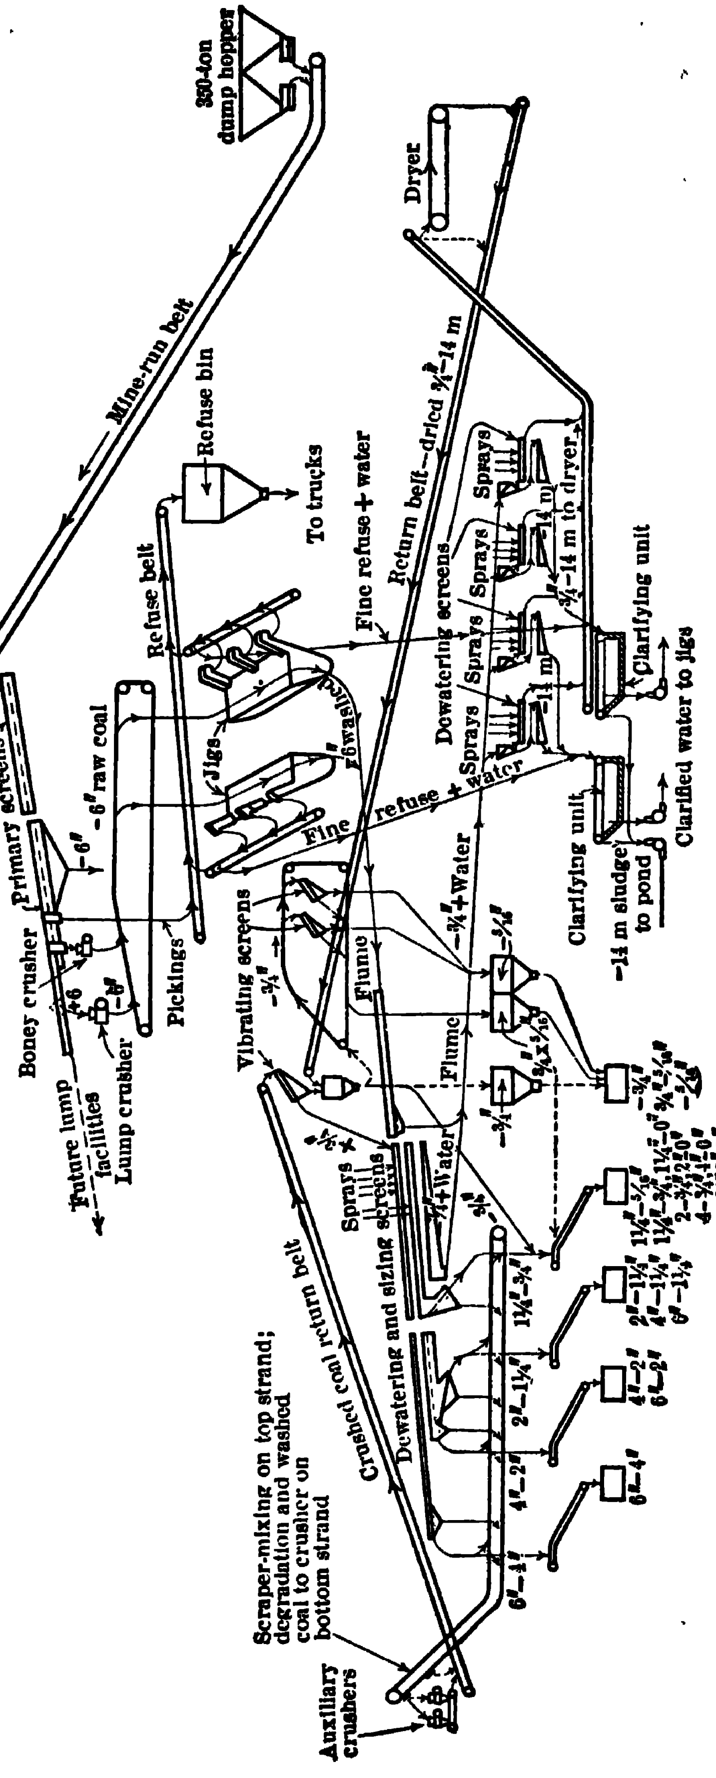

Fig 18. Baum Jig Plant

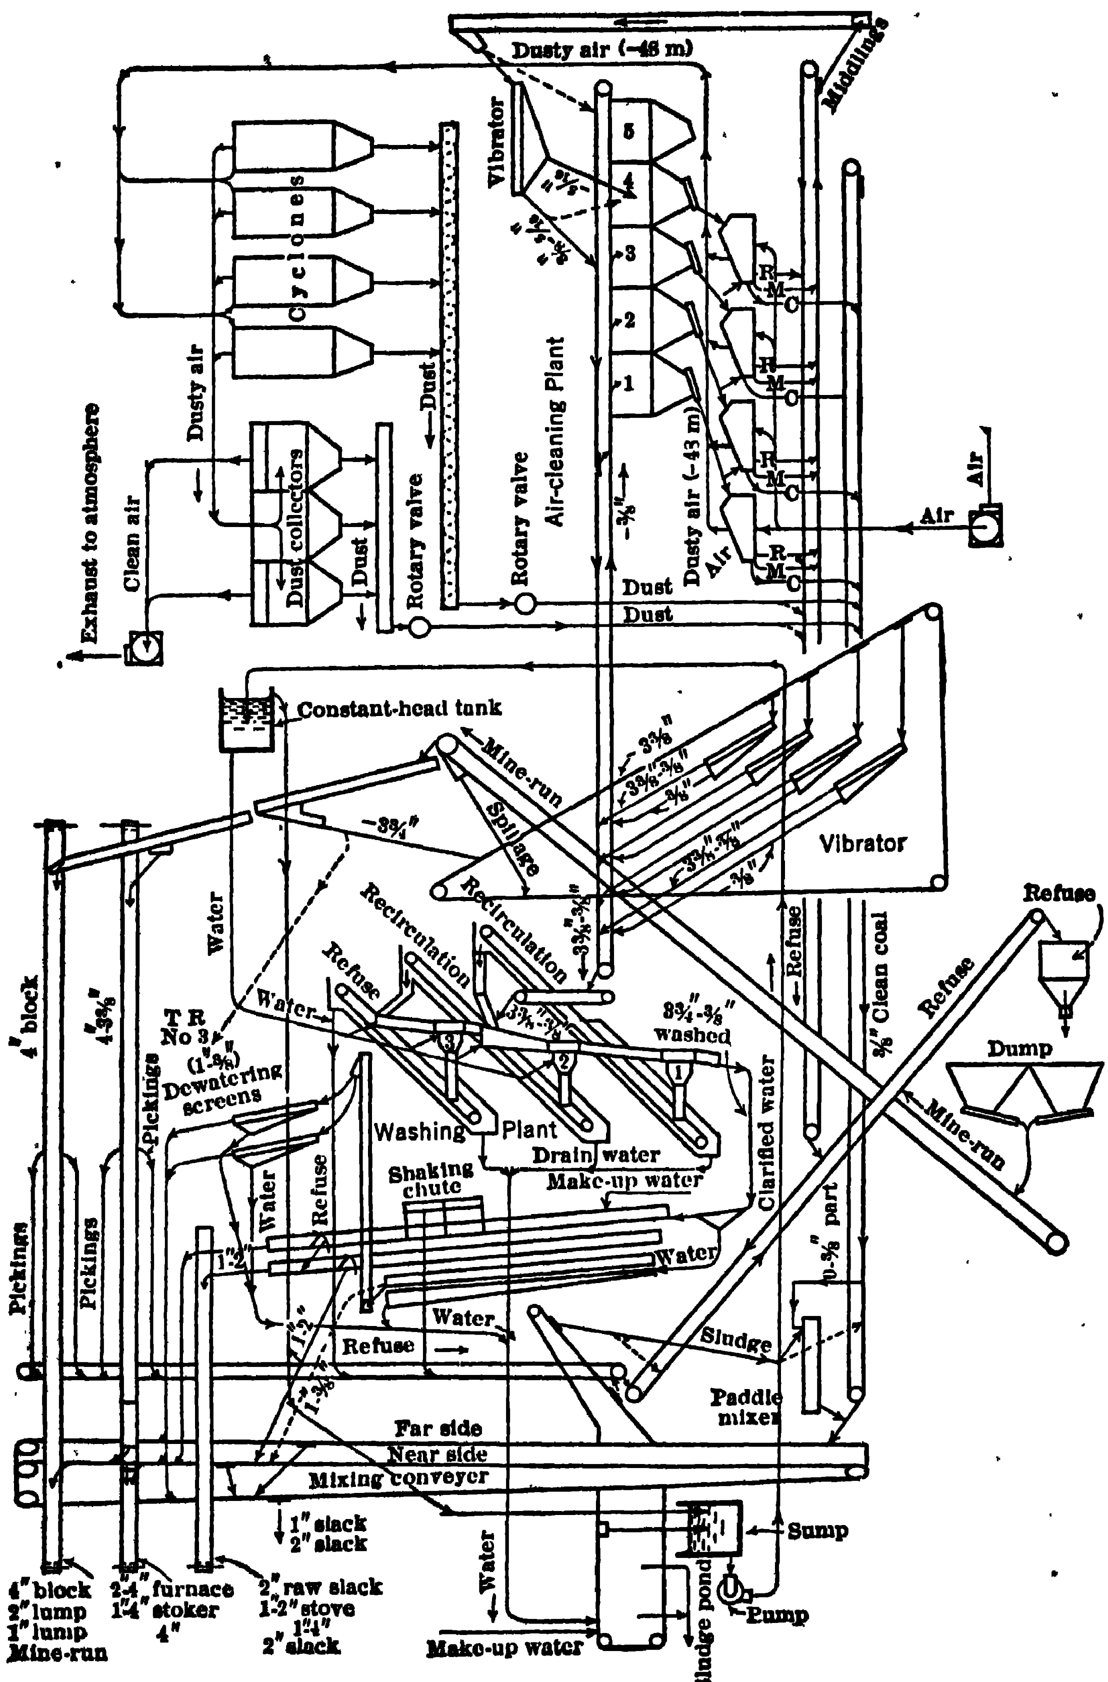

Fig 19. Combination Rheolaveur and Stump Air-flow Plant (*Coal Age*, Jan, 1938)

of the Christie dryer. Dryers usually have a variable-speed drive. Gases preferably are heated by a stoker-fed furnace, and fans used to supply the air. Cyclones sometimes recover the coal in the exhausted air, which may be added to the stoker feed.

17. FLOTATION (see also Sec 31)

Flotation, as applied to coal, separates fine particles of coal, pyrite, shale, and clay, in a pulp, by means of air bubbles produced by vigorous agitation (13). Reagents are added to cause selective adhesion of the bubbles to the coal particles. The bubbles and their burden of coal rise to the surface as a froth, which overflows and is recovered. The refuse material, to which the bubbles do not adhere, is withdrawn from below and discarded; it usually contains only a small proportion of coal.

Froth-flotation has improved the yield and quality of marketable coal in all plants where it has been installed (10). Numerous reagents are suitable. Plants located near by-product coking ovens generally use coal-tar derivatives, as creosote oil, cresylic acid, tar-oil distillates, and naphthalene or anthracene oils; others employ gas oil, petroleum, and wood-tar distillates. Reagent consumption is 1–2 lb per ton of dry raw coal. Pulp feed usually contains 20–25% solids. Coal froths contain 50–70% moisture. See Taggart's Handbook of Ore Dressing.

18. FLOWSHEETS

The preceding flowsheets show arrangement of 3 types of coal preparation plants: (*a*) Tipple equipped for hand-picking only (Fig 17); (*b*) Baum-jig plant with accessories (Fig 18); (*c*) a plant combining Rheolaveurs with Stump air-flow (Fig 19). Still more elaborate combinations are practicable, such as Baum jigs with hydro-separators and Stump air-flow equipment.

COKE

19. COMPOSITION AND PRODUCTION

Composition. Coke is the residue after driving off the volatile constituents of bituminous coal, out of contact with air; it consists essentially of carbon (the "fixed carbon" of the coal), with ash and a little water, and H, O and N gas. Color, silvery gray (from long-continued, high heat) to dull black (from quick burning, at low heat); texture, vesicular or pumice-like.

Production in United States, Net Tons (2)

1929 (Maximum year)

By-product coke,	53 411 826	tons,	from	76 758 958	tons	coal;	yield	69.6%,	without	breeze
Bee-hive	"	6 472 019	"	"	10 027 516	"	"	"	64.5%	"	"
Total,		59 883 845	"	"	86 786 474	"	"	"	69.0%	"	"

1936

By-product coke,	44 569 121	tons,	from	63 243 517	tons	coal;	yield	70.5%,	without	breeze
Bee-hive	"	1 706 063	"	"	2 698 158	"	"	"	63.2%	"	"
Total,		46 275 184	"	"	65 941 675	"	"	"	70.2%	"	"

Breeze is very fine coke, too small for furnace or domestic use, but can be burned under boilers. It is rarely recovered at bee-hive oven plants, and not entirely at by-product plants, but in 1936 an amount equal to 5.6% was actually recovered.

Aver yield of coke. Bee-hive, 1 ton coke from 1.55 tons coal, or 2.2 tons per day
By-product, 1 " " " 1.44 " " " 20.0 " " "

Methods of coking: (*a*) Mounds or heaps; time, 5 to 8 days (long obsolete). (*b*) Bee-hive and horizontal ovens; time, 48 to 72 hr (now nearly obsolete, excepting in times of large consumption). (*c*) Retorts or closed ovens, by-product; time, 14 to 22 hr.

20. BEE-HIVE OVENS

While there are still some thousands of beehive and the later rectangular ovens in existence, no more of either type are likely to be built, and those now existing are used only when the supply of coke from by-product plants is too small to meet the demand. For these reasons the reader is referred to pp 2028–2033 of the second edition of this handbook for data on bee-hive ovens and the machinery used in connection with them, for charging and drawing.

21. BY-PRODUCT OVENS (4, 5)

Coke manufacture in by-product ovens is a highly technical process, wholly different from bee-hive oven practice. The possibility of saving the by-products was known as early as 1766; satisfactory commercial results were first obtained in Europe about 1883.

The results of by-product coke making are so much superior commercially to former practice, that practically all blast-furnace plants of any size in the U S now obtain their coke from by-product ovens.

Location of plant. Bee-hive ovens, with few exceptions, have been built at the mines. By-product ovens are always at steel or furnace plants, or near large industrial centers. Such locations give the following advantages: convenience for obtaining coals from various sources; ready market for surplus gas; market for "breeze" (fines) and coke dust, always wasted at bee-hive plants; close supervision of coke making by the consumer; proximity to markets for tar and ammonium sulphate.

Kinds of oven (26–29). Although the designs of by-product ovens have been numerous, the following list of those used in the U S, Jan 1, 1937, shows that 3 types are now in most general use:

	Koppers	Semet-Solvay	Wilputte	All Others	Totals
At merchant plants......	1 953	1 080	221	421	3 675
At furnace plants........	7 833	716	505	120	9 174
Totals............	9 786	1 796	726	541	12 849

Design. Of the above types of oven, all have vert flues except the Solvay, which has horiz flues. Extensive improvements have been made in both design and capacity of the Koppers and Semet-Solvay ovens, and by-product coke making in the U S is now far ahead of foreign practice. The first Koppers oven in this country was built in 1908, and, as shown above, more than three-fourths of the total number of by-product ovens now (1938) in operation here are of this make.

Present capacity of by-product ovens is from 4.5 net tons per charge in small gas plants, to 20 net tons per charge in large steel plant installations. Coking time, 10–16 hr.

The latest designs (1929) of the Koppers (Becker type), Semet-Solvay and Otto-Wilputte by-product ovens, which are the most important types now in use, are shown in Fig 20, 21, 22.

Operation. The details of this subject being too complicated and extensive to be included in a book primarily on mining, the reader is referred for further information to Bibliography 23 to 29, at end of this section.

Gases. The coking process begins as soon as the oven has been charged, the charge leveled and the doors sealed. First gases from the ovens are rich in illuminants; usually about the first half of the gas evolved, or that given off in the first 6–10 hr, is used for illuminating purposes. The remaining gas is much poorer, and is used for heating the ovens or other fuel purposes. The rich gas has a heat value of 580 to 620 Btu per cu ft; lean gas varies from 500 to 580 Btu per cu ft. In a number of later installations, particularly those at gas plants, the ovens are heated by a low heat-value gas (such as producer or blast furnace gas) and all of the gas from the oven is utilized elsewhere.

The raw gas leaves the ovens at about 560° F, and is taken through a system of pipes, which are either sprayed or have a stream of flush water running in the bottom to keep the tar soft, this being condensed out of the gas. The condensed tar is removed by a trap, after which the gas passes to the primary coolers, of the multi-tubular, counter-flow type. Here most of the tar, the naphthalene and about 20% of the ammonia collect, the latter being dissolved in the water. Exhausters take the gas from the primary coolers to tar extractors, usually of impact type, where the remainder of the tar is removed. In most U S plants, the gas passes from the tar extractor to a reheater, where

it is heated by steam coils to 80°–130° F. It then passes to saturators, where it bubbles through a bath of H_2SO_4; the ammonia in the gas unites with the acid to make ammonium sulphate, the crystals of which fall to bottom of the tank, whence they are removed, purified and are ready for market. This process does not affect quality of the gas, and no free acid is carried away by it. The gas then passes to the final cooler, where direct contact with cooling water reduces its tempera-

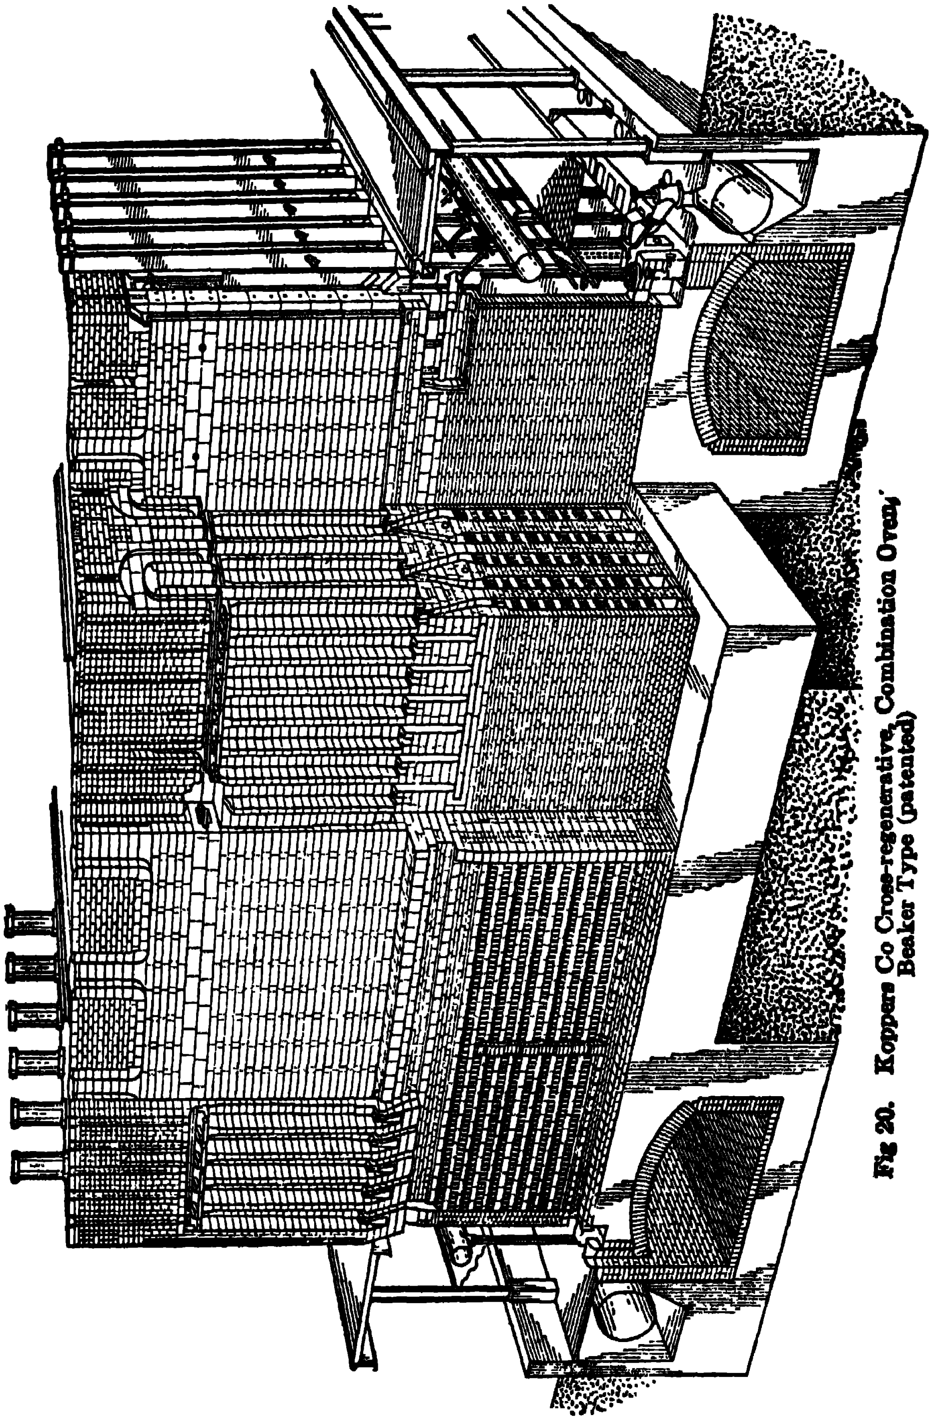

Fig 20. Koppers Co Cross-regenerative, Combination Oven, Becker Type (patented)

ture and removes the remaining naphthalene. Thence it passes to the gas holders, or (at most U S plants) to the benzol recovery plant. In the latter the gas is intimately mixed, in a counter-current flow, with "straw" oil in large washers, from which the gas goes to the holders, and the oil to stills, where the light oil is purified. This light oil is a mixture of benzol, toluol, xylol and solvent naphtha. It is distilled in large stills by steam into a number of fractions, depending upon the market for the products.

Diagram Showing Derivation of By-products

- Product, metallurgical and domestic coke. Yield, 70 to 80% of coal charged
- By-products
  - Coke dust
  - Coke breeze
  - Gas.......... Surplus ranges from 4 300 to 7 500 cu ft per net ton coal charged
    - Illuminating and heating, 500 to 600 Btu per cu ft
    - Total gas yield, 10 000–12 000 cu ft per net ton of coal
    - Bensol
  - Tar.......... Yield, 6–13 gal per net ton coal
    - If heated to following temp: to 170° C
      - Ammonia liquor
      - Light oils....
        - Bensol
        - Naphtha
    - 170° to 230° C
      - Middle oils..
        - Naphthalene
        - Carbolic acid
    - 230° to 270° C
      - Creosote
      - Heavy lubricating oils
    - 270° to 360° C
      - Anthracene
      - Pitch
  - Ammonia..... Yield, 25 lb per net ton coal
    - Concentrated to 15–22% strength
    - Sulphate of ammonia, by combination with H_2SO_4; approx 20% nitrogen
    - Yield, 16–30 lb per net ton coal; aver, about 25 lb.

Uses of the By-products

Coke dust.....	In steel mill soaking pits Up to 1/4-in size, burned under boilers on automatic stoker grates
Coke breeze...	Domestic fuel As fuel in gas producers, for heating coke oven to release entire yield of oven gas
Gas..........	Domestic purposes Industrial fuel Gas engines Steel-plant heating furnaces, open-hearth furnaces, etc Cement kilns
Tar..........	For road tar, roofing tars, roofing felts Heavy-oil engines, and in open-hearth furnaces Waterproof paint, briquette binders
Bensol........	Chemical industries: for dyes; a solvent in making perfumes and medicines; in making high explosives; as motor fuel
Naphtha......	Solvent
Naphthalene..	Insecticide, moth balls, chemicals
Carbolic acid..	Disinfectant
Creosote......	Medicinal Wood preservative Sheep dip
Heavy oils....	Lubrication
Anthracene....	Chemical manufacture
Pitch.........	Paving, waterproofing, fuel briquetting Manufacture of electrodes
Concentrated ammonia	Medicinal, household and refrigeration uses In production of soda ash. Manufacture of explosives
Ammonia sulphate....	Chemicals; fertilizer, usually mixed with phosphates and potash

Recent developments have been in removing water from the gas before it enters the distribution system, in removing phenol from the waste products to prevent stream pollution, and the liquid purification of gas to completely remove sulphur.

By-products, besides coke and gas, are usually tar and ammonium sulphate. Bensol and a number of other derivatives can be made, although taking out additional products is likely to interfere with the production of the others (27–29).

Surplus gas. Total gas produced from by-product ovens is 10 000–12 000 cu ft per net ton of coal. In many of the latest plants, it has been found economical to heat the ovens with producer or blast-furnace gas and to utilize all of the coal gas produced for fuel or lighting purposes.

Design and construction of a modern by-product plant are a highly technical problem, and should be undertaken by the companies building such plants only after they have been furnished with all the necessary basic local data.

22. MISCELLANY

Basic coke. Many attempts have been made to lower the sulphur content of coke during its manufacture, some experiments being along the line of adding limestone to the coal charged, but a basic coke has not yet been commercially produced.

Coke tests. For this subject see Bibliography, 27, 28.

Low-temperature distillation of coal. For many years much effort and money have been expended, both abroad and in the U S, to develop an effic process for obtaining a more satisfactory fuel and by-products from coal at lower temperatures than those used in by-product ovens, as it is thought that the fuel will be better for domestic use, the yield of tar and oils much greater, and that a lower cost for both plant and operation will result. A number of plants of this type are in commercial use in European countries, including Great Britain; in the U S, due to differing fuel conditions, only one plant is in operation, though several others are in an experimental stage.

SECTION 36

MATHEMATICS AND MECHANICS

BY

C. H. BURNSIDE

FORMERLY ASSOCIATE PROFESSOR OF MECHANICS, COLUMBIA UNIVERSITY

MATHEMATICS AND MECHANICS

ALGEBRA

1. ELEMENTARY OPERATIONS

Symbols of operation are the same in algebra as in arithmetic. The symbol of addition is often omitted in arithmetic. Thus, $3^2/_7$ means $3 + {}^2/_7$. If a symbol of operation is omitted in algebra, it is that of multiplication. Thus, $2\frac{x}{y}$ means $2 \times \frac{x}{y}$. $4 > x^2$ means that 4 is greater than x^2. $3 < ab$ means that 3 is less than $a \times b$.

Symbols of aggregation are the bar, | ; vinculum, ——; parenthesis, ( ); bracket, [ ]; and brace, { }. Thus, each of the expressions $\left.\begin{matrix} a \\ +c \end{matrix}\right|$, $\overline{a+c}$, $(a + c)$, $[a + c]$, $\{a + c\}$, means that $a + c$ is to be treated as a single number. If an expression within a parenthesis is preceded by a plus sign, the parenthesis may be removed. If an expression within a parenthesis is preceded by a minus sign, the parenthesis may be removed if the sign of every term within it be changed. Thus, $2 + (a - b) = 2 + a - b$; and $2 - (a - b) = 2 - a + b$. If parentheses occur within parentheses, these may be removed, in succession, by removing first the innermost parenthesis; next, the innermost of all that remain and so on:

$$a - [6 + c - \{d + 3\}] = a - [6 + c - d - 3] = a - [3 + c - d] = a - 3 - c + d$$

Addition. To add like terms, perform the indicated arithmetical operations on the numerical coefficients; this gives the coeff of the answer. Thus,

$$-7\,a + 6\,a - 2\,a + a = -2\,a$$

To add terms which are not all like, combine the like terms and write down the others, each preceded by its proper sign. Thus,

$$-2\,ax + 4\,z + 5\,ax - 3\,z - c = 3\,ax + z - c$$

Polynomials are added by adding their respective terms.

Thus, to add $m^5 - 3\,m^4n - 6\,m^3n^2$, $+\,m^3n^2 + m^2n^3 - 5\,m^4n$ and $-\,n^5 + 2\,m^5 + 7\,m^4n$, write:

$$\begin{array}{rrrrr}
+\;m^5 & -\,3\,m^4n & -\,6\,m^3n^2 & & \\
 & -\,5\,m^4n & +\;m^3n^2 & +\;m^2n^3 & \\
+2\,m^5 & +\,7\,m^4n & & & -\,n^5 \\
\hline
+3\,m^5 & -\;m^4n & -\,5\,m^3n^2 & +\,m^2n^3 & -\,n^5
\end{array}$$

Subtraction. One polynomial may be subtracted from another by changing the sign of each term of the subtrahend and adding.

Thus, $(a^3x^2 + 2\,a^2x^3 - 4\,ax^4) - (a^5 + 4\,a^3x^2 - 3\,a^2x^3 - 4\,ax^4) =$
$a^3x^2 + 2\,a^2x^3 - 4\,ax^4 - a^5 - 4\,a^3x^2 + 3\,a^2x^3 + 4\,ax^4 = -a^5 - 3\,a^3x^2 + 5\,a^2x^3$

Multiplication. To find the product of monomials, annex the literal factors to the product of the numerical factors. Thus, $4\,a \times 2\,b \times 3\,z = 24\,abz$. Like signs produce plus; unlike signs produce minus.

Thus, $4\,a \times 3\,c = +\,12\,ac$; $4\,a \times (-\,3\,c) = -\,12\,ac$; $-\,4\,a \times (-3\,c) = +12ac$; $a^2 \times a^3 = a^{2+3} = aa \times aaa = aaaaa = a^5$; $4\,a^2c \cdot ac^3 = 4\,aac \cdot accc = 4\,aaa \cdot cccc = 4\,a^3c^4$; $6\,ab^2y^3 \times 2\,b^3y^3 \times (-5\,a^2y) = -60\,a^3b^5y^7$.

To multiply two polynomials, multiply each term of one factor by each term of the other factor and add the partial products.

Thus, to multiply $(-a^3 + 2\,a^2b - b^3)$ by $(+4a^2 + 8\,ab)$, the operation may be arranged and carried out thus:

$$\begin{array}{rrrrr}
-a^3 & +\,2\,a^2b & -\,b^3 & & \\
4\,a^2 & +\,8\,ab & & & \\
\hline
-4\,a^5 & +\,8\,a^4b & -\,4\,a^2b^3 & & \\
 & -\,8\,a^4b & & +\,16\,a^3b^2 & -\,8\,ab^4 \\
\hline
-4\,a^5 & & -\,4\,a^2b^3 & +\,16\,a^3b^2 & -\,8\,ab^4
\end{array}$$

Multiplication of polynomials may be indicated by inclosing each in a parenthesis and writing them one after the other.

Thus: $(2b-3)(2b+3)(4b^2+9)$ indicates that the three binomials are to be multiplied together. The indicated operations are performed as follows:

$$\begin{array}{lll} 2b-3 & & \\ 2b+3 & & \text{Multiply the first two.} \\ \hline 4b^2-6b & & \\ \quad +6b-9 & & \\ \hline 4b^2 \quad -9 & & \\ 4b^2 \quad +9 & & \text{Multiply by the third.} \\ \hline 16b^4 \quad -36b^2 & & \\ \quad +36b^2-81 & & \\ 16b^4 \quad -81 & & \text{The final result.} \end{array}$$

Division is the operation by which, if a product and one of its factors are given, the other factor is determined. The product is called the DIVIDEND; the given factor the DIVISOR; and the required factor the QUOTIENT. The quotient is positive if dividend and divisor have like signs; it is negative if dividend and divisor have unlike signs.

$$m^5p^2x^4 \div mp^2x^2 = \frac{m^5p^2x^4}{mp^2x^2} = m^4x^2; \qquad -51\,abdy^2 \div 3\,bdy = \frac{-51\,abdy^2}{3\,bdy} = -17\,ay$$

To divide a polynomial by a polynomial, arrange both dividend and divisor according to the ascending or descending powers of some common letter, and keep this order throughout the operation. Arrange the computation thus: Dividend $\frac{\text{Divisor}}{\text{Quotient}}$. Divide the first term of the dividend by the first term of the divisor and write the result as the first term of the quotient. Multiply all terms of the divisor by the first term of the quotient. Subtract the product from the dividend. If there be a remainder, consider it as a new dividend and proceed as before.

Thus: $(22\,a^2b^2 + 15\,b^4 + 3\,a^4 - 10\,a^3b - 22\,ab^3) \div (a^2 + 3\,b^2 - 2\,ab)$

$$\begin{array}{l|l} 3a^4 - 10a^3b + 22a^2b^2 - 22ab^3 + 15b^4 & a^2 - 2ab + 3b^2 \\ \underline{3a^4 - 6a^3b + 9a^2b^2} & 3a^2 - 4ab + 5b^2 \\ -4a^3b + 13a^2b^2 - 22ab^3 + 15b^4 & \\ \underline{-4a^3b + 8a^2b^2 - 12ab^3} & \\ 5a^2b^2 - 10ab^3 + 15b^4 & \\ \underline{5a^2b^2 - 10ab^3 + 15b^4} & \end{array}$$

The quotient is $(3\,a^2 - 4\,ab + 5\,b^2)$.

Factoring is the process of finding two or more expressions the product of which is equal to a given expression. First, factor out any monomial common to each term; then treat the polynomial by one of the following TYPE FORMS:

1. $ax + ay + bx + by = a(x+y) + b(x+y) = (a+b)(x+y)$
2. $a^2 + 2\,ab + b^2 = (a+b)(a+b)$
3. $y^2 + by + c = (y+p)(y+g)$, if p and g are two numbers the sum of which is b and the product is c.
4. $ax^2 + bx + c$

Find two numbers the algebraic sum of which is b and the product is $a \cdot c$. Replace bx by two terms in x, the coefficients of which are the numbers just found, and factor by grouping terms.

Thus: $4\,x^2 - 5\,x - 6 = 4\,x^2 - 8\,x + 3\,x - 6 = 4\,x(x-2) + 3(x-2) = (4\,x+3)(x-2)$

5. $a^2 - b^2 = (a+b)(a-b)$
6. $a^4 + ka^2b^2 + b^4$. This type can sometimes be reduced to type 5 by adding and subtracting a multiple of a^2b^2. Thus:

$$\begin{aligned} 9\,x^4 + 3\,x^2y^2 + 4\,y^4 &= (9\,x^4 + 12\,x^2y^2 + 4\,y^4) - 9\,x^2y^2 \\ &= (3\,x^2 + 2\,y^2)^2 - 9\,x^2y^2 \\ &= (3\,x^2 + 2\,y^2 + 3\,xy)(3\,x^2 + 2\,y^2 - 3\,xy) \end{aligned}$$

7. $\left\{\begin{aligned} a^n + b^n &= (a+b)(a^{n-1} - a^{n-2}b + a^{n-3}b^2 \ldots + b^{n-1}) \\ a^n - b^n &= (a-b)(a^{n-1} + a^{n-2}b + a^{n-3}b^2 \ldots + b^{n-1}) \end{aligned}\right\}$ if n is odd.

If n is even, $(a^n - b^n)$ becomes type 5. In all other cases, if n is a multiple of 3, apply one of the special types,

$$\begin{aligned} a^3 + b^3 &= (a+b)(a^2 - ab + b^2) \\ a^3 - b^3 &= (a-b)(a^2 + ab + b^2) \end{aligned}$$

8. $a^2 + b^2 + c^2 + 2\,ab + 2\,ac + 2\,bc = (a+b+c)^2$

2. POWERS, ROOTS AND RADICALS

The relation between exponential and radical notation is expressed by the formula, $\sqrt[b]{x^a} = (\sqrt[b]{x})^a = x^{\frac{a}{b}}$, in which a and b are any numbers and b is not zero. In such a fractional exponent, the numerator indicates the power to which the number is to be raised and the denominator gives the index of the root which is to be extracted. The fundamental laws of exponents are as follows:

1. $(+a)^n = +a^n$
2. $(-a)^{2n} = -a^{2n}$
3. $(-a)^{2n+1} = -a^{2n+1}$
4. $a^m a^n = a^{m+n}$
5. $a^m \div a^n = a^{m-n}$
6. $a^m b^m = (ab)^m$
7. $a^m \div b^m = (a \div b)^m$
8. $1 \div a^m = (1 \div a)^m = a^{-m}$
9. $a^m = (1 \div a)^{-m} = 1 \div a^{-m}$
10. $(a^m)^n = a^{mn} = (a^n)^m$

11. $a^0 = 1$; $0a = 0$; $0^0 =$ indeterminate.

12. $\sqrt[2n]{+a}$ is positive or negative; $\sqrt[(2n+1)]{+a}$ is positive; $\sqrt[(2n+1)]{-a}$ is negative.

The root of $\sqrt[2n]{-a}$ is impossible or imaginary and the simplest one is $\sqrt{-1}$, which is represented by the symbol i. A complex quantity is partly real and partly imaginary:

$$i = \sqrt{-1};\quad i^2 = -1;\quad i^3 = -i;\quad i^4 = +1;\quad \frac{1}{i} = -i;$$

$$i^{4n+m} = i^m;\quad i^{4n} = +1;\quad i^{4n+1} = +i;\quad i^{4n+2} = -1;\quad i^{4n+3} = -i.$$

13. $\sqrt[m]{ab} = \sqrt[m]{a}\sqrt[m]{b} = (ab)^{\frac{1}{m}}$

14. $\sqrt[m]{a \div b} = \sqrt[m]{a} \div \sqrt[m]{b} = \left(\frac{a}{b}\right)^{\frac{1}{m}}$

15. $\sqrt[m]{\frac{1}{a}} = \frac{1}{\sqrt[m]{a}} = \frac{1}{a^{\frac{1}{m}}} = a^{-\frac{1}{m}}$

16. $\sqrt[m]{\sqrt[n]{a}} = \sqrt[mn]{a} = a^{\frac{1}{mn}} = \sqrt[n]{\sqrt[m]{a}}$

17. $\sqrt{a + b + 2\sqrt{ab}} = \sqrt{a} + \sqrt{b}$

The following approximations are often convenient and are sufficiently accurate if x and y are small compared with 1:

18. $(1 + x)^2 = 1 + 2x$
19. $(1 + x)^{\frac{1}{2}} = 1 + \frac{x}{2}$
20. $\frac{1}{1 + x} = 1 - x$
21. $\frac{1}{1 - x} = 1 + x$
22. $(1 + x)(1 + y) = 1 + x + y$
23. $(1 + x)(1 - y) = 1 + x - y$
24. $(1 + x)^2 (1 - 2y)^2 = 1 + 2x - 4y$

If a and b are nearly equal,

25. $\sqrt{ab} = (a + b) \div 2$

If b is small compared with a,

26. $\sqrt{a^2 \pm b} = a \pm \frac{b}{2a}$
27. $\sqrt[3]{a^3 \pm b} = a \pm \frac{b}{3a^2}$

28. $\sqrt{a^2 + b^2} = 0.960\,a + 0.398\,b$. This is within 4% of the true value if $a > b$. A closer approximation is $\sqrt{a^2 + b^2} = 0.9938\,a + 0.0703\,b + 0.3567\,\frac{b^2}{a}$.

29. $\sqrt{a^2 + b^2 + c^2} = 0.939\,a + 0.389\,b + 0\ 297\,c$. This is within 6% of the true value if $a > b > c$. For instance, for the numbers 43, 42 and 41, the error $< 5.2\%$.

3. BINOMIAL THEOREM

Binomial theorem is used to expand a binomial expression into a series as follows:

$$(a \pm b)^n = a^n \pm na^{(n-1)}\,b + \frac{n\,(n-1)}{1 \cdot 2}\,a^{(n-2)}\,b^2 + \frac{n\,(n-1)\,(n-2)}{1 \cdot 2 \cdot 3}\,a^{(n-3)}\,b^3 + \cdots$$

The series is finite if n is a positive whole number; it is infinite if n is fractional or negative; and it is convergent for $a > b$. The product $1 \cdot 2 \cdot 3 \ldots r$ is called factorial r and may be written $r!$. The coefficients of the powers are called binomial coeds, and the rth coeff is $\frac{n\,(n-1)\,(n-2)\ldots[n-(r-1)]}{1 \cdot 2 \cdot 3 \ldots r}$. The binomial $(a \pm b)^n = a^n\ (1 \pm x)^n$, in which $x = b \div a$.

It is often more convenient to expand the second form than the first. The four following special forms can be used if n is any positive integer and for any negative or fractional value of n, if x lies between 0 and 1:

$$(1 \pm x)^n = 1 \pm nx + \frac{n(n-1)}{1\cdot 2}x^2 \pm \frac{n(n-1)(n-2)}{1\cdot 2\cdot 3}x^3 + \frac{n(n-1)(n-2)(n-3)}{1\cdot 2\cdot 3\cdot 4}x^4 \pm \cdots$$

$$\frac{1}{1 \pm x} = (1 \pm x)^{-1} = 1 \mp x + x^2 \mp x^3 + x^4 \mp x^5 \cdots$$

$$\sqrt{1 \pm x} = (1 \pm x)^{1/2} = 1 \pm \frac{1}{2}x - \frac{1}{2\cdot 4}x^2 \pm \frac{1\cdot 3}{2\cdot 4\cdot 6}x^3 - \frac{1\cdot 3\cdot 5}{2\cdot 4\cdot 6\cdot 8}x^4 \pm \frac{1\cdot 3\cdot 5\cdot 7}{2\cdot 4\cdot 6\cdot 8\cdot 10}x^5 \cdots$$

$$\frac{1}{\sqrt{1 \pm x}} = (1 \pm x)^{-1/2} = 1 \mp \frac{1}{2}x + \frac{1\cdot 3}{2\cdot 4}x^2 \mp \frac{1\cdot 3\cdot 5}{2\cdot 4\cdot 6}x^3 + \cdots$$

Proportion $a : b :: c : d$ may be written $\frac{a}{b} = \frac{c}{d}$.

Hence, $ad = bc$, $\frac{b}{a} = \frac{d}{c}$, $\frac{a}{c} = \frac{b}{d}$, $\frac{a+b}{b} = \frac{c+d}{d}$, $\frac{a-b}{b} = \frac{c-d}{d}$, $\frac{a+b}{a-b} = \frac{c+d}{c-d}$.

4. SERIES

Series is a succession of numbers which proceed according to some fixed law. Any one of the numbers is called a TERM of the series. A series continued indefinitely is an INFINITE SERIES, and one that ends with some particular term is a FINITE SERIES.

Arithmetical series or progression is a series in which the difference between any two adjacent terms is equal to the difference between any other two adjacent terms. The common difference may be plus or minus. The formula for the nth term is, $t_n = a + (n-1)d$. The sum of n terms is $Sn = \frac{n}{2}(a + t_n)$, in which a is the first term and d the common difference. From the above equations, any one of the quantities, a, d, t_n, n, or S, may be found if any three of the others are given.

Geometrical series or progression. In this, each succeeding term is obtained by multiplying the preceding term by a constant multiplier. If a is the first term, r the constant multiplier, and t_n the nth term, $t_n = ar^{(n-1)}$. GEOMETRICAL MEAN between two numbers is the number which stands between them and makes, with them, a geometrical series. If a and b denote two numbers, then $G = \sqrt{ab}$ is their geometrical mean. If it is desired to insert m means between the numbers, the constant multiplier is given by the formula $r^{(m+1)} = b \div a$. The sum of n terms is $S = \frac{a(r^n - 1)}{r-1} = \frac{rb - a}{r-1}$, b being the nth term.

Special Series:

1. $1 + 2 + 3 + 4 + \cdots + (n-1) + n = n(n+1) \div 2$
2. $p + (p+1) + (p+2) + \cdots + (q-1) + q = (q+p)(q-p+1) \div 2$
3. $2 + 4 + 6 + 8 + \cdots + (2n-2) + 2n = n(n+1)$
4. $1 + 3 + 5 + 7 + \cdots + (2n-3) + (2n-1) = n^2$
5. $1^2 + 2^2 + 3^2 + 4^2 + \cdots + (n-1)^2 + n^2 = n(n+1)(2n+1) \div (1\cdot 2\cdot 3)$
6. $1^3 + 2^3 + 3^3 + 4^3 + \cdots + (n-1)^3 + n^3 = [n(n+1) \div 2]^2$
7. $1^4 + 2^4 + 3^4 \cdots + (n-1)^4 + n^4 = n(n+1)(2n+1)(3n^2 + 3n - 1) \div 30$
8. $\frac{1 + 2 + 3 + 4 + 5 \cdots + n}{n^2} = \frac{1}{2}$
9. $\frac{1 + 2^2 + 3^2 + 4^2 + \cdots + n^2}{n^3} = \frac{1}{3}$ as n approaches ∞
10. $\frac{1 + 2^3 + 3^3 + 4^3 + \cdots + n^3}{n^4} = \frac{1}{4}$
11. $e = \lim_{n\to\infty}\left(1 + \frac{1^n}{n}\right) = 1 + \frac{1}{1!} + \frac{1}{2!} + \frac{1}{3!} + \frac{1}{4!} + \cdots = 2.71828$, in which e is the base of Naperian system of logarithms, and $\lim_{n\to\infty}$ means "the limit as n approaches infinity."
12. $a^x = 1 + \frac{x}{1}\log_e a + \frac{x^2}{2!}(\log_e a)^2 + \frac{x^3}{3!}(\log_e a)^3 + \cdots$
13. $e^x = 1 + \frac{x}{1} + \frac{x^2}{2!} + \frac{x^3}{3!} + \frac{x^4}{4!} + \cdots$

$$\left.\begin{array}{l}14.\ \text{Log}_e\,(1 \pm x) = \pm x - \dfrac{x^2}{2} \pm \dfrac{x^3}{3} + \dfrac{x^4}{4} \pm \dfrac{x^5}{5} \cdots \\ 15.\ \text{Log}_e\left(\dfrac{1+x}{1-x}\right) = 2\left(x + \dfrac{x^3}{3} + \dfrac{x^5}{5} + \dfrac{x^7}{7} + \cdots\right)\end{array}\right\}\text{if } -1 < x < +1$$

$$16.\ \text{Log}_e\left(\frac{x+1}{x-1}\right) = 2\left(\frac{1}{x} + \frac{1}{3x^3} + \frac{1}{5x^5} + \frac{1}{7x^7} + \cdots\right)\text{if } -1 > x, \text{ or } x > +1$$

$$\left.\begin{array}{l}17.\ \sin x = x - \dfrac{x^3}{3!} + \dfrac{x^5}{5!} + \dfrac{x^7}{7!} + \cdots \\ 18.\ \cos x = 1 - \dfrac{x^2}{2!} + \dfrac{x^4}{4!} - \dfrac{x^6}{6!} + \dfrac{x^8}{8!} \cdots \\ 19.\ \tan x = x + \dfrac{x^3}{3} + \dfrac{2x^5}{3 \cdot 5} + \dfrac{17x^7}{3^2 \cdot 5 \cdot 7} + \dfrac{62x^9}{3^2 \cdot 5 \cdot 7 \cdot 9} + \cdots\end{array}\right\}\begin{array}{l}\text{The angle } x \text{ is in RADIANS,} \\ \text{and } = \text{ angle in degrees} \\ \times \dfrac{\pi}{180}\end{array}$$

5. LOGARITHMS

A Logarithm is the power to which a given fixed number must be raised to produce another number. In $y = b^x$, b is the base, x the logarithm or power, and y the number which is produced. For common, or Briggs, logarithms the base is 10. The only other system in common use is the Naperian, natural or hyperbolic system, for which the base is 2.71828. The abbreviation *log* means the logarithm of a number to the base 10. The notation Nap log 6, or $\log_e 6$, means the logarithm of 6 to the base e; and log 6 means the logarithm of 6 to the base 10. Thus, $\log 100 = 2$, because $100 = 10^2$; $\log 10 = 1$, because $10 = 10^1$; $\log 1 = 0$, because $1 = 10^0$; $\log 0.1 = -1$, because $0.1 = 10^{-1}$. Any number > 1 has a positive logarithm and any number < 1 has a negative logarithm. Numbers which are not whole powers of 10 must result from raising 10 to some fractional or irrational power. The decimal part of such powers, or logarithms, may be obtained from a table of logarithms. Since 10 is larger than e (2.71828), it takes a higher power of e to produce a given number than it does of 10. This means that the logarithm of a number to base e, is larger than to base 10. Relation between the two systems of logarithms is:

$$\log_e n = \log_{10} n \div \log_{10} e$$

or

$$\log_e n = \log_{10} n \div 0.4343 = \log_{10} n \times 2.303$$

6. CHOICE AND CHANCE

Permutations or choice. If one thing can be done in a different ways and another thing can be done in b different ways, then both together can be done in $a \times b$ different ways. If one thing can be done in a ways, a second in b ways, a third in c ways and a fourth in d ways, the number of ways of doing all these things will be $a \times b \times c \times d$. The number of arrangements of n different elements or things, taken all at a time, is

$$n\,(n-1)\,(n-2)\,(n-3)\cdots 3 \times 2 \times 1 = n!$$

Probability or chance. If an event may happen in a ways and fail in b ways, each way being equally probable, the chance or probability that it will happen in a ways is $a \div (a+b)$; the chance that it will fail is $b \div (a+b)$. The sum of the chances is 1. Odds in favor of the event is the ratio of chance of happening to chance of failure. Odds in favor are $a \div b$; odds against, $b \div a$.

7. QUADRATIC AND CUBIC EQUATIONS

Linear equations, or those of the first degree, contain the first power only of the unknown, and have but one root. Thus, $x = -\dfrac{b}{a}$ is the root of $ax + b = 0$.

Quadratic equations, or those of the second degree, contain the second power of the unknown and have two roots. If equation is written in the form $ax^2 + bx + c = 0$, the roots are $x = (-b \pm \sqrt{b^2 - 4\,ac}) \div 2\,a$. If $(b^2 - 4\,ac) > 0$, the roots are real; if $(b^2 - 4\,ac) < 0$, the roots are imaginary; if $(b^2 - 4\,ac)$ is a perfect square, the roots are rational; if $(b^2 - 4\,ac) = 0$, the roots are equal but opposite in sign. Following is an Euclidean (graphical) construction for the roots of a quadratic. The equation should be put in the form,

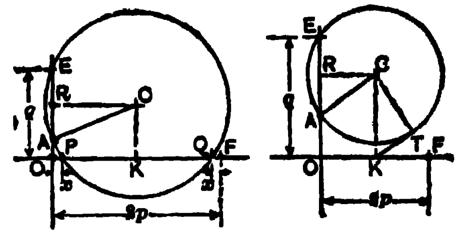
$$x^2 - 2\,px + q = 0, \text{ or } x\,(2\,p - x) = q$$

Case 1. p and q are both positive factors. On intersecting axes, ox and oy, not necessarily at right angles (Fig 1a), lay off OA = unity and $OE = q$, both upwards, and $OF = 2\,p$, to the right. From C, the intersection of the perpendicular bisectors KC and RC of lines OF and AE, as a center, with CA as a radius, describe a circle; its intercepts, OP and OQ, on OX, are the roots required.

Case 2. p negative and q positive. Lay off $2\,p = OF$ to the left, and proceed as before. Both roots will be negative, because measured to the left.

Case 3. p and q are negative factors. Lay off $OE = q$, downward, $OF = 2\,p$ to left, OA = unity upward, and proceed as before. One root will be negative.

Case 4. p positive and q negative. Lay off $OF = 2\,p$ to right, OA = unity, upwards, $OE = q$ downwards, and proceed as before. One root will be negative.



(a) (b)

Fig 1

Case 5. THE CIRCLE DOES NOT CUT OX, therefore the roots are imaginary. The real part of the imaginary root can be found by drawing a tangent to the circle from K (Fig 1b). If T is the point of tangency, KT will be the real part of the imaginary roots.

Cubic equation, or one of the third degree, contains the third power of the unknown, may contain the second, first, and zero powers; it has 3 roots, 2 of which may be imaginary. TRIGONOMETRIC SOLUTION OF THE CUBIC. If the equation is in the form $y^3 + by^2 + cy^1 + d = 0$, it is necessary to transform it to a cubic, in which the second power does not appear. This is done by making $y = x - (b \div 3)$, expanding and collecting terms; it will then be in the form $x^3 + px + q = 0$. Three cases must be distinguished:

$$\left.\begin{array}{l} 1.\ x^3 + px + q = 0 \\ 2.\ x^3 - px + q = 0, \text{ and } (p^3 \div 27) < (q^2 \div 4) \\ 3.\ x^3 - px + q = 0, \text{ and } (p^3 \div 27) > (q^2 \div 4) \end{array}\right\}$$ In these, p is necessarily positive and q is positive or negative.

Formulas for Case 1: $tan\ A = \dfrac{2\,p}{3\,q}\sqrt{\dfrac{p}{3}}$, $tan\ \dfrac{1}{2}B = \sqrt[3]{tan\ \dfrac{1}{2}A}$;

the roots are, $x_1 = -2\sqrt{\dfrac{p}{3}}\ cot\ B$, $x_2 = \sqrt{\dfrac{p}{3}}\ cot\ B + cosec\ B\sqrt{p}\sqrt{-1}$, and

$x_3 = \sqrt{\dfrac{p}{3}}\ cot\ B - cosec\ B\sqrt{p}\sqrt{-1}$

Formulas for Case 2: $sin\ A = \dfrac{2\,p}{3\,q}\sqrt{\dfrac{p}{3}}$, $tan\ \dfrac{1}{2}B = \sqrt[3]{tan\ \dfrac{1}{2}A}$;

the roots are, $x_1 = -2\sqrt{\dfrac{p}{3}}\ cosec\ B$, $x_2 = \sqrt{\dfrac{p}{3}}\ cosec\ B + cot\ B\sqrt{p}\sqrt{-1}$, and

$x_3 = \sqrt{\dfrac{p}{3}}\ cosec\ B - cot\ B\sqrt{p}\sqrt{-1}$

Formula for Case 3: $sin\ A = \dfrac{3\,q}{2\,p}\sqrt{\dfrac{3}{p}}$; the roots are, $x_1 = 2\sqrt{\dfrac{p}{3}}\ sin\ \dfrac{A}{3}$,

$x_2 = 2\sqrt{\dfrac{p}{3}}\ sin\left(60° - \dfrac{A}{3}\right)$ and $x_3 = -2\sqrt{\dfrac{p}{3}}\ sin\left(60° + \dfrac{A}{3}\right)$

8. INTEREST

Simple interest. Let principal = P, yearly rate = $r\%$, amount of \$1 for 1 year = R, number of years = n, and amount of P for n years = A; then $R = 1 + r$, the interest on P for n years = Pnr, and $A = P\,(1 + nr)$. P is sometimes called the present worth of A. If d = any number of days, simple interest for that time is given by following formulas: at 4%, interest = $Pd \div 9\,000$; 5%, $Pd \div 7\,200$; 6%, $Pd \div 6\,000$; 8%, $Pd \div 4\,500$.

As 6% is a very common rate, it is worth recalling that interest for 1 month = $(P \times 6) \div (12 \times 100) = P \div 200$; divide this by 30 to get the interest for 1 day, and multiply the last result by d to get the interest for d days. Proportional parts of these results may be taken for other percentages.

Example. The interest on \$5 284 for 30 days at 6% = 5 284 ÷ 200 = \$26.42; interest for 1 day = 26.42 ÷ 30 = \$0.8807; interest for 12 days = 12 × 0.8807 = \$10.568. By the 6% formula given above the interest for 12 days would be (\$5 284 × 12)

+ 6 000 = \$10.568. At 4%, the interest for the 12 days would be $^4/_6$ \$10.57 = \$7.04. At 7%, the interest would be $^7/_6$ \$10.57 = \$12.33.

Compound interest. If, at the end of a period, interest is added to principal, and then interest charged on the new principal, the second period's interest added to form a new principal and so on, the interest is said to be compounded. With notation as before, $A = PR^n$, or $P = A \div R^n$.

Example. In 12 years at 6%, \$400 amounts to $A = 400\ (1.06)^{12} = \$804.88$.

Present worth of \$5 000 due in 15 yr at 5% comp'd interest is $P = \dfrac{5\ 000}{(1.05)^{15}} = \$2\ 405.09$

If interest is to be added to principal g times each year, $A = P\left(1 + \dfrac{r}{g}\right)^{gn}$

Example. The amount of \$400 in 12 years with interest at 6% and compounded quarterly will be $A = 400\left(1 + \dfrac{0.06}{4}\right)^{4\times 12} = \$817.39$, instead of \$804.88 if compounded yearly, and instead of \$688.00 by simple interest.

Sinking fund is created to pay a debt that falls due, or to provide for expenditure that must be made, at some future time. If S is the sum set apart each time to be put at compound interest, and other notation is as above, then

$$A = S\ (R^n - 1) \div (R - 1) = S\ (R^n - 1) \div r, \quad \text{or} \quad S = Ar \div (R^n - 1)$$

Amortization. $d\%$ = annual dividend rate required to yield $r\%$ of simple interest, and to furnish annual instalments of P dollars each, which, if placed in a sinking fund at $s\%$ compound interest, will return original investment at end of n years:

$$d = [s + r\ (S^n - 1)] \div (S^n - 1), \quad \text{and} \quad n = \log\left[(s + d - r) \div (d - r)\right] \div \log S$$

in which S is the amount of \$1 for one year at $s\%$. (See Table 5, Sec 25.)

Buying on instalments. Interest is added to principal at time of payment and amount of instalment deducted.

Q = amount of debt, P = amount of instalment, n = number of equal instalments, $r\%$ = rate of interest, R = amount of \$1 for one instalment period, and A_n = amount of debt after payment of n instalments; then, $A_n = QR^n - [P\ (R^n - 1) \div (R - 1)]$. To cancel debt, make $A_n = 0$; then

$$P = QR^n\ (R - 1) \div (R^n - 1), \quad \text{and} \quad n = [\log P - \log (P - QR + Q)] \div \log R$$

GEOMETRY AND MENSURATION

9. CONSTRUCTIONS

Lines. To divide a given line into two equal parts (Fig 2).

Let AB be the given line. With any radius (obviously greater than 0.5 AB) describe 2 arcs with A and B as centers. The line CD, through points of intersection of the arcs, is a perpendicular bisector of the given line.

To divide a given line into any number of equal parts (Fig 3).

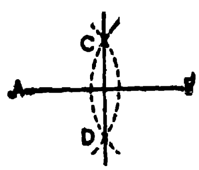


Fig 2

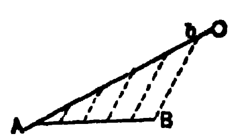

Fig 3

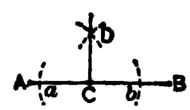

Fig 4

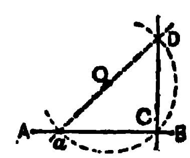

Fig 5

Let AB be the given line and let the number of equal parts be five. Draw line AC at any convenient angle with AB, and step off any 5 equal spaces from A to b. Connect b with B, and draw parallels through the other points in AC. The intersections of these parallels with AB determine the required equal parts on the given line.

To draw a perpendicular to a given line through any given point on the line.

Case 1. Point C is near the middle of the line AB (Fig 4). With C as center, describe arcs of equal radius intersecting AB at a and b. With a and b as centers, and any radius greater than Ca, describe arcs intersecting at D. CD is the required perpendicular.

Case 2. Point C is near the extremity of the line AB (Fig 5). With any point O, as center, and radius OC, describe an arc intersecting AB at a. Extend aO to intersect the arc at D. CD is the required perpendicular.

To draw a perpendicular to a given line through any given point outside of the line,

Case 1. Point C is opposite, or nearly opposite, the middle of the line AB (Fig 6). With C as center, describe an arc intersecting AB at a and b. With a and b as centers, the same radius as before, describe arcs intersecting at D. CD is the required perpendicular.

Case 2. Point C is opposite, or nearly opposite, the extremity of line AB (Fig 7). Through C, draw any line intersecting AB at a. Divide line Ca into 2 equal parts, ab and bC (method given above). With b as center, and radius bC, describe an arc intersecting AB at D. CD is required perpendicular.

Angles. To bisect a given angle.

Case 1. Vertex B is accessible (Fig 8). Let ABC be the given angle. With B as center, and a large radius, describe an arc intersecting AB and BC at a and c respectively.

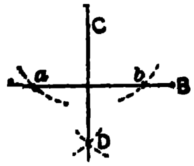

Fig 6

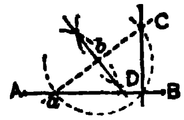

Fig 7

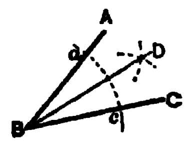

Fig 9

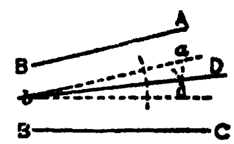

Fig 9

With a and c as centers, describe arcs of equal radius intersecting at D. DB is the required bisector.

Case 2. Vertex B is inaccessible (Fig 9). Let the given angle be the inclination between lines AB and BC. Draw lines ab and bc parallel to the given lines, and at equal distances from them, intersecting at b. Let Db bisect angle abc (method given above). Db is the required bisector.

Circles. To draw a circle through 3 given points not in same straight line (Fig 10). Let A, B and C be the given points. Bisect the imaginary chords AB and BC. Draw bisecting lines and produce them to intersect at O. Point O is center of required circle.

To draw a tangent to a circle from any given point.

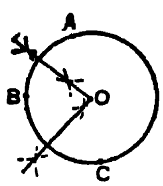

Fig 10

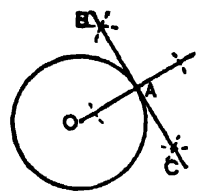

Fig 11

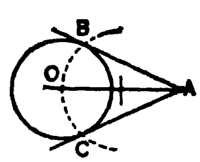

Fig 12

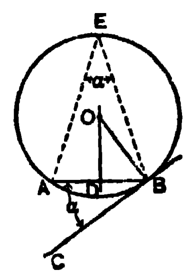

Fig 13

Case 1. Point A is on the circumference of circle O (Fig 11). Draw radius OA. Through A, perpendicular to OA, draw BAC, the required tangent.

Case 2. Point A is not on circumference of circle O (Fig 12). Two tangents may be drawn. Join O and A. With OA as diam, describe a circumference intersecting the given circle at B and C. BA and CA are the required tangents.

To construct, upon a given chord, a segment of a circle in which a given angle may be inscribed (Fig 13). Let AB be the given line, and α the given angle. Construct angle ABC equal to angle α. Bisect line AB by the perpendicular at D. Draw a perpendicular to BC from point B. With O, the point of intersection of the perpendiculars, as center, and OB as radius, describe a circumference. AEB is the required segment, and vertex E may be located anywhere on the arc AEB.

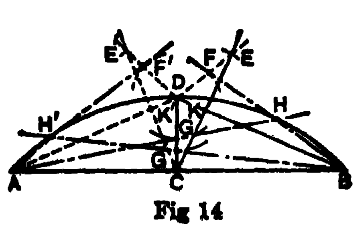

Fig 14

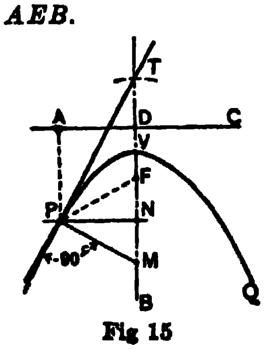

Fig 15

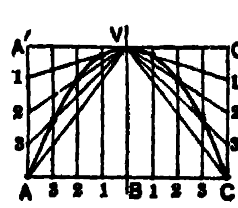

Fig 16

To construct points on a circular arc without locating the center of the circle having given the chord and the rise (Fig 14). Let ACB be the given chord and CD the given rise. Draw BD. Draw CE perpendicular to BD, and make $KE = KC$. Draw DE.

Choose any distance DF, and make $DG = DF$. Line AG, produced, meets BF at H, a point on the required arc. For other points on arc $ADHB$, use other values of DF and repeat the construction.

Parabola is a curve for which the distance of any point from a fixed line, called DIRECTRIX, is equal to the focal radius of the point; that is, $AP = PF$ (Fig 15).

To inscribe a parabola within a rectangle (Fig 16). Let $ABCC'A'$ be the given rectangle. Divide CC' and BC, also AA' and AB, into the same number of equal parts. Number the divisions on the base from the center each way. Number divisions on $C'C$ and $A'A$ from the top, downward. From the divisions on BC and AB, draw parallels to axis BV. From the divisions on CC' and AA', draw lines converging to the vertex V. The intersections of corresponding lines, such as 1 with 1 and 2 with 2, determine points on the required parabola. This construction applies equally well for inscribing a parabola within a parallelogram, in which case, axis BV is parallel to a side of the parallelogram.

To draw a tangent to a parabola from any given point.

Case 1. Point P is on the curve (Fig 15). Draw PN perpendicular to axis VB. With N as center, and radius $= 2\,NP$, describe an arc intersecting the axis at T. TP is the required tangent. NT is called the SUBTANGENT. PM being normal to the curve, NM is called the SUBNORMAL. Distance from vertex V to focus F equals 0.5 NM. Line AC, perpendicular to the axis at D, is the directrix. $DF = NM$.

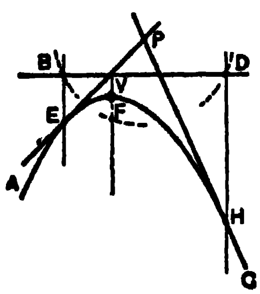

Fig 17

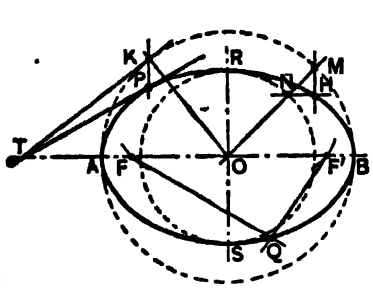

Fig 18

Case 2. Point P is not on the curve (Fig 17). Let F be the focus. With P as center, and PF as radius, draw arcs intersecting the directrix at B and D. Through B and D draw lines parallel to axis, intersecting the parabola at E and H. PE and PH are the required tangents.

Ellipse is a curve for which the sum of the focal radii to any point is a constant, that is, $FQ + QF' = AB =$ constant.

To inscribe an ellipse within a rectangle (Fig 18). Let AOB and ROS be the length and width, respectively, of the given rectangle. With O as center, and OB and OR as radii, describe circles. From O draw any radial line intersecting the circles at M and N. Through M draw a line parallel to OR, and through N a line parallel to OB. These lines intersect at H, a point on the ellipse. Repeat the construction to obtain other points. AB and RS are major and minor axes, respectively.

To locate the FOCI of an ellipse, having given the axes (Fig 18). With R as center, and radius $= AO$, describe arcs intersecting AB at F and F', the required foci.

To draw an ellipse, having given an axis and the foci (Fig 18). A cord or thread, of length equal to the major axis, should be pinned or fixed, at its ends, to the foci F and F'. With a pencil inside the loop, keeping the cord taut so as to guide the pencil point, trace the outline of the ellipse (Q represents the pencil point and length FQF' the cord).

To draw a tangent to an ellipse from any given point.

Case 1. The point P is on the curve (Fig 18). With O as center, and OB as radius, describe a circle. Through P draw a line parallel to OR, intersecting the circle at K. Through K draw a tangent to the circle, intersecting the major axis at T. PT is the required tangent.

Case 2. Point P is not on the curve (Fig 19). With P as center, and radius PF', describe an arc. With F as center, and radius AB, describe an arc intersecting the first arc at M and N. Draw FM and FN, intersecting the ellipse at E and G. PE and PG are the required tangents.

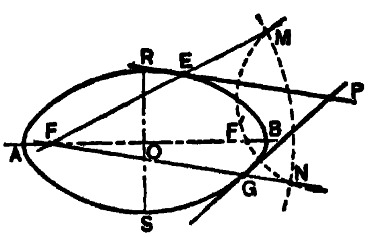

Fig 19

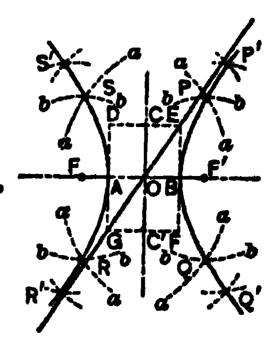

Fig 20

Hyperbola is a curve for which the difference of the focal radii to any point is a constant; that is (Fig 20), $FQ - F'Q = FQ' - F'Q' = AB =$ constant.

To construct an hyperbola by points, having given the foci and the constant difference of the focal radii. Let F and F' (Fig 20) be the foci, and transverse axis AOB the differ-

ence of the focal radii. $AF = F'B$. $AO = OB$. A and B are points on the required curve. With centers F and F', and any radius greater than FB or $F'A$, describe arcs a–a. With same centers, and radius equal to the difference between the first radius and transverse axis AOB, describe arcs b–b, intersecting arcs a–a at P, Q, R, and S, points on the required curve. Repeat the construction for additional points.

Make $BC = BC' = OF = OF'$, and construct the rectangle $DCEBFC'GAD$. The diagonals DF and EG, produced, are called ASYMPTOTES. The hyperbola is tangent to its asymptotes at infinity. If the axes CO and OB are given, the foci can be determined by making $OF = OF' = BC$.

To draw a tangent to an hyperbola from any point.

Case 1. Point P is on the curve (Fig 21). Draw lines connecting P with the foci. Bisect the angle $F'PF$. The bisecting line TP is the required tangent.

Case 2. Point P is on the convex side of the hyperbola (Fig 22). With P as center and radius PF', describe an arc. With F as center, and radius AB, describe an arc intersecting the first arc at M and N. Produce lines FM and FN to intersect the curve at E and G. PE and PG are the required tangents.

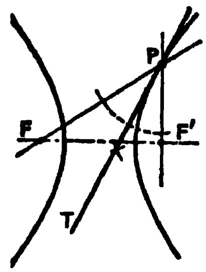

Fig 21

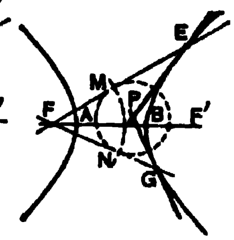

Fig 22

Reference units for angles. The natural unit is 4 right angles, called a PERIGON, and equals 360 degrees of angle. One degree equals 60 minutes. One minute equals 60 seconds. In circular measure the unit is the RADIAN. One radian is the measure of an angle subtended at the center of a circle by an arc equal in length to the radius.

360 degrees of angle $= 2\pi$ radians of angle.

1 radian $= 180 \div \pi$ degrees $= 57.29578$ degrees $= 57° 17' 44.8''$.

Length of arc $= r\theta$; where $r =$ radius of circular arc, $\theta =$ subtended angle, in radians.

10. LINES AND AREAS (A = Area)

 Fig 23. Rectangle	Perimeter $= 2\,(a + b)$ Diagonal $= \sqrt{a^2 + b^2}$ $A = a \times b$
 Fig 24. Triangle	Perimeter $= a + b + c$ $A = \frac{a \times h}{2} = \frac{m \times c}{2}$ If $s = \frac{(a + b + c)}{2}$, $A = \sqrt{s\,(s - a)\,(s - b)\,(s - c)}$
 Fig 25. Quadrilateral	$A = \frac{d_1 \times d_2 \times \sin \alpha}{2}$
 Fig 26. Parallelogram	$A = a \times h$ $= a \times b \times \sin \alpha$
 Fig 27. Trapezoid	$A = \frac{(a + b)\,h}{2}$
 Fig 28. Regular Polygon	Perimeter $= n \times a$ $A = \frac{nar}{2} = nr^2 \tan \alpha = \frac{nR^2}{2} \sin 2\,\alpha$

Lines and Areas (*Continued*)

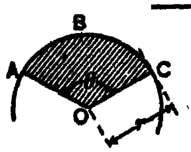

Fig 29. Circular Sector

$$A_{OABCO} = \frac{\pi r^2 \theta(\text{degrees})}{360} = \text{arc } ABC \times \frac{r}{2}$$

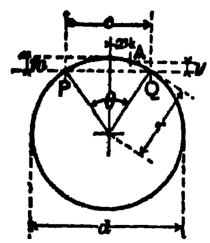

Fig 30. Circle

Circumference $= 2\pi r = \pi d$

Length of arc $PAQ = \theta$ (radians) $\times r = \theta$ (deg) $\times \frac{\pi}{180} \times r$

$= \theta$ (deg) $\times 0.017453 \times r$

Relation of radius, chord, and rise:

$$\text{Radius, } r = \frac{m^2 + \frac{1}{4}c^2}{2\,m} = \frac{\frac{1}{2}c}{\sin \frac{1}{2}\theta}$$

$$\text{Chord, } c = 2\sqrt{2\,mr - m^2} = 2\,r \sin \tfrac{1}{2}\theta$$

Rise or mid-ordinate,

$$m = r \pm \sqrt{r^2 - \frac{c^2}{4}} \quad \begin{bmatrix}\text{use } - \text{ if arc} \leqq 180^\circ \\ \text{use } + \text{ if arc} \geqq 180^\circ\end{bmatrix}$$

$$m = \tfrac{1}{2}c \times \tan \tfrac{1}{4}\theta = 2r \sin^2 \tfrac{1}{4}\theta = r + y - \sqrt{r^2 - x^2}$$

Side ordinate, $y = m - r + \sqrt{r^2 - x^2}$. $A = \pi \times r^2$

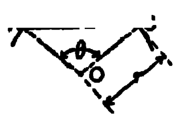

Fig 31. Circular Segment

Circumference $= \pi\,(a + b) \times k$

where $k = \left(1 + \frac{c^2}{4} + \frac{c^4}{64} + \frac{c^6}{256} + \cdots\right)$

and $c = (a - b) \div (a + b)$

Circumference $= \pi\sqrt{2\,(a^2 + b^2)}$ [approx]. $A = \pi \times a \times b$

$A_{ABCD} = (x \times y) + ab \sin^{-1}(x \div a)$

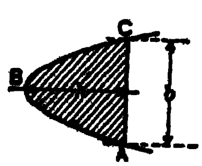

Fig 35. Parabola

If l = length of curve ABC and $n = h \div b$

$$l = b\left\{\tfrac{1}{2}(1 + 16\,n^2)^{\frac{1}{2}} + \frac{1}{8\,n} \text{ nap log} \times [4\,n + (1 + 16\,n^2)^{\frac{1}{2}}]\right\}$$

$$l = b\left(1 + \frac{8\,n^2}{3} - \frac{32\,n^4}{5} + \cdots\right) \text{ [approx]}$$

$A_{ABC} = \frac{2}{3} \times b \times h$

Lines and Areas (*Continued*)

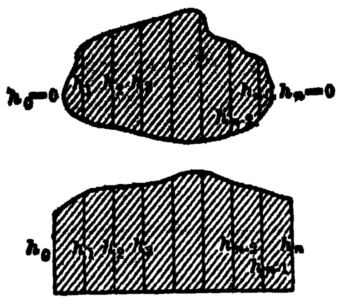

Fig 36. Irregular Figures

Determination of Area

Divide the figure into an even number of strips by equidistant ordinates, thus obtaining an odd number of ordinates. (The greater the number of strips, the greater the accuracy in the results.) The ordinates are the distances between boundary lines, represented by $h_0, h_1, h_2 \cdots h_{n-1}, h_n$.

n = the number of strips

$(n + 1)$ = the total number of ordinates, including the first and last

d = common distance between ordinates

The total area, A is approximately as follows:

Trapezoidal Rule	$A = d\left[\frac{h_0 + h_n}{2} + h_1 + h_2 + \cdots h_{n-1}\right]$
Simpson's Rule	$A = \frac{d}{3}[(h_0 + h_n) + 2(h_2 + h_4 + \cdots h_{n-2}) + 4(h_1 + h_3 + \cdots h_{n-1})]$
Durand's Rule	$A = d[0.04(h_0 + h_n) + 1.1(h_1 + h_{n-1}) + h_2 + h_3 + \cdots h_{n-2}]$
Weddle's Rule	If 6 strips (7 ordinates) are used, then $A = {}^3/_{10} \times d[5(h_1 + h_5) + 6h_3 + h_0 + h_2 + h_4 + h_6]$

11. SURFACES AND VOLUMES

S = lateral or convex surface; T = total surface; V = volume; A = area of base; A_1 = area of a right section as indicated in the illustrations.

$$S = \frac{2}{3} \times \pi \times \frac{b}{h^2}\left[\left(\frac{b^2}{16} + h^2\right)^{3/2} - \left(\frac{b}{4}\right)^3\right]$$
$$V = \frac{\pi}{8} \times b^2 \times h$$

Surfaces and Volumes (*Continued*)

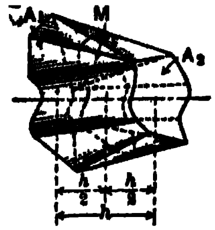

Fig 56. Prismatoid [Irregular solid with bases in parallel planes]

Prismoidal Formula.

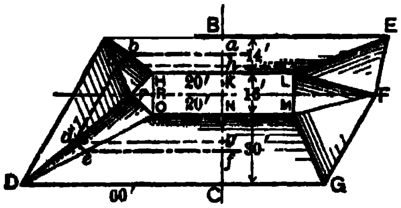

Fig 57

If surfaces connecting the bases are curved or warped they may be replaced by plane surfaces, best suited to the contour, bounded by straight lines from one of the parallel bases to the other. These planes may be parallelograms, triangles, or trapezoids.

Let A_1 = the area of one of the bases.
A_2 = the area of the other base.
M = the area of the cross-section parallel to, and midway between, the two bases.
h = the altitude of the prismatoid. (The perpendicular distance between the two parallel bases.)
V = vol of the solid = $\frac{1}{6}h[A_1 + 4M + A_2]$

[Area of cross-sec M should be computed from dimensions of the polygon formed by the intersection, with the solid, of a plane parallel to the bases through middle point of the altitude. In only exceptional cases is this cross-sec the aver of the base areas. However, the perimeter of this mid-polygon is half the sum of the basal perimeters].

Example. Find the volume of the irregular solid shown in Fig 57. $AEFGD$ is the lower base; $HLMOP$ is the upper base. To simplify the problem, let the perpendicular plane $BKNC$ divide the solid into two parts; find the volumes of the parts separately and sum them for total volume. For the left portion of the solid: $ABCD$ is the trapezoidal lower base, $HKNOP$, the pentagonal upper base. The given data are as follows: Altitude, or perpendicular distance between bases = 50 ft

AB = 40 ft BK = 14 ft KN = 16 ft BC = 60 ft
HK = ON = 20 ft DC = 60 ft NC = 30 ft HR = RO = PR = 8 ft

Dimensions necessary to calculate area of cross-section M are:
ef = 40 ft, dg = 44 ft, ch = 34 ft, ba = 30 ft, fg = 4 ft, gh = 30 ft, ha = 4 ft

Check: Perimeter of lower base = 223.24 ft; perimeter of upper base = 78.62 ft; perimeter of mid-polygon = 150.93 ft;

$$\text{half sum of basal perimeters} = \frac{223.24 + 78.62}{2} = 150.93\text{ ft}$$

Area $ABCD$ = A_1 = 3 000 sq ft; area $HKNOP$ = A_2 = 384 sq ft; area $afedcb$ = M = 1 466 sq ft; hence $V_{to\ left} = \frac{50}{6}[3\,000 + 4\,(1\,466) + 384] = \frac{50}{6}[9\,248]$ = 77 067 cu ft.

The volume to the right of plane $BKNC$ may be found in a similar manner.

PLANE TRIGONOMETRY

12. LINE VALUES OF FUNCTIONS

Let the radius of a circle (Fig 58) = AF = AB = AE = 1, the circle being called a UNIT CIRCLE, and let A = angle BAC = angle subtended by arc BE.

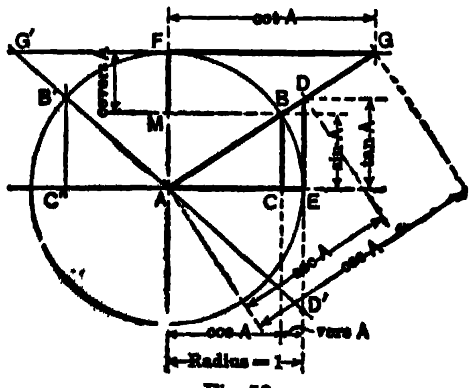

Fig 58

sine of A = $\sin A = \frac{BC}{AB} = \frac{BC}{1} = BC$

cosine of A = $\cos A = \frac{AC}{AB} = \frac{AC}{1} = AC$

tangent of A = $\tan A = \frac{DE}{AE} = \frac{DE}{1} = DE$

cotangent of A = $\cot A = \frac{FG}{AF} = \frac{FG}{1} = FG$

secant of A = $\sec A = \frac{AD}{AE} = \frac{AD}{1} = AD$

cosecant of A = $\csc A = \frac{AG}{AF} = \frac{AG}{1} = AG$

versed sine of A = $\text{vers } A = 1 - \cos A = AE - AC = CE$
coversed sine of A = $\text{covers } A = 1 - \sin A = AF - BC = FM$

If the radius AB of the circle (Fig 58) generates an angle by turning about the center A from the initial horizontal position AE, the angle will be measured by the arc described by point B, and may have any magnitude. POSITIVE ANGLES are generated by counterclockwise turning of AB; NEGATIVE ANGLES by clockwise turning. For any magnitude of angle A:

$\sin A$ = vertical projection of moving radius.
$\cos A$ = horizontal projection of moving radius.
$\tan A$ = distance from E along a tangent to intersection with moving radius produced.
$\cot A$ = distance from F along a tangent to intersection with moving radius produced.
For angle EAG': $\sin A = B'C'$; $\cos A = AC'$; $\tan A = D'E$; $\cot A = FG'$.

Algebraic signs of functions. Assume the functions of an angle in the first quadrant to be positive, then: (*a*) sines and tangents extending from the horiz diam UPWARD are positive; DOWNWARD, negative. (*b*) cosines and cotangents extending from the vert diam TOWARD THE RIGHT, are positive; TOWARD THE LEFT, negative.

13. FUNCTIONS OF RIGHT-ANGLED TRIANGLES

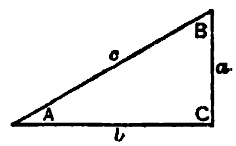

Fig 59

In any right-angled triangle ABC (Fig 59) let $AB = c$, $AC = b$, and $BC = a$.

1. $\sin A = a \div c = \cos B$
2. $\cos A = b \div c = \sin B$
3. $\tan A = a \div b = \cot B$
4. $\cot A = b \div a = \tan B$
5. $\sec A = c \div b = \csc B$
6. $\csc A = c \div a = \sec B$
7. $\operatorname{vers} A = (c - b) \div c = \operatorname{covers} B$
8. $\operatorname{covers} A = (c - a) \div c = \operatorname{vers} B$
9. $C = 90° = A + B$
10. $a = c \sin A = b \tan A$
11. $a = c \cos B = b \cot B$
12. $a = \sqrt{c^2 - b^2} = \sqrt{(c + b)(c - b)}$
13. $b = c \cos A = a \cot A$
14. $b = c \sin B = a \tan B$
15. $b = \sqrt{c^2 - a^2} = \sqrt{(c + a)(c - a)}$
16. $c = \dfrac{a}{\sin A} = \dfrac{b}{\cos A}$
17. $c = \dfrac{a}{\cos B} = \dfrac{b}{\sin B}$
18. $c = \sqrt{a^2 + b^2}$

$$19.\ \text{Area} = \frac{ab}{2} = \frac{a}{2}\sqrt{c^2 - a^2} = \frac{a^2}{2}\cot A = \frac{b^2}{2}\tan A = \frac{c^2}{2}\sin A \cos A$$

Functions of complementary angles. Each function of an acute angle is equal to the co-named function of the complementary angle, that is, $\sin A = \cos(90° - A)$; $\tan A = \cot(90° - A)$; $\sec A = \csc(90° - A)$; $\cos A = \sin(90° - A)$; $\cot A = \tan(90° - A)$; $\csc A = \sec(90° - A)$.

14. FORMULAS

$$20.\ \sin A = \frac{1}{\csc A} = \pm\sqrt{1 - \cos^2 A} = \tan A \cos A$$

$$21.\ \sin A = 2 \sin {}^1\!/_2 A \cos {}^1\!/_2 A = \operatorname{vers} A \cot {}^1\!/_2 A$$

$$22.\ \sin A = \pm\sqrt{{}^1\!/_2 (1 - \cos 2A)} = \pm\sqrt{{}^1\!/_2 \operatorname{vers} 2A}$$

$$23.\ \cos A = \frac{1}{\sec A} = \pm\sqrt{1 - \sin^2 A} = \cot A \sin A$$

$$24.\ \cos A = \cos^2 {}^1\!/_2 A - \sin^2 {}^1\!/_2 A = 2\cos^2 {}^1\!/_2 A - 1 = 1 - 2\sin^2 {}^1\!/_2 A$$

$$25.\ \cos A = \pm\sqrt{{}^1\!/_2 + {}^1\!/_2 \cos 2A} = 1 - \operatorname{vers} A$$

26. $\tan A = \dfrac{1}{\cot A} = \dfrac{\sin A}{\cos A} = \pm\sqrt{\sec^2 A - 1}$

27. $\tan A = \pm\sqrt{\dfrac{1}{\cos^2 A} - 1} = \dfrac{\pm\sqrt{1-\cos^2 A}}{\cos A} = \dfrac{2\tan {}^1/_2 A}{1 - \tan^2 {}^1/_2 A}$

28. $\tan A = \dfrac{1-\cos 2A}{\sin 2A} = \dfrac{\sin 2A}{1+\cos 2A} = \pm\sqrt{\dfrac{1-\cos 2A}{1+\cos 2A}} = \dfrac{\operatorname{vers} 2A}{\sin 2A}$

29. $\cot A = \dfrac{1}{\tan A} = \dfrac{\cos A}{\sin A} = \pm\sqrt{\csc^2 A - 1}$

30. $\operatorname{vers} A = 1 - \cos A = \sin A \tan {}^1/_2 A = 2\sin^2 {}^1/_2 A$

31. $\operatorname{covers} A = 1 - \sin A$

32. $\sin \dfrac{1}{2} A = \pm\sqrt{\dfrac{1-\cos A}{2}} = \pm\sqrt{\dfrac{\operatorname{vers} A}{2}}$

33. $\cos \dfrac{1}{2} A = \pm\sqrt{\dfrac{1+\cos A}{2}}$

34. $\tan \dfrac{1}{2} A = \pm\sqrt{\dfrac{1-\cos A}{1+\cos A}} = \dfrac{1-\cos A}{\sin A} = \dfrac{\sin A}{1+\cos A} = \dfrac{\tan A}{1+\sec A} = \dfrac{\operatorname{vers} A}{\sin A}$

35. $\cot \dfrac{1}{2} A = \pm\sqrt{\dfrac{1+\cos A}{1-\cos A}} = \dfrac{\sin A}{\operatorname{vers} A}$

36. $\operatorname{vers} \dfrac{1}{2} A = \dfrac{{}^1/_2 \operatorname{vers} A}{1 + \sqrt{1 - {}^1/_2 \operatorname{vers} A}} = \dfrac{1-\cos A}{2 + \sqrt{2(1+\cos A)}}$

37. $\sin 2A = 2\sin A \cos A$

38. $\cos 2A = 2\cos^2 A - 1 = \cos^2 A - \sin^2 A = 1 - 2\sin^2 A$

39. $\tan 2A = \dfrac{2\tan A}{1 - \tan^2 A}$

40. $\cot 2A = \dfrac{\cot^2 A - 1}{2\cot A}$

41. $\operatorname{vers} 2A = 2\sin^2 A = 2\sin A \cos A \tan A = 1 - \cos 2A$

42. $\sin(A \pm B) = \sin A \cdot \cos B \pm \sin B \cdot \cos A$

43. $\cos(A \pm B) = \cos A \cdot \cos B \mp \sin A \cdot \sin B$

44. $\tan(A + B) = \dfrac{\tan A \pm \tan B}{1 \mp \tan A \cdot \tan B}$

45. $\cot(A \pm B) = \dfrac{\cot A \cdot \cot B \mp 1}{\cot B \pm \cot A}$

46. $\sin A + \sin B = 2\sin {}^1/_2 (A+B) \cos {}^1/_2 (A-B)$

47. $\sin A - \sin B = 2\cos {}^1/_2 (A+B) \sin {}^1/_2 (A-B)$

48. $\cos A + \cos B = 2\cos {}^1/_2 (A+B) \cos {}^1/_2 (A-B)$

49. $\cos A - \cos B = -2\sin {}^1/_2 (A+B) \sin {}^1/_2 (A-B)$

50. $\tan A + \tan B = \dfrac{\sin(A+B)}{\cos A \cdot \cos B}$

51. $\tan A - \tan B = \dfrac{\sin(A-B)}{\cos A \cdot \cos B}$

52. $\sin^2 A - \sin^2 B = \cos^2 B - \cos^2 A = \sin(A+B)\sin(A-B)$

53. $\cos^2 A - \sin^2 B = \cos^2 B - \sin^2 A = \cos(A+B)\cos(A-B)$

15. OBLIQUE TRIANGLES

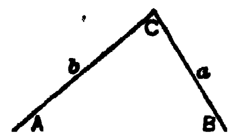

Fig 60

Given Data	To Find	Formulas
Two Angles and a Side $A, B, a,$	b, c, C Area	$b = a \cdot \dfrac{\sin B}{\sin A} \qquad c = a \cdot \dfrac{\sin (A + B)}{\sin A}$ $C = 180° - (A + B)$ $K = \dfrac{a^2}{2} \cdot \dfrac{\sin B \cdot \sin C}{\sin A}$
Two Sides and an Angle Opposite One of Them a, b, A	B, C, c Area	If $a < b$ and $A > 90°$, or if $a < b \sin A$ and $A < 90°$. No solution. If $a \geqq b$, or if $a = b \sin A$. One solution. If $a < b$, but $> b \sin A$, and $A < 90°$, there may be two solutions. If $\sin B = (b \div a) \sin A$, B may have two values, say B_1 and B_2. $C_1 = 180° - (A + B_1)$, $C_2 = 180° - (A + B_2)$ $c_1 = a \cdot \dfrac{\sin C_1}{\sin A} \qquad c_2 = a \cdot \dfrac{\sin C_2}{\sin A}$ $K = \tfrac{1}{2}\, ab \cdot \sin C$
Two Sides and the Included Angle a, b, C	A, B, c Area	$\tfrac{1}{2}(A + B) = 90° - \tfrac{1}{2} C$ $\tan \tfrac{1}{2}(A - B) = \dfrac{a - b}{a + b} \cdot \tan \tfrac{1}{2}(A + B)$ $A = \tfrac{1}{2}(A + B) + \tfrac{1}{2}(A - B)$ $B = \tfrac{1}{2}(A + B) - \tfrac{1}{2}(A - B)$ $c = a \cdot \dfrac{\sin C}{\sin A} = b \cdot \dfrac{\sin C}{\sin B}$ $c = (a + b)\dfrac{\cos \frac{1}{2}(A + B)}{\cos \frac{1}{2}(A - B)} = (a - b)\dfrac{\sin \frac{1}{2}(A + B)}{\sin \frac{1}{2}(A - B)}$ $K = \tfrac{1}{2}\, ab \cdot \sin C$
Three Sides a, b, c	A, B, C Area	Let $S = \tfrac{1}{2}(a + b + c) =$ the semi-perimeter $\sin \tfrac{1}{2} A = \sqrt{\dfrac{(s - b)(s - c)}{bc}}$ $\cos \tfrac{1}{2} A = \sqrt{\dfrac{s (s - a)}{bc}}$ $\tan \tfrac{1}{2} A = \sqrt{\dfrac{(s - b)(s - c)}{s (s - a)}}$ $\sin A = \dfrac{2}{bc}\sqrt{s (s - a)(s - b)(s - c)}$ $\tan \tfrac{1}{2} B = \sqrt{\dfrac{(s - a)(s - c)}{s (s - b)}}$ $C = 180° - (A + B)$ $K = \sqrt{s (s - a)(s - b)(s - c)}$

ANALYTICAL GEOMETRY

16. STRAIGHT LINE

Rectangular and polar coordinates (Fig 61). Rectangular coordinates (x, y) and polar coordinates (ρ, θ) of any point P are related thus: $x = \rho \cos \theta$; $y = \rho \sin \theta$; $x^2 + y^2 = \rho^2$; $\tan \theta = y \div x$.

Note.—The x's and y's in following formulas are rectangular coordinates.

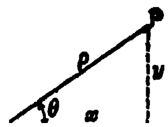

Fig 61

Fig 62

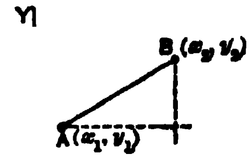

Fig 63

Slope. The slope of a line is the tangent of the angle α from the x-axis to the line. It is denoted by m, $m = \tan \alpha$. If two lines are parallel, their slopes, m and m', are equal. If the lines are perpendicular to each other, $m = -1 \div m'$. The slope of the line through A (x_1, y_1) and B (x_2, y_2), Fig 63, is

$$m = (y_2 - y_1) \div (x_2 - x_1)$$

Distance between two points, A (x_1, y_1) and B (x_2, y_2) is

$$d = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}$$

Line divided in given ratio. The coordinates (x, y) of the point that divides the line from A (x_1, y_1) to B (x_2, y_2) in the ratio r are

$$x = (x_1 + rx_2) \div (1 + r), \qquad y = (y_1 + ry_2) \div (1 + r)$$

Equation of straight line. Every equation of the first degree in x and y, as $Ax + By + C = 0$, represents a straight line. Its slope is $-A \div B$.

Line with slope m and y-intercept b, $y = mx + b$

Line with slope m and through point (x', y'), $y - y' = m\,(x - x')$

Line through two points (x', y') and (x'', y''), $(y - y') \div (y'' - y') = (x - x') \div (x'' - x')$

Line with x-intercept a and y-intercept b, $(x \div a) + (y \div b) = 1$

Angle θ from line with slope m to line with slope m' is found by

$$\tan \theta = (m' - m) \div (1 + mm')$$

Distance from point (x', y') **to line** $Ax + By + C = 0$ is

$$d = (Ax' + By' + C) \div \sqrt{A^2 + B^2}$$

Area of triangle with vertices (x_1, y_1), (x_2, y_2), (x_3, y_3) is

$$A = [x_1\,(y_2 - y_3) + x_2\,(y_3 - y_1) + x_3\,(y_1 - y_2)] \div 2$$

17. CIRCLE

Equation. The equation of the circle with center at the origin and radius r is $x^2 + y^2 = r^2$. If the center is (a, b) the equation is $(x - a)^2 + (y - b)^2 = r^2$. Every equation of the form

$$x^2 + y^2 + 2\,Ax + 2\,By + C = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (C)$$

represents a circle. The center is $(-A, -B)$ and the radius, $\sqrt{A^2 + B^2 - C}$.

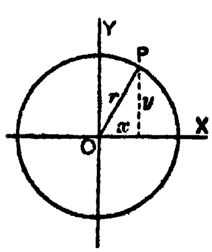

Fig 64

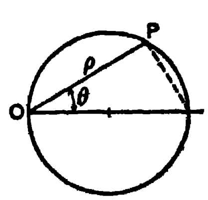

Fig 65

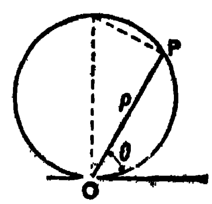

Fig 66

Tangents. Equation of tangent to the circle $x^2 + y^2 = r^2$ at the point (x', y') on the curve is $x'x + y'y = r^2$. Equation of tangent with slope m, $y = mx \pm r\sqrt{1 + m^2}$. Length of tangent from any point (x', y') outside the circle, to any other circle,

$$x^2 + y^2 + 2\,Ax + 2\,By + C = 0, \text{ is } l = \sqrt{x'^2 + y'^2 + 2\,Ax' + 2\,By' + C}$$

Circle through three points. To find equation of circle through three points, as (3, 1), (−1, 2), (5, 4), substitute these pairs of values for x and y in the equation (C) above, and find A, B, C from the resulting 3 equations.

Polar equation. Origin on circumference (Fig 65), diameter a along initial line, equation of circle is $\rho = a \cos\theta$. Diameter along line 90° from initial line (Fig 66) is $\rho = a \sin\theta$.

18. ELLIPSE

Equation of ellipse with center at origin and foci F' and F on the x-axis (Fig 67), is

$$(x^2 \div a^2) + (y^2 \div b^2) = 1 \quad \ldots\ldots\ldots\ldots (E)$$

where a is the major semiaxis and b the minor semiaxis.

Distance $OF = \sqrt{a^2 - b^2}$; distance $BF = OA = a$; focal width $QR = 2\,b^2 \div a$.

Eccentricity e of ellipse is $e = \sqrt{a^2 - b^2} \div a = OF \div OA$, and e is always less than 1. When e is nearly 0, the ellipse is nearly a circle, and the foci are near the center. When e is nearly 1, ellipse is long and narrow, and foci are near ends of the major axis. If two ellipses have the same eccentricity, the ratio of semiaxes, $a : b$, is the same for both, and conversely. The equation $(x^2 \div a^2) + (y^2 \div b^2) = k$ where a and b are fixed, represents, whenever any positive value is assigned to k, an ellipse; and all these ellipses have the same e.

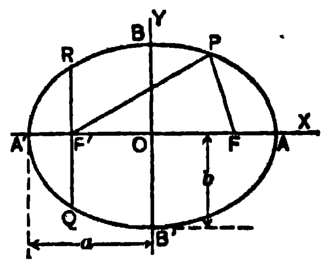

Fig 67

Confocal ellipses. If two ellipses $(x^2 \div a^2) + (y^2 \div b^2) = 1$ and $(x^2 \div a'^2) + (y^2 \div b'^2) = 1$ have the same foci, then $a^2 - b^2 = a'^2 - b'^2$. That is, $a^2 - a'^2 = b^2 - b'^2$.

Focal radii to the point P (x', y') on the ellipse are $F'P = a + ex'$ and $FP = a - ex'$. This makes $F'P + FP = 2\,a = A'A$.

Tangent to the ellipse (Eq E, above) at (x', y') on the curve is $(x'x \div a^2) + (y'y \div b^2) = 1$; with slope m, $y = mx \pm \sqrt{a^2m^2 + b^2}$.

Diameters (Fig 68). Equation of diameter AB, which bisects all chords having slope m, as CD, EF, in ellipse (E) is $y = (-b^2 \div a^2m)x$. If the slopes m and m' of two diameters of (E) are such that $mm' = -b^2 \div a^2$, each diam bisects all chords parallel to the other. They are called conjugate diameters; for example, AB and JK.

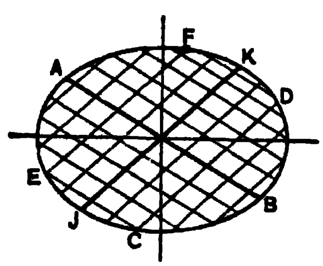

Fig 68

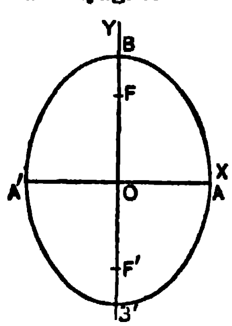

Fig 69

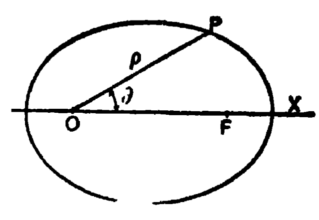

Fig 70

Foci on y-axis (Fig 69). If the foci of an ellipse are on the y-axis, its equation is (E) as above, but b is the major semiaxis, a the minor, so that $OF = \sqrt{b^2 - a^2}$, $AF = b$, and $e = \sqrt{(b^2 - a^2)} \div b$.

Polar equation (Fig 70). Initial line along major axis of ellipse, origin at left-hand focus is $\rho = b^2 \div a(1 - e \cos\theta)$. With origin at right-hand focus, $\rho = b^2 \div a(1 + e \cos\theta)$. With origin at center, $\rho^2 = b^2 \div (1 - e^2 \cos^2\theta)$, where e is the eccentricity.

19. HYPERBOLA

Equation. Equation of hyperbola having foci F' and F on the x-axis, origin at center (Fig 71):

$$(x^2 \div a^2) - (y^2 \div b^2) = 1 \quad \ldots\ldots\ldots\ldots (H)$$

where a is the principal semiaxis, b the conjugate semiaxis. Distance $OF = \sqrt{a^2 + b^2} = BA$, A being one end of principal axis, B one end of conjugate axis. Focal width $= 2\,b^2 \div a$.

Asymptotes. Equations of asymptotes to hyperbola (H): $ay = bx$ and $ay = -\,bx$. If $2\,\alpha$ is the angle between the asymptotes, $\tan\alpha = b \div a$. If P is any point on a hyperbola, the product of perpendicular distances from P to the asymptotes is constant, and is equal to $a^2b^2 \div (a^2 + b^2)$.

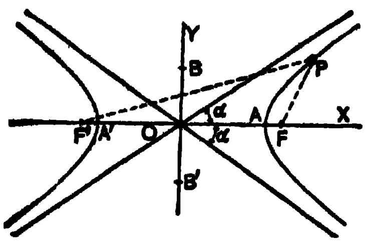

Fig 71

Eccentricity of hyperbola is greater than 1: $e = \sqrt{a^2 + b^2} \div a = \sec\alpha$, where α is half the angle between the asymptotes. When $e = \sqrt{2} = 1.4 +$, the angle $2\,\alpha$ between the asymptotes is a right angle. When $e > \sqrt{2}$, $2\,\alpha > 90°$; and when e is between $\sqrt{2}$ and 1, $2\,\alpha$ is between 90° and 0°.

If two hyperbolas, such as (H), have the same eccentricity, they have the same asymptotes, and conversely. They also have the same ratio of semiaxis, $a:b$, and conversely.

The equation $(x^2 \div a^2) - (y^2 \div b^2) = k$, where a and b are fixed, but k may take various values, represents various hyperbolas, all of which have the same ratio of semiaxes. The semiaxes are $a\sqrt{k}$ and $b\sqrt{k}$.

Focal radii to any point $P\ (x', y')$ on hyperbola (H) are

$F'P = ae + x'$ and $FP = ae - x'$ (e = eccentricity). So that $F'P - FP = 2\,a = A'A$.

Tangent to hyperbola (H) at (x', y') on the curve is $(x'x \div a^2) - (y'y \div b^2) = 1$; with slope m, $y = mx \pm \sqrt{a^2m^2 - b^2}$.

Diameter (Fig 72). Equation of diam which bisects all chords of hyperbola (H) that have slope m is $y = (b^2 \div a^2m)\,x$. If the slopes m and m' of two diameters of (H) are such that $mm' = b^2 \div a^2$, each bisects all chords parallel to the other. They are called conjugate diameters.

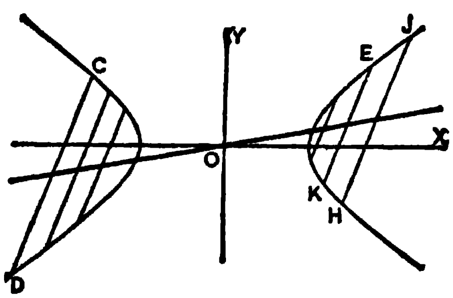

Fig 72

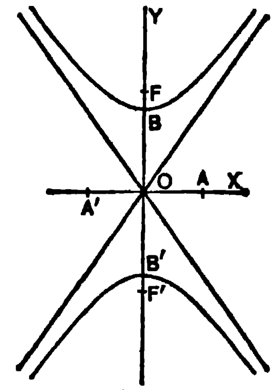

Fig 73

Foci on y-axis (Fig 73). If the foci of the hyperbola are on the y-axis, origin being at center, the equation of the hyperbola is

$$(y^2 \div b^2) - (x^2 \div a^2) = 1 \qquad (H')$$

where b is principal semiaxis, and a is conjugate semiaxis. In this case,

eccentricity $e = \sqrt{a^2 + b^2} \div b$; asymptotes are $ay = bx$ and $ay = -\,bx$.

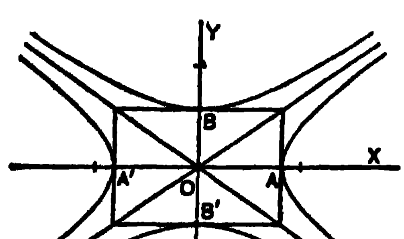

Fig 74

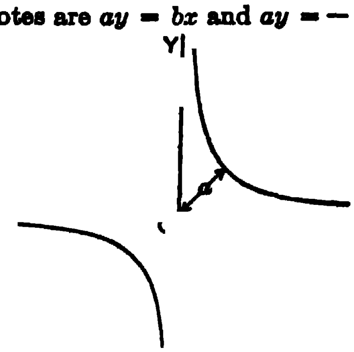

Fig 75

Conjugate hyperbolas, that is, the hyperbolas (H) and (H'), have the same asymptotes (Fig 74). The diam which bisects a set of parallel chords in one bisects the same set of

parallel chords in the other. The two segments intercepted on any straight line by two conjugate hyperbolas are equal. Eccentricities e and e' of conjugate hyperbolas are related thus: $(1 + e^2) + (1 + e'^2) = 1$.

Rectangular or equilateral hyperbola is one having its axes equal, so that $a = b$. The equation (H) is then $x^2 - y^2 = a^2$. (H'')

Asymptotes of (H'') are perpendicular to each other.

Asymptotes as axes of coordinates (Fig 75). In this case, the equation of the rectangular hyperbola is $xy = a^2 + 2$. If the hyperbola is not rectangular (Fig 76), the asymptotes are not perpendicular. But if they are taken as axes and the coordinates x and y are measured parallel to the asymptotes, the equation of the hyperbola is

$$4\,xy = a^2 + b^2$$

Polar equation is same as for ellipse, with $-b^2$ in place of b^2.

Confocal hyperbolas. If two hyperbolas, $(x^2 + a^2) - (y^2 + b^2) = 1$ and $(x^2 + a'^2)\ (y^2 + b'^2) = 1$, have the same foci, then $a^2 + b^2 = a'^2 + b'^2$.

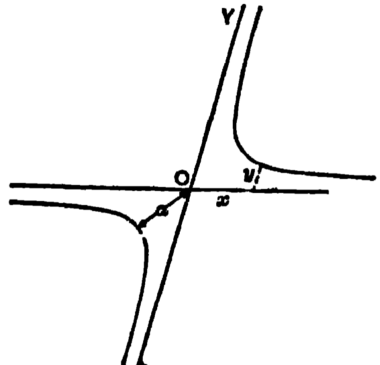

Fig 76

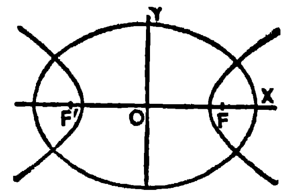

Fig 77

Confocal ellipse and hyperbola. If an ellipse and a hyperbola have same foci, they intersect at right angles (Fig 77).

20. PARABOLA

Equation. With focus on x-axis and origin at vertex, equation of parabola is $y^2 = 4\,px$, where $p = OF$ = distance from vertex to focus (Fig 78). If p is positive, parabola runs to the right; if negative, to the left.

Focal width, $QR = 4\,p$.

Focal radius to any point $P\,(x', y')$ on parabola is $FP = p + x'$.

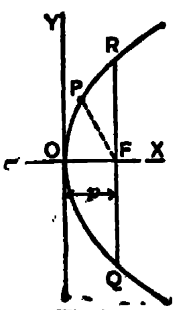

Fig 78

Tangent to parabola $y^2 = 4\,px$ at (x', y') on the curve is $y'y = 2\,p\,(x + x')$; with slope m, $y = mx + p \div m$.

Diameter. Equation of diam bisecting all chords of parabola $y^2 = 4\,px$ that have slope m is $y = 2\,p \div m$. Every diam of a parabola is parallel to the axis.

Focus on y-axis (Fig 79). Equation of parabola having focus on y-axis and origin at vertex is $x^2 = 4\,py$, where $p = OF$. This parabola runs in direction of positive end of y-axis (usually taken upward) if p is positive; in direction of negative end of y-axis if p is negative.

Polar equation of parabola, origin being at vertex, $\rho = 2\,p \div (1 - \cos\theta)$.

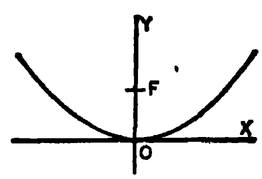

Fig 79

21. CURVES IN GENERAL

An equation of second degree in x and y,

$$ax^2 + 2\,hxy + by^2 + 2\,gx + 2\,fy + c = 0 \qquad (G)$$

represents a conic section: an ellipse, if $h^2 < ab$; an hyperbola, if $h^2 > ab$; a parabola, if $h^2 = ab$; a circle, if $a = b$ and $h = 0$. In the special case where $abc - af^2 - bg^2 - ch^2 + 2\,fgh = 0$, the curve breaks down into a pair of straight lines, or a point.

Inclination of axis. The angle θ of inclination of the principal axis of the conic (G) to the x-axis is given by $\tan 2\,\theta = 2\,h \div (a - b)$.

Center (x', y') of ellipse or hyperbola is found by solving simultaneous equations: $ax' + hy' + g = 0$, $hx' + by' + f = 0$.

Intersections of two curves are found by solving their equations as simultaneous.

Intercepts. To find x-intercepts of a curve, set $y = 0$ in its equation, and solve for x; to find y-intercepts, set $x = 0$ in the equation, and solve for y.

Special Curves. Logarithmic and exponential curves, and the cycloid:

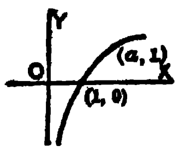

Fig 80

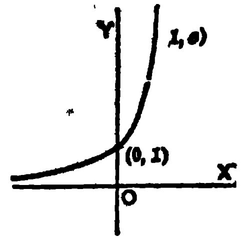

Fig 81

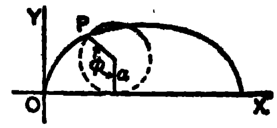

Fig 82

$y = \log_a x$ (Fig 80) $\qquad y = e^x$ (Fig 81) $\qquad \left\{\begin{array}{l} x = a\,(\phi - \sin\phi) \\ y = a\,(1 - \cos\phi) \end{array}\right\}$ (Fig 82)

Change of axes changes the equation of a curve. To find the new equation, when origin is moved to the point (h, k), axes remaining parallel to old positions, substitute $x + h$ for x, and $y + k$ for y. If axes are rotated through angle θ, with origin unchanged, substitute $x \cos\theta - y \sin\theta$ for x, and $x \sin\theta + y \cos\theta$ for y.

22. SOLID GEOMETRY

Distance from $P_1\ (x_1, y_1, z_1)$ to $P_2\ (x_2, y_2, z_2)$ is

$$d = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2 + (z_2 - z_1)^2}$$

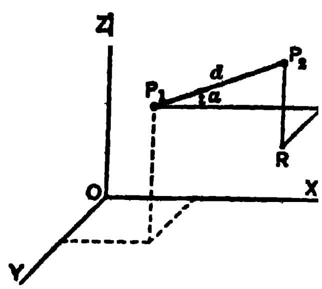

Fig 83

Also, $P_1Q = x_2 - x_1$, $QR = y_2 - y_1$, $RP_2 = z_2 - z_1$, these segments being parallel to the axes (Fig 83).

Direction cosines of P_1P_2 are

$$x_2 - x_1 \qquad \cos\beta = \frac{y_2 - y_1}{d}, \quad \cos\gamma = \frac{z_2 - z_1}{d},$$

where d is the distance from P_1 to P_2, given above. The sum of the squares of direction cosines is always 1; $\cos^2\alpha + \cos^2\beta + \cos^2\gamma = 1$. If the direction cosines of a line are proportional to a, b, c, they are $\cos\alpha = a \div k$, $\cos\beta = b \div k$, $\cos\gamma = c \div k$, where $k = \sqrt{a^2 + b^2 + c^2}$.

Plane. Every equation of first degree in x, y, and z, as $Ax + By + Cz = D$ $\quad (P)$ represents a plane. Its intercepts on the x-, y- and z-axes are $D \div A$, $D \div B$, $D \div C$. If the plane goes through the origin, $D = 0$. The direction cosines of a line perpendicular to the plane are $\cos\alpha = A \div q$, $\cos\beta = B \div q$, $\cos\gamma = C \div q$, where $q = \sqrt{A^2 + B^2 + C^2}$.

Distance from point (x', y', z') **to plane** (P) is $r = (Ax' + By' + Cz' - D) \div q$. Distance from origin to plane is $p = D \div q$.

Angle θ between two planes, $Ax + By + Cz = D$, and $A'x + B'y + C'z = D'$, is given by $\cos\theta = (AA' + BB' + CC') \div \sqrt{A^2 + B^2 + C^2}\cdot\sqrt{A'^2 + B'^2 + C'^2}$,

or
$$\cos\theta = \cos\alpha\cos\alpha' + \cos\beta\cos\beta' + \cos\gamma\cos\gamma'$$

where $\cos\alpha$, $\cos\beta$, $\cos\gamma$ are direction cosines of a perpendicular to one plane, and $\cos\alpha'$, $\cos\beta'$, $\cos\gamma'$ are direction cosines of a perpendicular to the other. ANGLE BETWEEN TWO LINES, the direction cosines of which are known, is given by the second of the foregoing formulas.

Perpendicular lines or planes. Two lines are perpendicular if

$$\cos\alpha\cos\alpha' + \cos\beta\cos\beta' + \cos\gamma\cos\gamma' = 0$$

The same condition holds for planes. More simply, the two planes

$$Ax + By + Cz = D \quad \text{and} \quad A'x + B'y + C'z = D'$$

are perpendicular if $AA' + BB' + CC' = 0$.

Line of intersection of two planes, $Ax + By + Cz = D$ and $A'x + B'y + C'z = D'$, has the direction cosines: $\cos\alpha = a \div s$, $\cos\beta = b \div s$, $\cos\gamma = c \div s$, where

$$a = BC' - B'C,\ b = AC' - A'C,\ c = AB' - A'B, \text{ and } s = \sqrt{a^2 + b^2 + c^2}$$

Equations of straight line through two points (x_1, y_1, z_1) and (x_2, y_2, z_2):

$$(x - x_1) \div (x_2 - x_1) = (y - y_1) \div (y_2 - y_1) = (z - z_1) \div (z_2 - z_1)$$

Equations of line through (x_1, y_1, z_1), **with direction cosines** $\cos\alpha$, $\cos\beta$, $\cos\gamma$:

$$(x - x_1) \div \cos\alpha = (y - y_1) \div \cos\beta = (z - z_1) \div \cos\gamma$$

Plane through three points, $P(x_1, y_1, z_1)$, $Q(x_2, y_2, z_2)$, $R(x_3, y_3, z_3)$. The equation of the plane may be taken as $ax + by + cz = 1$, by dividing (P) above by D, unless $D = 0$. Substitute in this equation, for x, y, and z, the coordinates of P, then those of Q and finally those of R. This gives three equations, from which the unknowns a, b, and c can be found. This process fails if the plane through P, Q, R goes through the origin, in which case, the equation is $Ax + By + Cz = 0$, and may be divided by A, becoming $x + by + cz = 0$.

Sphere. Equation of sphere, with center (a, b, c) and radius r, is

$$(x - a)^2 + (y - b)^2 + (z - c)^2 = r^2$$

Cylinder. Equation of circular cylinder, with axis on z-axis and radius r, is $x^2 + y^2 = r^2$. Every equation containing only two of the variables x, y, z, represents in solid geometry a cylinder, the base of which is the curve determined in one of the coordinate planes by the given equation.

Surface of revolution. If any curve $y = f(x)$ rotates about the x-axis, the equation of the surface generated is $y^2 + z^2 = [f(x)]^2$. Thus, if the ellipse $(x^2 \div a^2) + (y^2 \div b^2) = 1$ (that is, $y = (b \div a)\sqrt{a^2 - x^2}$) rotates about the x-axis, the equation of the resulting ellipsoid of revolution is $y^2 + z^2 = (b^2 \div a^2)(a^2 - x^2)$, or $(x^2 \div a^2) + (y^2 \div b^2) + (z^2 \div c^2) = 1$.

Intercepts. The x-intercept of any surface is found by setting $y = 0$ and $z = 0$ in the equation of the surface; similarly for y and z intercepts.

Traces. The trace of any surface on the xy-plane is the curve found by putting $z = 0$ in the equation of the surface; similarly for the xz-trace and yz-trace. Thus, the xy-trace of the plane $2x - y + 3z = 11$ is the line $2x - y = 11$. The yz-trace is $-y + 3z = 11$.

Cross-section of surface. The equation of the cross-section of any surface the equation of which is known, taken parallel to the xy-plane at the distance k from the xy-plane, is found by putting $z = k$ in the equation of the surface. For cross-section parallel to yz, put $x = k$. For cross-sec parallel to xz, put $y = k$. Thus, cross-sec of sphere $x^2 + y^2 + z^2 = 36$, parallel to xy at distance $z = 2$, is $x^2 + y^2 + 4 = 36$, or $x^2 + y^2 = 32$. It is a circle with radius $\sqrt{32}$.

Dip and strike of strata. (See also Sec 10.) Suppose three points of a stratum (Fig 84), which is approx a true plane, are determined as follows:

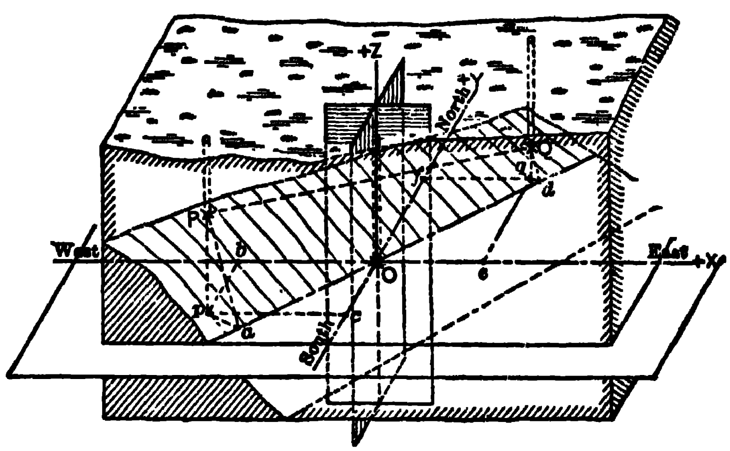

Fig 84

Point	Latitude	Departure	Elev	x	y	z
O	−312.5	305.4	517.4	0	0	0
P	−624 2	124.6	759.7	−311.7	−180.8	242.3
Q	− 48.0	558.7	621.4	264.5	−253 3	104.0

Take a horiz plane through the lowest point O as xy-plane, and the vertical through O as z-axis (elev). Then the coordinates of O, P, and Q are as above. Let the equation of the stratum plane be $x + by + cz = 0$. (See Equation of Plane Through Three Points above.) Substituting the coordinates of P, and then of Q, for x, y and z,

$$-311.7 - 180.8\,b \times 242.3\,c = 0, \text{ and } 264.5 + 253.3\,b + 104\,c = 0;$$

or $0.746\,b + c = +1.286$, and $2.435\,b + c = -2.543$. Hence $b = -2.267$, $c = 2.977$, and the equation of the stratum plane is $x - 2.267\,y + 2.977\,z = 0$ $\quad (S)$

Equation of xy or horiz plane is $z = 0$, or $0x + 0y + z = 0$ $\quad (H)$

As dip is the angle between (H) and (S) (see Angle between Two Planes),

$$\cos\theta = \frac{1 \times 0 - 2.267 \times 0 + 2.977 \times 1}{\sqrt{1^2 + (-2.267)^2 + 2.977^2} \times \sqrt{0^2 + 0^2 + 1^2}} = 0.769$$

Hence $\theta = 39° \, 40'$ approx = dip.

To find the strike, find the intersection of stratum plane (S) with horis plane (H). That is, put $z = 0$ in Eq (S). This gives the horis line

$$x - 2.267\,y = 0, \text{ or } y = 0.441\,x \qquad (L)$$

The slope of this line, $\tan\alpha$, is the tangent of the complement of the strike angle. But $\tan\alpha = 0.441$. Hence, $\alpha = 23°\,50'$, $\beta = 90° - \alpha = 66°\,10'$, and strike = N 66° 10′ E.

CALCULUS

23. DERIVATIVES

Let $f(x)$ be any function of x, and denote it by y; then $y = f(x)$. When x changes by any amount, Δx, then y changes by some amount, Δy. The derivative of the function with respect to x, denoted by $\frac{dy}{dx}$ or $f'(x)$, is

$$\operatorname*{limit}_{\Delta x \doteq 0} \frac{\Delta y}{\Delta x} = \operatorname*{limit}_{\Delta x \doteq 0} \frac{f(x + \Delta x) - f(x)}{\Delta x} = \frac{dy}{dx} = f'(x)$$

For a table of derivatives see Art 25. (Symbol $\doteq$ means "approaching.")

Slope. Value of the derivative for a particular value of x, $x = x_1$, is the slope of the curve $y = f(x)$ at the point (x_1, y_1).

Tangent and normal. Equation of the tangent to any curve $y = f(x)$ at any point (x_1, y_1) is $y - y_1 = f'(x_1)\,(x - x_1)$, where $f'(x_1)$ denotes the value of $f'(x)$ when $x = x_1$.

Equation of normal at (x_1, y_1) is $y - y_1 = (-1 \div f'(x_1))\,(x - x_1)$.

Maxima and minima. To find maximum or minimum of a given function $f(x)$, set $f'(x) = 0$ and find its roots, say $x = x_1$, $x = x_2$, ... Then $f(x)$ has a

maximum for $x = x_1$ if $f''(x_1)$ is negative,
minimum for $x = x_1$ if $f''(x_1)$ is positive,

where $f''(x_1)$ means the result of substituting x_1 for x in $f''(x)$, the second derivative of $f(x)$ with respect to x.

If, however, $f''(x_1) = 0$, compute $f'''(x_1)$, $f''''(x_1)$ and further derivatives, until one of them, say the kth, is found which is not zero when $x = x_1$. Then $f(x)$ has a maximum for $x = x_1$ if k is even and $f^k(x_1)$ is negative, a minimum if k is even and $f^k(x_1)$ is positive, but a point of inflexion on a horizontal tangent if k is odd.

Point of inflexion. To find points of inflexion of the curve $y = f(x)$, find the roots of $f''(x) = 0$. Any such root x_1 gives a point of inflexion, unless $f'''(x_1) = 0$ also. For this exceptional case, see preceding note.

Curvature. Curvature k of curve $y = f(x)$, at any point (x, y), is

$$k = f''(x) \div \sqrt{(1 + [f'(x)]^2)^3}$$

Radius R of curvature is the reciprocal of curvature, $R = 1 \div k$.

Center (a, b) of curvature,

$$a = x - f'(x)\,(1 + [f'(x)]^2) \div f''(x), \quad \text{and} \quad b = y + (1 + [f'(x)]^2) \div f''(x)$$

Angle from radius vector to tangent, in polar coordinates. If the equation of the curve is $\rho = f(\theta)$, the angle ϕ from radius vector to tangent is given by $\tan\phi = \rho(d\theta \div d)$.

Taylor's series for expanding a function $f(x)$ in powers of $x - a$, with certain restrictions, is

$$f(x) = f(a) + f'(a)\,(x - a) + [f''(a)\,(x - a)^2 \div 2!] + [f'''(a)\,(x - a)^3 \div 3!] + \cdots,$$

where $3!$ denotes $3 \cdot 2 \cdot 1$. If $a = 0$, it becomes Maclaurin's series,

$$f(x) = f(0) + f'(0)\,x + [f''(0)\,x^2 \div 2!] + [f'''(0) \div 3!] + \cdots$$

Usually this series is more and more nearly equal to $f(x)$ when more and more terms are taken, but there are many exceptions.

Derivative of arc. If s denotes length of arc of a curve $y = f(x)$, s varying as the point (x, y) moves along the curve, then $\frac{ds}{dx} = \sqrt{1 + \left(\frac{dy}{dx}\right)^2}$

Function of a function. If y is a function of u and u is a function of x, $\frac{dy}{dx}$ may be found by $\frac{dy}{dx} = \frac{dy}{du} \times \frac{du}{dx}$.

24. INTEGRATION

Integral. The integral of $f(x)$, denoted by $\int f(x)\,dx$, means the function of which the derivative is $f(x)$. For example, $\int 3x^2\,dx = x^3 + C$, C being any constant.

For a table of integrals of a few functions, see Art 26.

Definite integral. The symbol $\int_a^b f(x)\,dx$ denotes the result of finding $\int f(x)\,dx$, substituting in the resulting function b for x, then a for x and subtracting, thus:

$$\int_a^b f(x)\,dx = \phi(b) - \phi(a), \text{ where } \phi(x) = \int f(x)\,dx$$

The definite integral gives the value of the limit of the sum of terms, constructed as follows: Divide the interval from a to b into n equal parts, and denote the abscissas x of the points of division by $x_0, x_1, x_2, \ldots x_n$, x_0 being a and x_n being b. Let each part of the interval thus divided be Δx. Then

$$\int_a^b f(x)\,dx = \lim_{n \doteq \infty} [f(x_1)\,\Delta x + f(x_2)\,\Delta x + \cdots + f(x_n)\,\Delta x]$$

Area. In rectangular coordinates, the area under the curve $y = f(x)$, included between ordinates, at $x = a$ and $x = b$, is $A = \int_a^b f(x)\,dx$. If the curve crosses the x-axis between a and b, compute area to crossing, and then beyond. In polar coordinates, area between the curve $\rho = f(\theta)$ and two radii at $\theta = \theta_1$ and $\theta = \theta_2$ is given by $A = {}^1/_2 \int_{\theta_1}^{\theta_2} \rho^2\,d\theta$. For double integration the element of area dA is $dA = dy\,dx$, or $dA = \rho\,d\rho\,d\theta$.

Length of arc of curve $y = f(x)$ from $P_1\,(x_1, y_1)$ to $P_2\,(x_2, y_2)$:

$$s = \int_{x_1}^{x_2} \sqrt{1 + m^2}\,dx, \qquad \text{where } m = f'(x)$$

also,

$$s = \int_{\theta_1}^{\theta_2} \sqrt{\rho^2 + k^2}\,d\theta, \qquad \text{where } k = \frac{d\rho}{d\theta}$$

Volume and surface of revolution. If the curve $y = f(x)$ revolves about x-axis, the volume generated by area under the curve and between ordinates at $x = x_1$ and $x = x_2$, is $V = \pi \int_{x_1}^{x_2} y^2\,dx$, and surface generated by arc of curve is

$$S = 2\pi \int_{x_1}^{x_2} x\sqrt{1 + m^2}\,dx, \qquad \text{where } m = f'(x)$$

Water pressure. Pressure on vertical area bounded by the curve $y = f(x)$ and two horizontal lines at $y = y_1$ and $y = y_2$ is $P = k\int_{y_1}^{y_2} hw\,dy$, where h is the depth below water surface of a narrow horiz strip at distance y from origin, w is the width of this strip, and k is weight per unit volume. h and w must be expressed in terms of y before proceeding with the integration.

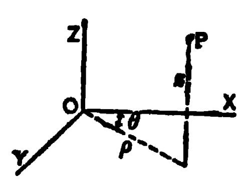

Fig 85

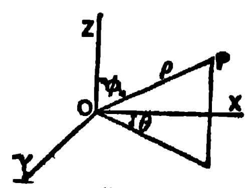

Fig 86

Element of volume, multiple integration. Element of volume under surface the equation of which is $z = f(x, y)$:

$dV = z\,dx\,dy$, for double integration ⎫ rectangular coordinates.
$dV = dz\,dx\,dy$, for triple integration ⎭
$dV = \rho\,d\rho\,d\theta\,dz$, cylindrical coordinates.
$dV = \rho^2 \sin\phi\,d\phi\,d\theta\,d\rho$, spherical coordinates.

25. TABLE OF DERIVATIVES

In this table u and v denote functions of x; a, c, and n are arbitrary constants:

$$\frac{d}{dx}c = 0 \qquad\qquad \frac{d}{dx}u^n = nu^{n-1}\frac{du}{dx}$$

$$\frac{d}{dx}(uv) = u\frac{dv}{dx} + v\frac{du}{dx} \qquad\qquad \frac{d}{dx}e^u = e^u\frac{du}{dx} \quad (\text{where } e = 2.718+)$$

$$\frac{d}{dx}\left(\frac{u}{v}\right) = \left(v\frac{du}{dx} - u\frac{dv}{dx}\right) \div v^2 \qquad\qquad \frac{d}{dx}a^u = a^u \log_e a \cdot \frac{du}{dx}$$

Table of Derivatives (*Continued*)

$$\frac{d}{dx}u^v = vu^{v-1}\frac{du}{dx} + u^v \log_e u \frac{dv}{dx}$$

$$\frac{d}{dx}\csc u = -\csc u \cot u \frac{du}{dx}$$

$$\frac{d}{dx}\log_e u = \frac{1}{u}\frac{du}{dx}$$

$$\frac{d}{dx}\sin^{-1} u = \frac{1}{\sqrt{1-u^2}}\frac{du}{dx}$$

$$\frac{d}{dx}\log_{10} u = \frac{\log_{10} e}{u}\cdot\frac{du}{dx}$$

$$\frac{d}{dx}\cos^{-1} u = -\frac{1}{\sqrt{1-u^2}}\frac{du}{dx}$$

$$\frac{d}{dx}\sin u = \cos u \frac{du}{dx} \quad (u \text{ in radians})$$

$$\frac{d}{dx}\tan^{-1} u = \frac{1}{1+u^2}\frac{du}{dx}$$

$$\frac{d}{dx}\cos u = -\sin u \frac{du}{dx}$$

$$\frac{d}{dx}\cot^{-1} u = -\frac{1}{1+u^2}\frac{du}{dx}$$

$$\frac{d}{dx}\tan u = \sec^2 u \frac{du}{dx}$$

$$\frac{d}{dx}\sec^{-1} u = \frac{1}{u\sqrt{u^2-1}}\frac{du}{dx}$$

$$\frac{d}{dx}\cot u = -\csc^2 u \frac{du}{dx}$$

$$\frac{d}{dx}\csc^{-1} u = -\frac{1}{u\sqrt{u^2-1}}\frac{du}{dx}$$

$$\frac{d}{dx}\sec u = \sec u \tan u \frac{du}{dx}$$

26. TABLE OF INTEGRALS

The base e (Naperian system) is assumed for logarithms unless otherwise noted. A constant C is understood to be added to each result

$$\int dx = x + C$$

$$\int x^n\,dx = \frac{x^{n+1}}{n+1}, \quad \text{except when } n = -1$$

$$\int x^{-1}\,dx = \int \frac{dx}{x} = \log x$$

$$\int \frac{dx}{ax+b} = \frac{1}{a}\log(ax+b)$$

$$\int (ax+b)^n\,dx = \frac{(ax+b)^{n+1}}{a(n+1)}, \quad \text{except when } n = -1$$

$$\int \frac{dx}{ax^2+b} = \frac{1}{\sqrt{ab}}\tan^{-1}\left[x\sqrt{\frac{a}{b}}\right], \quad \text{when } a > 0 \text{ and } b > 0$$

$$\int \frac{dx}{ax^2-b} = \frac{1}{2\sqrt{ab}}\log\frac{\sqrt{a}\,x-\sqrt{b}}{\sqrt{a}\,x+\sqrt{b}}, \quad \text{when } a > 0 \text{ and } b > 0$$

$$\int \sqrt{x^2+a^2}\,dx = 1/2\left[x\sqrt{x^2+a^2} + a^2\log\left(x+\sqrt{x^2+a^2}\right)\right]$$

$$\int \sqrt{x^2-a^2}\,dx = \text{same as above, with } -a^2 \text{ for } a^2$$

$$\int \sqrt{a^2-x^2}\,dx = 1/2\left(x\sqrt{a^2-x^2} + a^2\sin^{-1}\frac{x}{a}\right)$$

$$\int \frac{dx}{\sqrt{a^2-x^2}} = \sin^{-1}\frac{x}{a}$$

$$\int \tan x\,dx = -\log\cos x$$

$$\int \log x\,dx = x(\log x - 1)$$

$$\int \cot x\,dx = \log\sin x$$

$$\int \log_{10} x\,dx = x\log_{10}\frac{x}{10}$$

$$\int \sec x\,dx = \log(\sec x + \tan x)$$

$$\int e^{ax}\,dx = \frac{e^{ax}}{a}$$

$$\int \sec^2 x\,dx = \tan x$$

$$\int a^x\,dx = \frac{a^x}{\log a}$$

$$\int \csc x\,dx = \log(\csc x - \cot x) = \log\tan\frac{x}{2}$$

$$\int xe^x\,dx = e^x(x-1)$$

$$\int \csc^2 x\,dx = -\cot x$$

$$\int \sin x\,dx = -\cos x$$

$$\int x\sin x\,dx = \sin x - x\cos x$$

$$\int \cos x\,dx = \sin x$$

$$\int x^2\sin x\,dx = 2x\sin x + (2-x^2)\cos x$$

$$\int \sin^2 x\,dx = \frac{x}{2} - \frac{\sin 2x}{4}$$

$$\int x\cos x\,dx = \cos x + x\sin x$$

$$\int \cos^2 x\,dx = \frac{x}{2} + \frac{\sin 2x}{4}$$

$$\int x^2\cos x\,dx = 2x\cos x + (x^2-2)\sin x$$

STATICS

27. DEFINITIONS

Mechanics is that branch of science which treats of forces and motion. STATICS deals with the action of forces on bodies at rest. DYNAMICS deals with the action of forces on bodies in motion.

Force is that which changes or tends to change the state of rest or motion of a body. A force is completely specified by its magnitude, direction and point of application. The word SENSE as applied to a force refers to one of the two directions along the line of action of the force. The effect of any force applied to a rigid body at rest is the same, no matter where in its own line of action the force is applied. This is known as the principle of the TRANSMISSIBILITY OF FORCE. A force may be represented graphically in magnitude and direction by a straight line drawn parallel to its line of action, the length being proportional to the magnitude of the force; its sense is indicated by an arrowhead placed on the line. The English engineers' UNIT OF FORCE is the pound, or the earth's pull on a mass of 1 lb. A drawing which indicates the lines of action of the various forces acting on a machine or structure is called a SPACE DIAGRAM; the part in which vectors are drawn to represent the magnitudes and directions of the forces is a VECTOR DIAGRAM. A force is indicated on a space diagram by two lower-case letters placed on opposite sides of the line of action of the force; the vector, representing its magnitude and direction, by the same capital letters placed at the ends. Thus, in Fig 87, AB represents the magnitude and direction of the force W, and ab its action line. The vector being read as AB indicates a downward sense; read as BA, an upward sense.

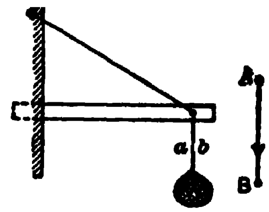

Fig 87

Forces are classified according to the arrangement of their action lines:

1. Coplanar: *a*. concurrent; *b*. nonconcurrent; *c*. parallel
2. Noncoplanar: *a*. concurrent; *b*. nonconcurrent; *c*. parallel

Any number of forces taken collectively is a system or set of forces. A system is coplanar or noncoplanar according as the lines of action of the forces do or do not lie in the same plane, and is concurrent or nonconcurrent according as they do or do not intersect in a point. Two or more forces which are the equivalent of a single force are COMPONENTS of the force. The operation of replacing a system of forces by a simpler system is called COMPOSITION of forces. RESOLUTION of forces is the operation of replacing a single force by a system of forces. RESULTANT of a force system is the simplest equivalent system. In some cases the simplest equivalent is a single force; in other cases, it is a couple; in still others it is a pair of forces which are not parallel and do not intersect (noncoplanar).

28. RESULTANTS OF CONCURRENT FORCES

Resultant of two concurrent forces. PARALLELOGRAM LAW. If two concurrent forces P and Q (Fig 88), acting at the point O of a body, are represented in magnitude and direction by the adjacent sides OB and OA of parallelogram $OACB$, their resultant is represented by diagonal OC passing through point of concurrency O. TRIANGLE LAW. If in the triangle ABC (Fig 89) AB and BC represent two concurrent forces in magnitude, direction

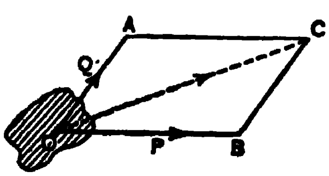

Fig 88

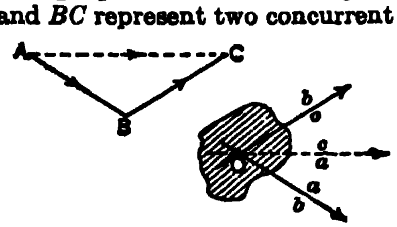

Fig 89

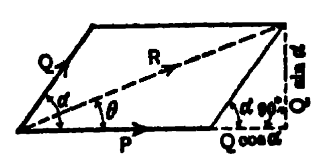

Fig 90

and sense, then AC will represent their resultant in magnitude, direction and sense; its action line will be ac, through the point of concurrency parallel to AC. The resultant may be found algebraically thus: In Fig 90, let α be the angle between the action lines of forces P and Q, and θ the angle between R and P. Then, $R^2 = P^2 + Q^2 + 2\,PQ\cos\alpha$, and $\tan\theta = \dfrac{Q\sin\alpha}{P + Q\cos\alpha}$. If $\alpha = 90°$, $R^2 = P^2 + Q^2$, and $\tan\theta = Q \div P$.

A force may be resolved into an infinite number of pairs of components by constructing different triangles as in Fig 91. The action lines of the components must be concurrent at a point on the action line of the force. A common problem is to resolve a force into rectangular components (often called resolved parts). In Fig 92, AB and BC are the

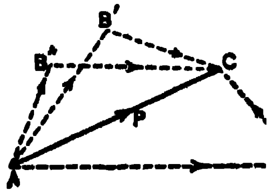

Fig 91

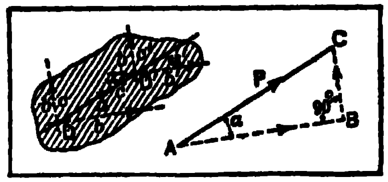

Fig 92

rectangular components of the force P. Expressed algebraically, $AB = P\cos\alpha$ and $BC = P\sin\alpha$. In general, the resolved part of a force along any line equals the magnitude of the force times the cosine of the angle between the lines of action of the force and its component. Action lines of the components are concurrent on the space diagram at some point on ac, as at D or D'.

Resultant of coplanar concurrent forces is found graphically as follows: In Fig 93, consider body G acted on by the 4 forces shown. Construct a force polygon. Plat AB parallel to ab, and scale it to represent 60 lb; from B plat BC parallel to bc, and scale it to represent 80 lb; in like manner plot CD and DE, so that the arrows lead confluently from A to E. The resultant of the system is AE in magnitude and sense = 114 lb, and its action line is ae, making an angle of $\theta = \tan^{-1} 0.146 = 8° 20'$ with the horizontal. ALGEBRAIC SOLUTION. Choose rectangular axes OX and OY. Resolve each force into its x and y components, considering components acting upward or to the right as positive, and those acting downward or to the left as negative. Arrange the results in tabular form, placing the forces in the first column, the x components in the second and the y components in the third. ΣF_x = algebraic sum of x components, and ΣF_y = algebraic sum of y components.

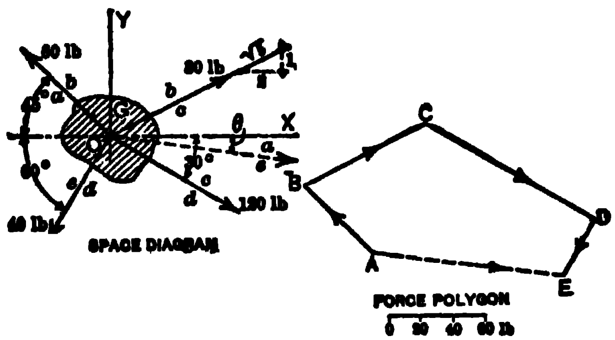

Fig 93

F, lb	F_x, lb	F_y, lb
$ab = 60$	$-60 \times 0.707 = -42.4$	$+60 \times 0.707 + 42.4$
$bc = 80$	$+80 \times 2/\sqrt{5} = +71.4$	$+80 \times 1/\sqrt{5} = +35.7$
$cd = 120$	$+120 \times 0.866 = +104$	$-120 \times 0.5 = -60$
$de = 40$	$-40 \times 0.5 = -20$	$-40 \times 0.866 = -34.6$
	$\Sigma F_x = +113$	$\Sigma F_y = -16.5$

Then $R = \sqrt{\overline{\Sigma F_x}^2 + \overline{\Sigma F_y}^2} = \sqrt{13\,041} = 114$ lb. Sense is downward and to the right (Fig 94). $\tan\theta = \dfrac{\Sigma F_y}{\Sigma F_x} = 0.146$; $\theta = 8° 20'$. If a concurrent system has a resultant, it is a single force.

Resultant of noncoplanar concurrent forces. PARALLELOPIPEDON LAW. Consider the 3 rectangular forces, P, Q, and S (Fig 95). On these forces construct to scale a parallelopiped.

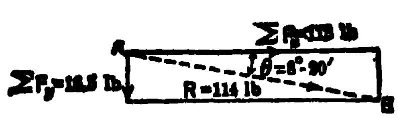

Fig 94

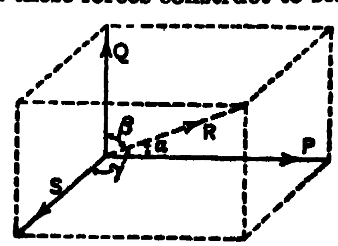

Fig 95

Resultant of the system is represented in magnitude and direction by the diagonal; its value is $R = \sqrt{P^2 + Q^2 + S^2}$. Its direction cosines with respect to the axes are: $\cos\alpha = P \div R$, $\cos\beta = Q \div R$, and $\cos\gamma = S \div R$.

Resultant of any number of concurrent forces. Let the forces be specified with respect to 3 rectangular axes passing through the point of concurrency: (*a*) Resolve each force into components along the X, Y and Z-axes; (*b*) Find the algebraic sums of the x, y and z components, and indicate them by ΣF_x, ΣF_y, and ΣF_z; (*c*) Find the resultant of these three partial resultants by the parallelopipedon law; its value is $R = \sqrt{\overline{\Sigma F_x}^2 + \overline{\Sigma F_y}^2 + \overline{\Sigma F_z}^2}$; its direction angles are $\alpha = \cos^{-1}\frac{\Sigma F_x}{R}$; $\beta = \cos^{-1}\frac{\Sigma F_y}{R}$; $\gamma = \cos^{-1}\frac{\Sigma F_z}{R}$

29. MOMENTS AND COUPLES

Moment or **torque** of a force about a point is the product of the force magnitude and the distance from the point to its action line. This perpendicular distance is called the arm of the force, and the point is the origin or center of moments. The product is the measure of the rotational tendency of the force. The name of the unit of moment is a combination of the names of force and distance units: thus: foot-pound, inch-pound or inch-ton. Moments tending to produce counterclockwise rotation of a body will be considered positive, and clockwise negative, unless contrary convention is mentioned. Thus, in Fig 96, the moment of force P about $O = P + OA$.

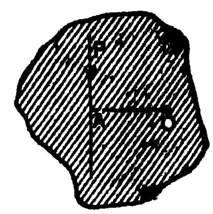

Fig 96

Moment of force about a line or axis. At any point on its action line, resolve the force into 2 rectangular components, one being parallel to the axis. The product of the perpendicular component and the perpendicular distance from the axis to the force is the moment of given force about the axis. Thus (Fig 97), $P \sin \alpha$ is the component parallel to the axis, and it has no turning effect. All the moment or turning effect is caused by the perpendicular component, and its value is $P \cos \alpha \times OE$, OE being the perpendicular distance between the axis and the parallel plane $ABCD$.

Principle of moments. Sum of the moments of any coplanar force system about any point in their plane is equal to the moment of their resultant about same point. Thus (Fig 98), R is the resultant of P and Q, and $R \times r = P \times p - Q \times q$. Sum of the moments of any force system about an axis is equal to the moment of their resultant about the axis. Thus (Fig 99), R is the resultant of the 3 rectangular forces, P, Q, and S. Moment of R about axis $X = S \times y - Q \times z$. P contributes nothing to the moment sum, as it is parallel to the axis of moments. In such a case, counterclockwise moment is called positive and clockwise negative, the observer looking toward the origin O, from the positive ends of the axes. Thus, Q has positive moment about axis Z, but negative moment about axis X. Moment of a force passing through the origin of moments is zero. Moment of a force intersecting the axis of moments is zero.

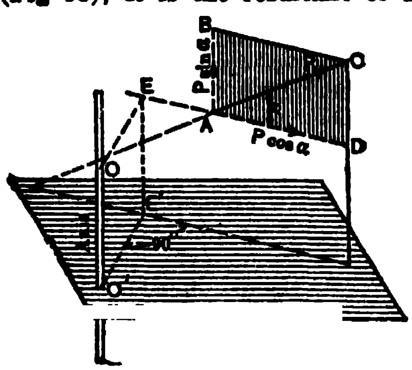

Fig 97

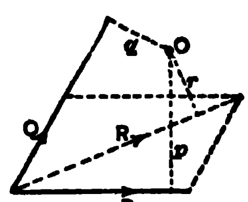

Fig 98

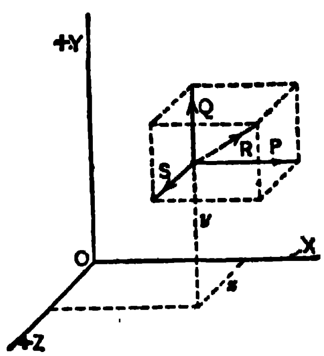

Fig 99

Couples. Two equal and parallel forces of opposite sense are called a couple. THE ARM OF THE COUPLE is the perpendicular distance between the lines of action of the forces. Moment of a couple is constant and independent of the origin of moments; it is equal to one of the forces times the arm of the couple. Its sense is positive or negative according as rotational tendency is counterclockwise or clockwise. Couples of equal moments, in the same or parallel planes, are equivalent and may be replaced one by the other. That is, a couple may be twisted or moved about in its plane, or transferred to any parallel plane without altering the resulting motion of the body on which it acts.

Resultant of any number of coplanar couples or of couples in parallel planes is a couple. Its moment and sense equal the algebraic sum of the moments of the component couples. A couple may be represented by a vector. Length of the vector to scale represents the

magnitude of the moment; it is drawn perpendicular to the plane of the couple from any origin, and an arrow is placed on it to represent the way in which the couple would cause a right-hand screw to advance. Resultant of any number of couples (in oblique or parallel planes) is a couple. The composition is effected thus: (*a*) Refer the couple vectors to three rectangular coordinate axes. (*b*) Resolve each vector into components parallel to the axes. (*c*) Take the sum of the components along the X, Y, and Z-axes. (*d*) Representing these sums by ΣC_x, ΣC_y, ΣC_z, and the resultant vector by C, its value is $C = \sqrt{\overline{\Sigma C_x}^2 + \overline{\Sigma C_y}^2 + \overline{\Sigma C_z}^2}$. Its direction angles are

$$\phi_x = \cos^{-1}\frac{\Sigma C_x}{C}\ ;\ \phi_y = \cos^{-1}\frac{\Sigma C_y}{C}\ ;\ \phi_z = \cos^{-1}\frac{\Sigma C_z}{C}$$

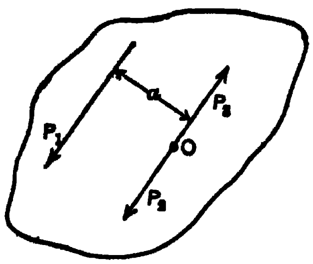

Fig 100

A force may be resolved into a force acting at a chosen point and a couple. In Fig 100, P_1 is the given force and O the chosen point. Through O apply a pair of forces, opposite in sense, equal and parallel to P_1. As P_2 and P_3 balance, no change is produced in motion of the body due to this addition. P_1 and P_3 constitute a couple of moment $= P \times a$, which is the same as moment of P_1 about O; and P_2 is a force just like P_1, but acting through the chosen point O. Conversely, a force and a couple in a plane compound into a single force parallel to given force, of same sense and magnitude, and so placed that its moment about any point in action line of given force is equal to moment of given couple.

30. RESULTANTS OF COPLANAR NONCONCURRENT FORCES

Resultant of coplanar parallel forces may be (*a*) a single force or (*b*) a couple.

Case (*a*). To find the resultant of the 4 parallel forces shown in Fig 101:

Graphical solution. (1) Plat AB to represent magnitude and sense of ab; then BC to represent magnitude and sense of bc; then CD and DE to represent the other two forces; (2) choose the pole O in any convenient position and draw the rays AO, BO, CO, DO, and EO; (3) from any point on ab, draw strings parallel to AO and OB; from intersection of ob and bc draw oc parallel to OC until it intersects cd; from that point draw od to intersect de; then oe to intersect oa at K; (4) AE, from the beginning to the end of vector diagram, represents the magnitude and sense of the resultant = 180 lb downward; its action line is ae, through K, parallel to AE, 5.3 ft to right of ab.

The polygon formed on the space diagram is called a string or funicular polygon; its sides represent the action lines of the components that replace the parallel forces. Thus

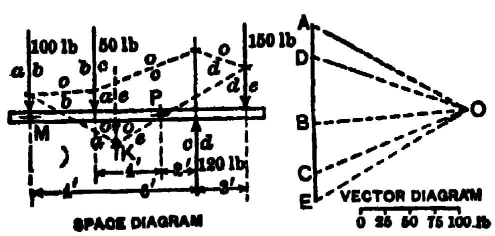

Fig 101

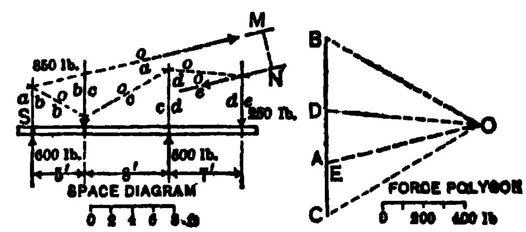

Fig 102

BC, acting in the line bo, is replaced by BO = 140 lb, and OC = 160 lb, acting in the lines bo and oc. AO and OE are components of the resultant AE. The object of the funicular polygon is to locate one point on the action line of the resultant.

Algebraic solution. The magnitude and sense of the resultant are given by $R = \Sigma F$; its position is determined by use of the principle of moments, the moment of the resultant being equal to the algebraic sum of the moments of the forces. Hence arm $= \Sigma M \div R$. It is best to call upward forces positive, and distances to right of moment origin positive. For solving example shown in Fig 101, tabulate the values as follows:

Force, lb	Arm from M	Moment about M	Arm from P	Moment about P
−100	0	0	−8	+800
−50	+4	−200	−4	+200
+120	+10	+1 200	+2	+240
−150	+13	−1 950	+5	−750
ΣF = −180 lb		ΣM_M = −950 ft-lb		ΣM_P = +490 ft-lb

R = 180 lb downward. Distance from $M = -950 \div -180 = +5.3$ ft. Distance from $P = +490 \div -180 = -2.7$ ft. Either of these distances locates the point K in Fig 101, and checks the graphical solution.

Case (*b*). $\Sigma F = 0$, and resultant is a couple.

Graphical solution. Consider the 4 parallel forces in Fig 102. The force polygon begins at A and ends at E, the same point; hence the resultant is not a single force (this is called a closed force polygon). Construct the funicular polygon as before. The first and last strings, *ao* and *oe*, being parallel, do not intersect. The forces acting in those lines, AO and OE, being equal and opposite in sense, form a couple. Hence the resultant of the system is a couple. The forces $AO = OE = 750$ lb. The arm $MN = 3.67$ ft. The moment $= 750 \times 3.67 = 2\,752$ ft-lb. The sense, by inspection of the space diagram, is clockwise. The moment of the couple is the same, no matter what pole O is selected.

Algebraic solution of the same example (see accompanying table):

Forces, lb	Arm from S	Moment about S	
+600	0	0	
−850	+ 5		−4 250
+500	+13	+6 500	
−250	+20		−5 000
$\Sigma F = 0$		$\Sigma M_s = -2\,750$ ft-lb	

Hence the resultant is a clockwise couple of moment equal to 2 750 ft-lb. Since couples of equal moment and sense in the same plane are equivalent, it is unnecessary to give more detail.

Special cases. Two parallel forces. Case (*a*). Forces alike in sense. Given the 2 forces P and Q, located as in Fig 103. The resultant lies between these forces, and is equal in magnitude to $P + Q$. The action line of the resultant is found from the equation. $a = (Q \times b) \div P$. Case (*b*). Forces opposite in sense. Given the 2 forces P and Q as in Fig 104. Resultant lies outside of the forces P and Q, is adjacent to the larger force, and is equal in magnitude to $Q - P$. The action line of the resultant is found from the equation, $a = (Q \times b) \div P$. The sense of the resultant is the same as that of larger force. In either case, the resultant divides the distance between the forces into segments inversely proportional to the adjacent forces; or, $P \div b = Q \div a = R \div c$.

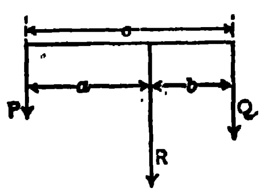

Fig 103

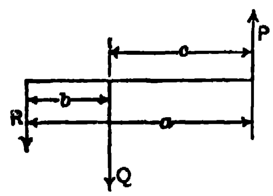

Fig 104

Resultant of coplanar nonconcurrent forces. **Case** (*a*). Resultant equals a single force.

Graphical solution. Construct a force polygon as if the forces were concurrent. The closing line gives the magnitude, sense, and angular direction of the resultant. The action line is found by drawing a funicular polygon. Thus, to find the resultant of the 4 forces in Fig 105: (1) Construct the force polygon $ABCDE$; (2) choose a convenient pole O, and draw the rays; (3) start at any point on *ab* and draw the funicular polygon; (4) determine K, the intersection of the first and last strings. This is one point on the action line of the resultant. Resultant $= AE =$ 67 lb, downward to the left, at angle $\theta = tan^{-1} \dfrac{0.784}{1.0} = 38° 6'$ to horizontal. Action line is *ae*, parallel to AE, through K.

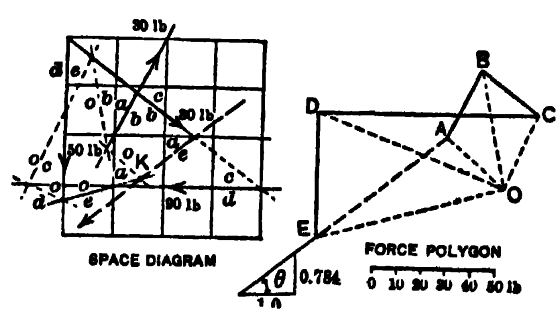

Fig 105

Second graphical method. Use the triangle law to find the resultant of two forces. Use the same law to find the resultant of this partial resultant and the third force. Repeat until the final resultant is obtained.

Algebraic solution. The resultant is found in magnitude, sense, and angular direction as if the forces were concurrent: $R = \sqrt{\overline{\Sigma F_x}^2 + \overline{\Sigma F_y}^2}$, $cos\ \theta = \dfrac{\Sigma F_x}{R}$, $sin\ \theta = \dfrac{\Sigma F_y}{R}$, in which θ is the angle between R and the X-axis. Use the principle of moments to locate the action line. Choose a convenient origin of mo-

Force, lb	F_x, lb	F_y, lb	M_o, ft-lb
50	−50	0	+150
70	−31.3	−62.6	−62.6
30	+ 7.3	−29.1	0
	$\Sigma F_x = -74$ lb	$\Sigma F_y = -91.7$ lb	$\Sigma M_o = 87.4$ ft-lb

ments and compute ΣM. The arm of the resultant $= \Sigma M \div R$, and is perpendicular to the angular direction of R found above. R is so located with respect to the origin that the sign of its moment is the same as that of ΣM. As an example, find the resultant of the 3 forces in Fig 106.

$$R = \sqrt{(74)^2 + (91.7)^2} = 118 \text{ lb downward to the left.}$$

Angle with X-axis $= \tan^{-1} \dfrac{91.7}{74} = 51° 8'$. Arm about $O = 87.4 \div 118 = 0.74$ ft.
In this case, R is to the left of O, because its moment must be $= \Sigma M_o = +87.4$ ft-lb.

Case (b). Resultant is a couple.

Graphical solution. Let forces V, P, Q, T, and S (Fig 107) represent a system of forces the force polygon of which closes, and which reduces to the 2 components AO and OF

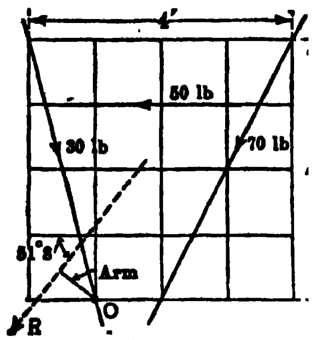

Fig 106

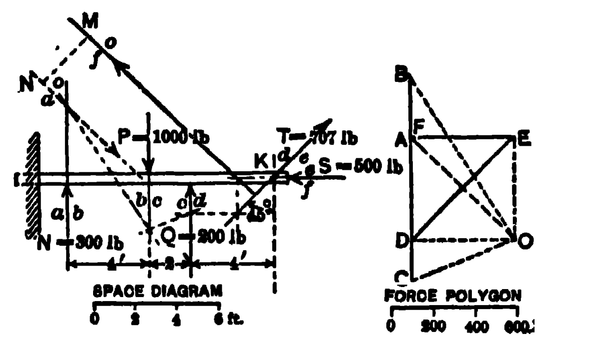

Fig 107

acting in ao and of. Since these components are equal, opposite and parallel, the resultant is a couple. The arm of the couple is the perpendicular distance MN, between the first and last strings. The moment is the product of OA (according to force scale) and the arm MN (according to scale of space diagram). The sense of the couple is counterclockwise, as found by inspection of the space diagram. The moment $= 710 \times 3.1 = 2\,200$ ft-lb.

Algebraic solution. Any couple the moment of which equals the algebraic sum of the moments of the given forces about any point may be regarded as the resultant. In Fig 107, assume forces acting as indicated. The algebraic sums of the x and y components are zero. Taking moments about point K,

$$\Sigma M_K = 1\,000 \times 6 - 300 \times 10 - 200 \times 4 = +\,2\,200 \text{ ft-lb}$$

Hence, the resultant of the system is a couple, of moment equal to 2 200 ft-lb and of counterclockwise sense.

31. RESULTANTS OF NONCOPLANAR NONCONCURRENT FORCES

Resultants of noncoplanar parallel forces may be a single force or a couple.

Choose a set of 3 rectangular axes, with the Z-axis parallel to the forces, and let the positions of the forces be specified by the x and y coordinates of their action lines. As an example, consider the 5 parallel forces shown in Fig 108 to be perpendicular to plane of the paper. Tabulate the computations as below:

Force, lb	x, ft	y, ft	M_x or $F \times y$, ft-lb	M_y or $F \times x$, ft-lb
+10	+3	+6	+ 60	+30
+30	+2	+4	+120	+60
+20	+2	−1	−20	+40
−40	−1	−1	+ 40	+40
−35	+3	+1	−35	−105
$\Sigma F = -15$ lb			$\Sigma M_x = +165$	$\Sigma M_y = +65$

$R = \Sigma F = -15$ lb, in the $-Z$ sense, or backward. $x_o = \dfrac{\Sigma M_y}{\Sigma F} = \dfrac{+65}{-15} = -4.33$ ft.

$y_o = \dfrac{\Sigma M_x}{\Sigma F} = \dfrac{+165}{-15} = -11$ ft. Hence the coordinates of the action line of the resultant are x_o, y_o, or $(-4.33$ ft, -11 ft). Position of the resultant is not indicated in Fig 108. In the above computation, the algebraic rules of signs for multiplication and division are followed throughout, so that the values of x_o and y_o may be interpreted algebraically.

This method agrees with the usual convention of signs for computing moments about the X-axis, but is the reverse of the usual convention for moments about the Y-axis.

If $\Sigma F = 0$, and if ΣM_x or ΣM_y does not equal zero, the resultant is a couple and not a force. The plane of the couple will be parallel to the Z-axis. It is necessary to deter-

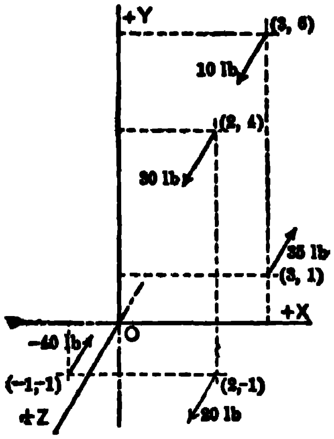

Fig 108

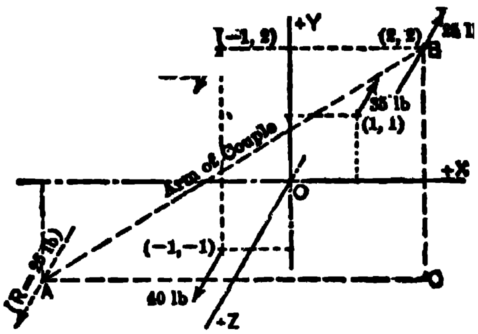

Fig 109

mine the moment of the couple, its sense, and the inclination of its plane with the XZ plane. Consider the 4 forces in Fig 109 as an example:

Force, lb	x, ft	y, ft	M_x, ft-lb	M_y, ft-lb
+20	−1	+2	+40	−20
+40	−1	−1	−40	−40
−35	+1	+1	−35	−35
−25	+2	+2	−50	−50
$\Sigma F = 0$			$\Sigma M_x = -85$	$\Sigma M_y = -145$

Since $\Sigma F = 0$, the resultant of all except one of the forces, with the omitted force, is a couple. Omitting the last force, $R = \Sigma F = +25$ lb. Its $x_o = \dfrac{\Sigma M_y}{\Sigma F} = \dfrac{-95}{+25} = -3.8$ ft, and $y_o = \dfrac{\Sigma M_x}{\Sigma F} = \dfrac{-35}{+25} = -1.4$ ft. AB is the arm of the couple, and from the triangle ABC its length is found to be 6.72 ft. The moment of the couple $= 25 \times 6.72 = 168$ ft-lb. BAC is angle its plane makes with horiz plane. Angle $BAC = \tan^{-1}\dfrac{3.4}{5.8} = 30° \, 21'$. Viewing the couple from plus end of Y-axis, its sense is observed to be counterclockwise.

Resultant of noncoplanar nonconcurrent nonparallel forces is generally a single force acting at a chosen point and a couple not coplanar with the force. The magnitude, sense, and angular direction of the single force is the same as if the forces were concurrent:

$$R = \sqrt{(\Sigma F_x)^2 + (\Sigma F_y)^2 + (\Sigma F_z)^2}; \quad \phi_x = \cos^{-1}\frac{\Sigma F_x}{R}; \quad \phi_y = \cos^{-1}\frac{\Sigma F_y}{R}; \quad \phi_z = \cos^{-1}\frac{\Sigma F_z}{R}$$

and R acts through the selected origin of reference. To determine the couple, compute the sums of the moments of the forces about the coordinate axes of reference. These moment sums represent 3 couples, which are axial components of the resultant couple. Consider ΣM_x as a vector along the X-axis, ΣM_y as a vector along Y, and ΣM_z along Z. The moment of the resultant couple is $C = \sqrt{(\Sigma M_x)^2 + (\Sigma M_y)^2 + (\Sigma M_z)^2}$, and the direction angles of its vector are

$$\theta_x = \cos^{-1}\frac{\Sigma M_x}{C}; \quad \theta_y = \cos^{-1}\frac{\Sigma M_y}{C}; \quad \theta_z = \cos^{-1}\frac{\Sigma M_z}{C}$$

R and C may be compounded into 2 forces which do not intersect. In a special problem R or C might be zero. Hence, the resultant might be a couple only, or a single force.

32. CONDITIONS OF EQUILIBRIUM

A body is in equilibrium with respect to adjacent bodies if it remains at rest with respect to them, or if it moves at constant velocity; that is, its state of motion does not change. A force system is in equilibrium if its resultant is zero. Such a system causes

no change in the state of motion of the body to which it is applied. If a body is in equilibrium with respect to adjacent bodies, then the external force system applied to it is in equilibrium. By this external force system is meant the pull of gravity and all the pulls or pushes exerted on the body by other bodies.

Depending on the kind of force system involved, varying numbers of tests or conditions must be applied to prove that the system is in equilibrium, or that no resultant exists. In the usual problem, a body is known to be in equilibrium; hence the system composed of all the external forces acting upon it must be in equilibrium. In such case the tests are not needed to ascertain if equilibrium exists, but they are used to set up relations involving unknown forces, distances, or angles, and the unknown elements are then computed provided they are not too numerous. Such computations are conducted either algebraically or graphically. (See following table.)

Special conditions of equilibrium. If 3 forces are in equilibrium they must be coplanar, and must be concurrent or parallel; if concurrent, each force is proportional to the sine of the angle between the other two; if parallel, each force is proportional to the distance between the other two. If a force system is in equilibrium, the resultant of any part must balance the resultant of the other part.

Necessary independent conditions of equilibrium for the various force systems

	System	Algebraical		Graphical	
		No	Conditions	No	Conditions
Coplanar	Collinear	1	$\Sigma F = 0$	1	Force polygon closes
Coplanar	Concurrent at point O	2	$\Sigma F_x = 0$, $\Sigma F_y = 0$, if the angle between x and y does not equal 180°; or, $\Sigma F_x = 0$, $\Sigma M_a = 0$, if x direction is not perpendicular to aO; or, $\Sigma M_a = 0$, $\Sigma M_b = 0$, if aOb is not a straight line	1	Force polygon closes
Coplanar	Parallel	2	$\Sigma F = 0, \Sigma M = 0$; or, $\Sigma M_a = 0$, $\Sigma M_b = 0$, if line ab is not parallel to forces	2	Force and funicular polygons close. Latter item means that first and last strings coincide
Coplanar	Nonparallel nonconcurrent	3	$\Sigma F_x = 0, \Sigma F_y = 0, \Sigma M = 0$; or, $\Sigma F_x = 0$, $\Sigma M_a = 0$, $\Sigma M_b = 0$, if x is not perpendicular to ab; or, $\Sigma M_a = 0$, $\Sigma M_b = 0$, $\Sigma M_c = 0$, if abc is not a straight line		Force and funicular polygons close
Noncoplanar	Concurrent at point O	3	$\Sigma F_x = 0$, $\Sigma F_y = 0$, $\Sigma F_z = 0$; or, ΣF_s in every direction and ΣM about every axis $= 0$. Combinations of moment and resolution equations can be arranged, but are not common	2	Force polygon closes. It is warped; hence plan and elevation must show closed. Not commonly used
Noncoplanar	Parallel	3	$\Sigma F_z = 0$, $\Sigma M_x = 0$, $\Sigma M_y = 0$, forces parallel to z-axis. Other combinations possible but not common		Not used
Noncoplanar	Noncon-current nonparallel	6	$\Sigma F_x = 0$, $\Sigma F_y = 0$, $\Sigma F_z = 0$, $\Sigma M_x = 0, \Sigma M_y = 0, \Sigma M_z = 0$. ΣM about every axis $= 0$, and it is often convenient to employ more than three moment equations, instead of using so many resolution equations		The projection of the system on any plane is in equilibrium, and algebraical or graphical conditions can be used to solve such projected systems

33. EQUILIBRIUM PROBLEMS

General method of solution. (*a*) Sketch or specify the free body that is in equilibrium, and indicate the complete external force system acting upon it. (*b*) Discuss the problem as to number and kinds of unknown quantities, to see if a solution is possible. If the first system tried cannot be solved, separate the original body discussed (say some machine) into simpler parts, and sketch and discuss them until one is found that permits of solution. (*c*) Apply the appropriate conditions of equilibrium and solve for the unknown forces, angles, or distances. (*d*) Make use of the acquired information to solve other systems.

If resolution equations are used, it is desirable each time to resolve perpendicular to one of the unknown forces, so as to avoid the solution of simultaneous equations and to make the answers independent of each other. If moment origins are used, it is best to select them on the action lines of some of the unknown forces. If moment axes are used, they should be selected so as to intersect some of the unknown forces. Equilibrium problems can be classified as to the kind of force system involved, and number and kind of unknown quantities. Following are a few typical problems, with details of their solutions.

Typical problem I. A SYSTEM OF COPLANAR CONCURRENT FORCES is in equilibrium and all but two are known; the action lines of these are known, required their magnitudes and senses. ALGEBRAIC SOLUTION. (*e*) Assume senses for both unknown forces. (*f*) Write a pair of equilibrium equations involving the unknown forces, and solve for the two unknowns. A plus answer indicates the sense correctly assumed. A minus answer indicates incorrect assumption. GRAPHICAL SOLUTION. (*g*) Letter the action lines of the wholly known forces, and then the action lines of the two unknown forces. (*h*) Draw the force polygon to the end of the last known vector, and close it by drawing parallels to the unknown forces through the ends of the first and last vectors, and mark the intersection of these lines as the last vertex in the polygon. (*i*) The senses must read confluently from starting point back to same point, the last two vectors representing the two unknown forces in magnitude and sense.

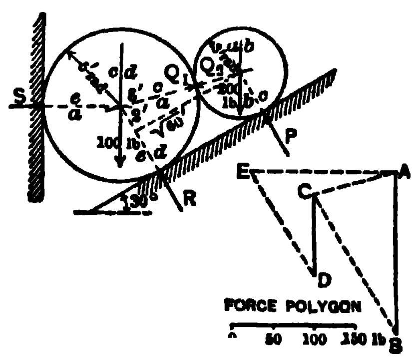

Fig 110

Example. Two smooth cylinders rest upon a 30° plane and against a vertical wall as shown in Fig 110. Determine all forces acting on each cylinder. (*a*) The forces involved are 100 lb, 200 lb, P, Q, R, and S, the last four being normal to the surfaces of contact (smooth surfaces). (*b*) Consider the two cylinders as a single free body. The external force system is 100 lb, 200 lb, P, R, and S (Q_1 and Q_2 are internal). The system is nonconcurrent, so does not come under typical problem I. Consider the large cylinder as a free body. The external force system is 100 lb, Q, R, and S. While this system is concurrent, it can not be solved because there are more than two unknown quantities. Next consider the small cylinder as a free body. The force system is 200 lb, P and Q, and this is typical problem I. ALGEBRAIC SOLUTION. Choose X and Y directions parallel and perpendicular to the plane. By (*c*) and (*e*), $\Sigma F_x = 0 = Q_1 \frac{\sqrt{60}}{8} - 200 \sin 30°$. Hence $Q_1 = \frac{800}{\sqrt{60}} = 103.3$ lb. $\Sigma F_y = 0 = P - 200 \cos 30° - 103.3 \times {}^2/_8$. Hence $P = 199$ lb. (*d*) Consider the large cylinder as a free body. $Q_1 = Q_2 = 103.3$ lb. Use the same X and Y directions. $\Sigma F_x = 0 = S \cos 30° - 103.3 \times \frac{\sqrt{60}}{8} - 100 \sin 30°$. Hence, $S = 173.2$ lb. $\Sigma F_y = 0 = R - 100 \cos 30° - 173.2 \sin 30° + 103.3 \times {}^2/_8$. Hence $R = 147.4$ lb. GRAPHICAL SOLUTION. Discussions (*a*) and (*b*) are same as above. The free body is the small cylinder. The force system is 200 lb, *ab*, *bc*, and *ca*, and the polygon is the triangle ABC (Fig 110). $BC = 199$ lb, $CA = 103.3$ lb. Next, consider the large cylinder as a free body. The force system is *ac*, *cd*, *de* and *ea*. Plat the known forces AC and CD. From D draw DE parallel to *de*, and from A, AE parallel to *ae*; these lines intersect at E. $DE = 147.4$ lb, and $EA = 173.2$ lb are the magnitudes and senses of the two unknowns. If the system is concurrent and all the forces are known except one, the two unknown elements will be one angle and one magnitude and sense. Both may be determined by writing the equilibrium equations, or by drawing the force polygon.

Typical problem II. A SYSTEM OF COPLANAR PARALLEL FORCES is in equilibrium and all are known except two; the action lines of these two are known; required their magni-

tudes and senses. ALGEBRAIC SOLUTION. (*e*) Assume senses for both unknown forces. (*f*) Write a pair of equilibrium equations involving the unknown forces and solve for the two unknowns. A plus answer indicates the sense correctly assumed. A minus answer indicates incorrect assumption. As a check on the results apply a third equilibrium equation. For problems of this type the algebraic solution is preferable to the graphical. GRAPHICAL SOLUTION. (*g*) Letter the action lines of the wholly known forces and then the action lines of the two unknown forces. (*h*) On a line of indefinite length parallel to the forces, often called the load line, form the force polygon by plotting vectors of the known forces continuously to end of last known force. The vector of the first unknown force extends from this point to some unknown point on the load line. The unknown point is to be found. (*i*) Construct a funicular polygon. Draw first string between first known force and last-lettered unknown force. Continue funicular polygon to intersection of last known string with first-lettered unknown force. Draw closing string from this point, to intersection of first string with last-lettered unknown force. Draw a ray through pole parallel to closing string; its intersection with the load line is the point sought. (*j*) The senses must read confluently from the starting point back to the same point. The last two vectors represent the two unknown forces in magnitude and sense.

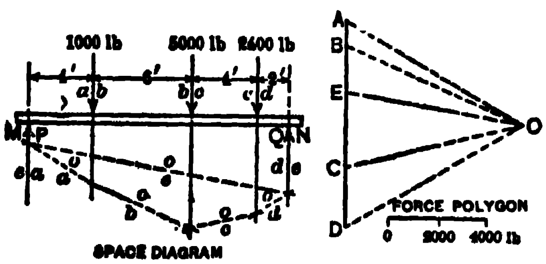

Fig 111

Example. A beam is loaded as shown in Fig 111 and supported at the points P and Q. (*a*) Determine the reactions of the supports. (*b*) Consider the beam as a free body. The external force system consists of the forces 1 000 lb, 5 000 lb, 2 400 lb, P, and Q. This is a coplanar parallel system and is typical problem II. ALGEBRAIC SOLUTION. (*c*) Assume senses for the reactions. By (*c*),

$$\Sigma M_P = 0 = -4 \times 1\,000 - 10 \times 5\,000 - 14 \times 2\,400 + 16\,Q = 0$$

Hence $Q = 5\,475$ lb; correct sense was assumed.

$$\Sigma M_Q = 0 = 2 \times 2\,400 + 6 \times 5\,000 + 12 \times 1\,000 - 16\,P = 0$$

Hence $P = 2\,925$ lb; correct sense assumed. As a check, apply condition, $\Sigma F = 0$.

$$\Sigma F = 0 = -5\,475 + 1\,000 + 5\,000 + 2\,400 - 2\,925 = 0$$

GRAPHICAL SOLUTION of the same problem involves the construction of a closed force polygon and a closed funicular polygon. Draw vectors, AB, BC, CD to represent 1 000 lb, 5 000 lb, 2 400 lb. Let DE represent Q and EA represent P. The problem is to locate point E. This is done with the aid of the funicular polygon. Draw the rays OA, OB, OC, and OD. Start on the action line of P and draw the string polygon. The closing line is oe. Draw the ray OE parallel to oe. The unknown reactions are DE and EA.

(Note.—This principle cannot be applied to beams having more than two points of support. Such problems require special treatment.)

Typical problem III. A SYSTEM OF COPLANAR NONCONCURRENT NONPARALLEL FORCES is in equilibrium, and all are known except two; the action line of one of these and a point in the action line of the other are known. Determine the magnitude and sense of the one, and the magnitude, sense, and angular direction of the other. ALGEBRAIC SOLUTION. (*a*) Assume sense for first unknown force. (*b*) Write a moment equation, center of moments being at given application point, to find first unknown force. (*c*) Assume sense and angular direction for second unknown force. (*d*) Write a pair of equilibrium equations involving the magnitude and angular direction of the second unknown force and solve for the two unknown quantities. A plus answer for the magnitude indicates the sense correctly assumed. A plus answer for the angular direction indicates it correctly assumed. A minus answer for either of the quantities indicates incorrect assumption for the one involved. Check results by means of an additional equilibrium equation. GRAPHICAL SOLUTION. (*e*) Letter the action lines of the wholly known forces, then the action line of the first unknown, and finally the force passing through the given application point. (*f*) Draw the force polygon for the known forces. Through the end of the last vector draw a line parallel to the action line of the first unknown force. Choose a pole and draw the rays. (*g*) Construct a funicular polygon, passing the first string through the application point of the second unknown force, and making the last, or closing, string pass through the same point. Draw a ray through the pole, parallel to closing string; its intersection with the vector drawn parallel to first unknown is last vertex in the force polygon. From this point, draw the closing line of the force polygon. (*h*) The senses

must read confluently from starting point back to same point. The last two vectors represent the two unknown forces.

Example. A roof truss is loaded as in Fig 112. The left end of the truss rests on a smooth horiz support. The right end is secured to a wall by means of a pin. Determine the reactions. (*a*) The external forces acting on the truss are the given loads, the left reaction P (vertical, on account of the smooth support), and the right reaction Q (inclined, through point M). (*b*) The unknown quantities are the reactions P and Q. This is typical problem III. ALGEBRAIC SOLUTION. (*c*) Assume P upward. By (*c*),

$$\Sigma M_M = 0 = 20\,000 \times 18 + 25\,000 \times 24 \cos 30° - 36\,P$$

hence, $P = 24\,430$ lb; correct sense assumed.

(*c'*) Assume Q upward to the left at angle θ with horizontal. By (*c*)

$$\Sigma F_x = 0 = 25\,000 \sin 30° - Q \cos \theta,$$
$$\Sigma F_y = 0 = 25\,000 \cos 30° + 20\,000 - 24\,430 - Q \sin \theta$$

Solving simultaneously, $Q = 21\,300$ lb, and $\theta = 54°$. Sense and direction were correctly assumed, hence Q acts upward to the left at 54° to the horiz. GRAPHICAL SOLUTION. (*d*) *ab* and *bc* are the action lines of the given loads, *cd* of the reaction P and *da* of the reaction Q. (*e*) Draw the vectors AB and BC, and a line through C, parallel to *cd*. Choose a pole and draw the rays. (*f*) Construct the funicular polygon, drawing *oa* through M, and draw closing string *od* from K to M. Draw OD through O to intersect CD at D. Draw DA. (*g*) Vectors CD and DA represent the two unknown forces, $P = 24\,430$ lb and $Q = 21\,300$ lb. The action line of Q is *da*, making angle with horiz = 54°.

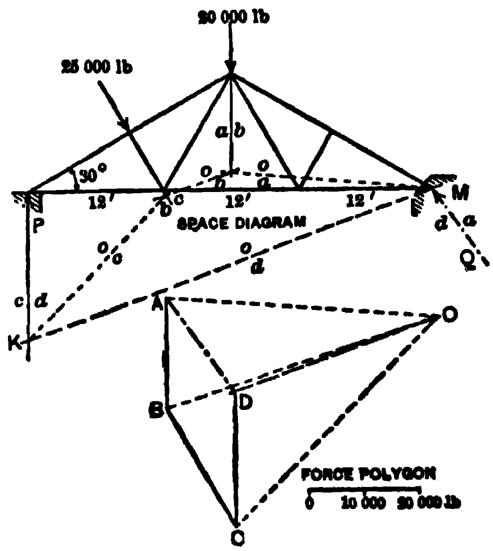

Fig 112

Typical problem IV. A SYSTEM OF COPLANAR NONCONCURRENT NONPARALLEL FORCES is in equilibrium and all except three are wholly known; the action lines of these three are known; required their magnitudes and senses. ALGEBRAIC SOLUTION. (*a*) Assume senses for the unknown forces. (*b*) To determine first unknown force, write a moment equation, center of moments at intersection of action lines of other unknown forces. (*c*) Write a pair of equilibrium equations involving the other two unknowns and solve for them. Check results by means of an additional equilibrium equation. GRAPHICAL SOLUTION. Assume any two of the unknown forces, replaced by their resultant at the point where their action lines intersect. This resultant, the third unknown force, and the known forces are in equilibrium and correspond to typical problem III. Proceed as specified in (*d*), (*e*), (*f*) and (*g*) for typical problem III, to determine the resultant and the third unknown force. (*h*) Resolve the resultant of the selected two unknown forces into components parallel to their action lines, thus determining their magnitudes and senses.

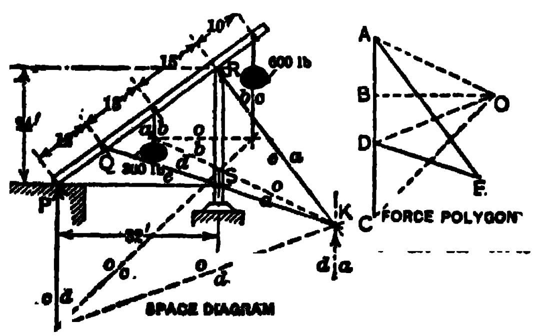

Fig 113

Example. The bar PQR (Fig 113), resting against a smooth floor at P and against a smooth post at R, is held by an inclined cord QS and carries two loads. Neglect the weight of the bar, and determine the forces acting on the bar at P and R, and the tension in the cord QS. (*a*) The external forces acting on the bar are the given loads, the reaction of the support at P (vertical on account of smooth surface), the reaction of the post at R (normal to the bar on account of smooth surface), and the pull of the cord at Q (direction is QS). (*b*) The unknown forces are the reactions P and R, and the tension Q. This is typical problem IV. ALGEBRAIC SOLUTION. (*c*) Assume P upward. By (*c*),

$$\Sigma M_K = 0 = 300 \times 35.6 + 600 \times 15.6 - P \times 55.6$$

Hence, $P = 360$ lb; correct sense assumed. Choose X and Y directions parallel and perpendicular to the bar. (*e*) Assume R upward to the left on bar, Q downward to right. By (*c*),

$$\Sigma F_x = 0 = 300 \times \frac{3}{5} + 600 \times \frac{3}{5} - 360 \times \frac{3}{5} - Q\frac{13.6}{23.5}$$

Hence $Q = 560$ lb; correct sense assumed.

$$\Sigma F_y = 0 = 300 \times \frac{4}{5} + 600 \times \frac{4}{5} + 560 \times \frac{19.2}{23.5} - 360 \times \frac{4}{5} - R$$

Hence $R = 890$ lb; correct sense assumed.

As a check, apply condition, $\Sigma M_Q = 0$: $\Sigma M_Q = 890 \times 28 - 360 \times {}^4/_5 \times 12 - 300 \times {}^4/_5 \times 13 - 600 \times {}^4/_5 \times 38 = 24\,900 - 24\,900 = 0$

GRAPHICAL SOLUTION. Assume Q and R replaced by their resultant. Its action line passes through point K. (*f*) *ab* and *bc* are the action lines of the given loads, *cd* of the reaction P, and *da* of the resultant of Q and R. (*g*), (*i*), and (*h*). Draw force and funicular polygons to determine the unknown vectors CD and DA. CD represents reaction $P = 360$ lb. (*j*) Resolve DA into components DE and EA, parallel to action lines *de* and *ea* of Q and R. (*h*) Vectors DE and EA represent the other unknown forces, $Q = 560$ lb, and $R = 890$ lb.

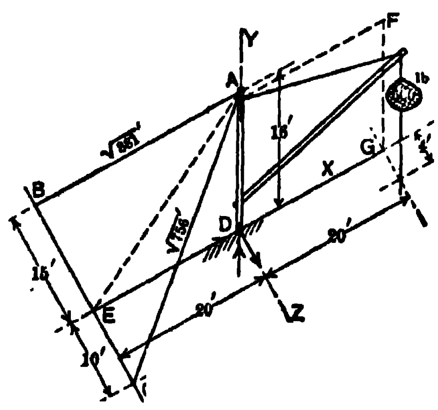

Fig 114

General noncoplanar system. Example. The crane (Fig 114), supported by a socket at the foot of the post at D, is kept from overturning by the back-stays AB and AC, and carries a load of 600 lb. (E, A, F, G, D, are in the vertical XY-plane.) Determine the axial components of the reaction on the post at D and the tensions in the back-stays. (*b*) The external forces acting on the post are the load, the reaction at D, and the tensions in the back-stays at A. The system of forces is noncoplanar, nonconcurrent, nonparallel. Moment equations are the most convenient to apply for this solution. By (*c*),

$$\Sigma M_{BC} = 0;\ D_y \quad \frac{600 \times 40}{20} \quad 1\,200 \text{ lb.}$$

$$\Sigma M_{Z_A} = 0;\ D_x \quad \frac{600 \times 20}{16} = 750 \text{ lb.}$$

$$\Sigma M_{X_A} = 0;\ D_z \quad \frac{600 \times 4}{16} = 150 \text{ lb.}$$

$$\Sigma M_{X_C} = 0 = AB \times \frac{16}{\sqrt{881}} \times 25 - 1\,200 \times 10 + 600 \times 6, \quad AB = 624 \text{ lb.}$$

$$\Sigma M_{X_B} = 0 = AC \times \frac{16}{\sqrt{756}} \times 25 + 600 \times 19 - 1\,200 \times 15; \quad AC = 454 \text{ lb.}$$

FRICTION

34. DEFINITIONS

A perfectly smooth surface is one that offers no resistance to the sliding of a body upon it. The force exerted by such a surface is normal to the surface of contact. If the surface is rough, the resultant thrust of the surface is oblique, and is called the TOTAL REACTION. The tangential component of the total reaction is called FRICTION and the normal component is called NORMAL REACTION. Friction is a passive resistance, and is developed as it is needed to prevent motion. For friction to exist there must be a tendency for a body to slip over a surface, due to the fact that the resultant of all the applied forces acting on the body (omitting total reaction of the surface) has a component parallel to the surface. If the surface is smooth, such a component causes motion of the body. If the surface is rough, it exerts a frictional force upon the body which neutralises the tendency to move. For any given conditions, there is a limit to the amount of friction, reached when slipping

impends, called LIMITING FRICTION. When the limiting friction is attained, the angle between the total reaction and the normal to the surface is the ANGLE OF FRICTION. In case there is no slipping, friction is called STATIC, and may have any magnitude from zero to the limiting friction, depending upon the tendency to move. If this tendency to move exceeds limiting friction, the body slips and KINETIC FRICTION still opposes motion; its value is less than limiting static friction.

Coefficient of friction is the ratio of the limiting friction to the corresponding normal reaction. If the angle of friction be ϕ, the normal reaction N, the limiting friction F', and the coeff of friction f, then $f = \tan\phi = F' \div N$. If a body be placed upon an inclined plane, the angle of inclination for which slipping of the body impends is the ANGLE OF REPOSE for the two rubbing surfaces. It is equal to the angle of friction.

35. FRICTION CONE

Consider a body, resting on a rough plane, to be acted upon by several forces (Fig 115). Draw the normal OP to the surface at the point where the resultant of all the applied forces, except the total reaction, cuts the surface; then draw OQ, making the angle ϕ with the normal equal to the angle of friction. The cone generated by revolving OQ about the axis OP, is the CONE OF FRICTION. The body will not slip if the resultant of all applied forces lies within this cone; it will slip if the resultant lies outside.

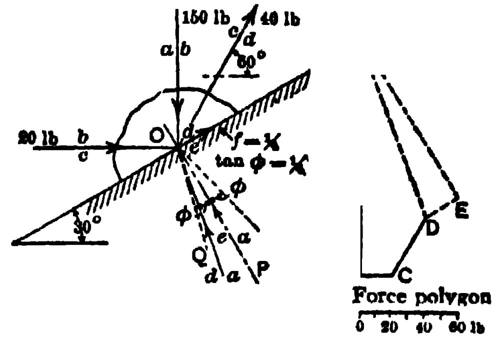

Fig 115

Assuming the data shown in Fig 115, a graphic solution is as follows: Draw a force polygon for the applied forces, $ABCD$. The resultant is AD, in magnitude and direction. Its action line ad falls inside the cone of friction, hence slipping will not occur. Total reaction of the plane is DA, opposite in sense to the resultant. Its components, parallel and normal to the surface, are DE and EA. Friction on the body is $DE = 23$ lb, upward along the surface, and the normal reaction $EA = 120$ lb, upward normal to the surface.

From the algebraic viewpoint, the normal reaction on the surface is

$$N = 150 \cos 30° + 20 \sin 30° - 40 \sin 30° = 120 \text{ lb}$$

Available or limiting friction $= fN = 120 \div 4 = 30$ lb. Sum of the force components parallel to the plane $= 150 \sin 30° - 20 \cos 30° - 40 \cos 30° = 23$ lb downward. If needed, the surface can supply 30 lb of friction; it actually does supply 23 lb, acting upwards on the body to preserve equilibrium.

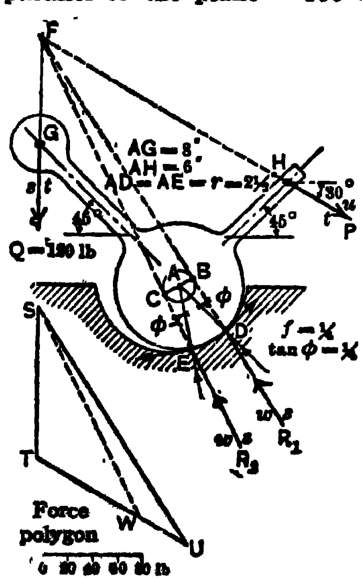

Fig 116

36. FRICTION CIRCLE

The reaction of a bearing on a journal is usually assumed to pass through the center of the journal. If the bearing is worn (as shown much exaggerated in Fig 116, for the journal A), the action line of the reaction still passes through center A if the surfaces are smooth. Otherwise, when slipping impends, the action line makes the friction angle ϕ with the normal AD to the contact surfaces on the line of contact between the journal and the bearing. If motion impends for clockwise rotation of the journal, DB is the action line; if for counterclockwise rotation, it is EC. If r be the journal radius, the perpendicular to the action lines from the journal center is AB or $AC = r \sin\phi$. For a given journal and bearing, this value is constant and may be represented by the radius of a circle with center at A. This is the FRICTION CIRCLE, and the bearing reaction is always tangent to it if slipping impends. For practical conditions, angle ϕ is so small that $r \tan\phi = r \sin\phi$ (approx). Radius of the friction circle may be taken as $r \times f$, nearly.

In a given problem, it is often impossible to observe D, the line of contact between

journal and bearing, but the action line of the bearing reaction must be tangent to the friction circle. Other known conditions may fix another point in this action line so that its position is readily found.

In Fig 116, with data as given, find what force P is needed to overcome Q (motion impending for clockwise rotation). The journal is under the action of 3 forces, P, Q, and R, concurrent at F. As R must be tangent to the friction circle, its action line is either FD or FE. The correct position is determined by resolving R into tangential and normal components, and making the choice so that friction opposes impending motion. The force polygon for the 3 forces is STU; then $R_1 = US = 226$ lb, and $P = TU = 142$ lb.

The greatest force P which Q can overcome (motion impending for counterclockwise rotation), is found from the triangle STW, corresponding to R_2; then $R_2 = WS = 188$ lb, and $P = TW = 96$ lb.

37. COEFFICIENTS OF FRICTION

Coefficients of static friction depend upon character of the surfaces, kind of material and lubricant used. Recent experiments prove that the coeff of static friction is not independent of the mormal pressure on the contact surfaces, nor of the time of contact between the surfaces.

Coefficients of Static Friction (Compiled from Rankine)

Dry masonry and brickwork.	0.6 to 0.7	Masonry on moist clay	0.33
Masonry and brickwork with damp mortar.......... .	0.74	Earth on earth	0.25 to 1.00
Timber on stone.......about	0.4	" " " dry sand, clay, and mixed earth..........	0.38 to 0.75
Iron on stone	0.3 to 0.7	Earth on earth, damp clay..	1.00
Timber on timber..........	0.2 to 0.5	" " " wet clay.....	0.31
" " metals	0.2 to 0.6	" " " shingle and gravel	0.81 to 1.11
Metals on metals	0.15 to 0.25		
Masonry on dry clay	0.51		

Coefficients of kinetic friction depend upon the velocity of the body in motion, and particularly upon the kind of lubricant. If a lubricant is used it has a greater influence upon the coeff of friction than has the kind of material in the bodies.

Coefficients of Kinetic Friction (Rough averages, compiled from Rankine)

Wood on wood, dry........	0.25 to 0.5	Leather on metals, greasy...	0.23
" " " soaped.....	0.20 to 0.04	" " " oily.....	0.15
Metals on oak, dry.........	0.50 to 0.60	Metals on metals, dry......	0.15 to 0.20
" " " wet.........	0.24 to 0.26	" " " wet......	0.30
" " " soaped......	0.20	Smooth surfaces, occasionally greased	0.07 to 0.08

Leather on oak............	0.27 to 0.38		
" " metals, dry.. ..	0.56		
" " " wet.....	0.36		

38. BELT OR COIL FRICTION

If a band is placed about a rough cylinder and a tensile force applied to each end, these forces may be very unequal without causing slipping of the band upon the cylinder, and are unequal even if slipping occurs. The band may be a belt, rope, or brake band, while the cylinder may be a pulley or sheave, post, capstan, or similar device.

Let T_1 be the larger of the forces acting upon the band, T_2 the smaller one, corresponding to the tensions in the tight and loose sides of a belt; and W the friction between band and cylinder. Then, $W = T_1 - T_2$. Let the arc covered by the band subtend an angle α at the center of the cylinder, α radians $= (\alpha \text{ degrees} \times \pi) \div 180$; e $(=2.718)$ is the base of the Naperian system of logarithms, and f the coeff of friction, care being taken to select a suitable value for either static or kinetic friction, depending on whether or not slipping occurs. Then, $T_1 = T_2 e^{f\alpha} = T_2\, 10^{\frac{\pi}{180}(0.4343) f\alpha^\circ}$. The first α is expressed in radians, the last α in degrees. For belting, the coeff of friction is often taken as 0.30.

Values of $e^{f\alpha}$ (slipping impending)

Angle of contact in decimal parts of circum = α radians ÷ 2π	Values of f (coeff of friction)								
	0.10	0.15	0.20	0.25	0.30	0.35	0.40	0.45	0.50

CENTERS OF GRAVITY

39. CENTROIDS AND CENTERS OF GRAVITY

Centroid of a system of parallel forces with fixed application points is the point through which their resultant always passes, no matter how the forces may be turned (but still remaining parallel). The force of gravitation acting on the particles of a body constitutes a system of forces practically parallel; and the centroid of these forces is the CENTER OF GRAVITY of the body. Referring the application points of such a force system to a set of coordinate axes, the coordinates of the centroid, or center of gravity, are given by:

$$\bar{x} = (\Sigma F\cdot x) \div \Sigma F,\ \bar{y} = (\Sigma F\cdot y) \div \Sigma F,\ \bar{z} = (\Sigma F\cdot z) \div \Sigma F$$

In these equations F represents one force (or the weight of one particle), and x the distance of its application point from the YZ-plane.

If the body is composed of parts of known weight, and the positions of their centers of gravity are known, the coordinates of the center of gravity of the whole body are:

$$\bar{x} = \frac{w_1\bar{x}_1 + w_2\bar{x}_2 + w_3\bar{x}_3 + \cdots}{w_1 + w_2 + w_3 + \cdots}$$
$$\bar{y} = \frac{w_1\bar{y}_1 + w_2\bar{y}_2 + w_3\bar{y}_3 + \cdots}{w_1 + w_2 + w_3 + \cdots} \qquad (A)$$
$$\bar{z} = \frac{w_1\bar{z}_1 + w_2\bar{z}_2 + w_3\bar{z}_3 + \cdots}{w_1 + w_2 + w_3 + \cdots}$$

in which w_1 represents the weight of one part and $\bar{x}_1$, $\bar{y}_1$, $\bar{z}_1$ are the coordinates of its center of gravity. Any one of the above expressions may be read as, "the sum of the moments divided by the sum of the forces." If in formulas (A) the weights are replaced by volumes, areas, surfaces, or lengths of lines, they determine the coordinates of the centroids, or centers of gravity, of the volumes, areas, surfaces, or lines. These centroids are often called the centers of gravity of the corresponding magnitudes.

Center of gravity of part of a body remaining after certain parts have been taken away is determined by the rule: The moment of the remainder of a body, with respect to any plane, equals the moment of the whole body minus the moments of the parts taken away.

40. FORMULAS

Centroids of lines and areas. CIRCULAR ARC (Fig 117). Centroid is on the axis of symmetry; its distance from the center is $\bar{x} = \frac{r \times c}{s} = \frac{r \sin \alpha}{\alpha}$, α being in radians. For a semicircle, $\bar{x} = 2\,r \div \pi$; for a quadrant, $\bar{x} = 2\,r\sqrt{2} \div \pi$. TRIANGLE. Centroid of a

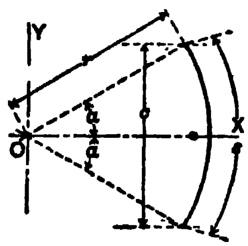

Fig 117

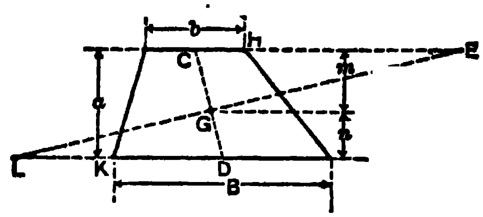

Fig 118

triangle is at the intersection of the medians; its perpendicular distance from any side equals one-third the altitude measured from that side. TRAPEZOID (Fig 118). Centroid lies on the median CD (joining the middle of the parallel sides), at a point G located by following equations:

$$m = \frac{a\,(2\,B + b)}{3\,(B + b)}\;;\; n = \frac{a\,(B + 2\,b)}{3\,(B + b)}$$

To locate the centroid graphically, make $HE = B$, $KL = b$. Draw LE, and the median CD; they intersect at G, the centroid. QUADRILATERAL (Fig 119). Divide each side of the quadrilateral $ABCD$ into thirds, and through the third points draw ef, hk, lm, and no. These lines form a parallelogram, the diagonals of which intersect at G, the centroid of the quadrilateral. SECTOR OF A CIRCLE (Fig 120). Centroid is on the axis of symmetry; its distance from the center is $\bar{x} = (2\,rc) \div (3\,s)$. For a semicircle, $\bar{x} = 4\,r \div 3\,\pi$. For a quadrant $\bar{x} = 4\,r\,\sqrt{2} \div 3\,\pi$; and the distance from each bounding radius $= 4\,r \div 3\,\pi$. SEGMENT OF A CIRCLE (Fig 121). Centroid is on the axis of symmetry; its distance from the center is $\bar{x} = (c^3 \div 12\,A)$, in which A is the area of the segment $= \frac{r^2}{2}(2\,\alpha - \sin 2\,\alpha)$, α being in radians.

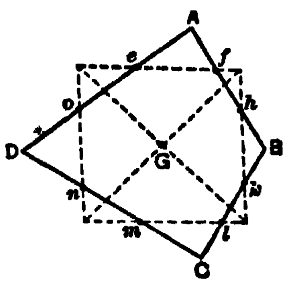

Fig 119

Centers of gravity of volumes. RIGHT CIRCULAR CYLINDER (Fig 122). Base is normal to the axis; top makes an angle α with base; mean height is h; radius of base $= r$. If

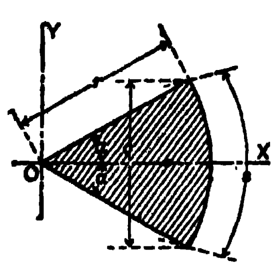

Fig 120

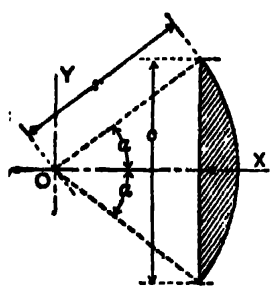

Fig 121

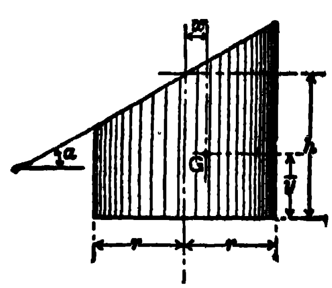

Fig 122

$\bar{y}$ is the distance of the center of gravity G from the base, and $\bar{x}$ is the distance to the right of the vertical center line,

$$\bar{x} = \frac{r^2 \tan \alpha}{4\,h}, \text{ and } \bar{y} = \frac{h}{2} + \frac{r^2 \tan^2 \alpha}{8\,h}$$

FRUSTUM OF A CIRCULAR CONE. Let R = radius of the larger base and r radius of the smaller base; a = the altitude. Distance of the centroid of the curved surface from large base is $\frac{a\,(R + 2r)}{3\,(R + r)}$ and from the smaller base $\frac{a\,(2\,R + r)}{3\,(R + r)}$. Distance from the center of gravity of the solid frustum to larger base is $\frac{a\,(R^2 + 2\,Rr + 3\,r^2)}{4\,(R^2 + Rr + r^2)}$. CONE AND PYRAMID.

Centroid of the surface (base excluded) is on a line joining the apex with the centroid of the perimeter of the base, at a distance of two-thirds its length from the apex. Center of gravity of the solid cone or pyramid is on the line joining the apex with the centroid of the base, at a distance of three-fourths its length from the apex. FRUSTUM OF A PYRAMID. If the frustum has regular bases, let R and r be lengths of the sides of the larger and smaller bases, and h the altitude. Distance of the centroid of the surface (bases excluded) from the larger base is $\dfrac{h\,(R + 2\,r)}{3\,(R + r)}$. For any bases, let A and a be the areas of large and small bases and h the altitude; the distance of center of gravity from the larger base is $\dfrac{h\,(A + 2\sqrt{Aa} + 3\,a)}{4\,(A + \sqrt{Aa} + a)}$. SPHERE. Centroid of the surface of any zone of a sphere is midway between the bases. Distance of the center of gravity of a solid segment from the base is $\dfrac{h\,(4\,r - h)}{4\,(3\,r - h)}$, where r = radius of the sphere, and h = height of the segment. For a hemisphere this distance is $3\,r \div 8$. Distance of center of gravity of a solid sector from center of the sphere $= {}^3/_8\,(1 + \cos\alpha)\,r = {}^3/_8\,(2\,r - h)$, where α = half the angle subtended by the sector. ELLIPSOID. Choose 3 coordinate axes x, y, and z; let a, b, and c denote the semi-lengths of the corresponding axes of the ellipsoid; the coordinates of the center of gravity of one octant of the solid are $\bar{x} = 3\,a \div 8$, $\bar{y} = 3\,b \div 8$, and $\bar{z} = 3\,c \div 8$.

MOMENTS OF INERTIA OF AREAS AND MASSES

41. AREAS

Moment of inertia of a plane area with respect to a given line is the sum of the products obtained by multiplying each element of area by the square of its distance from the line. The moment is called polar if the axis is perpendicular to the plane area. The common symbol for moment of inertia is I; and a subscript denotes the axis to which it refers. Let I = the moment of inertia about any axis; A the area of the figure and r the distance of any element of area from the given axis, then $I = \int r^2\,dA$. RADIUS OF GYRATION k, of any plane figure, is the square root of the moment of inertia divided by the area of the figure, thus $k = \sqrt{\dfrac{I}{A}}$, or $I = Ak^2$. PARALLEL AXIS THEOREM. $I = \bar{I} + Ad^2$, in which $\bar{I}$ is the moment of inertia with respect to an axis through the centroid and I is moment of inertia about a parallel axis at distance d.

Product of inertia J, of an area with respect to a pair of rectangular axes, is the sum of the products obtained by multiplying each element of area by its coordinates. Thus $J_{xy} = \int xy\,dA$. Product of inertia may be positive, negative, or zero, depending on the distribution of the area with respect to the axes. Moment of inertia is always positive and never zero. PARALLEL AXIS THEOREM. $J = \bar{J} + A\bar{x}\bar{y}$, in which $\bar{J}$ is product of inertia of area A with respect to a pair of centroidal axes, J is the product of inertia with respect to a set of parallel axes, and $\bar{x}$ and $\bar{y}$ are the distances from the parallel axes to the centroid of the area. For a rectangle, $J_{xy} = A^2 \div 4$; for a triangle, $J_{xy} = A^2 \div 8$ (Fig 123). J is zero for an axis of symmetry and any line perpendicular to that axis. The customary unit for both moment and product of inertia is biquadratic, inches = in^4.

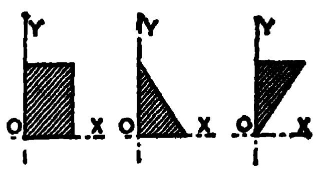

Fig 123

The principal axes of inertia at a point are those about which the moments of inertia are the greatest and the least; these axes will always be rectangular and the product of inertia for them is zero.

42. OBLIQUE AXES AND LEAST RADIUS OF GYRATION

Oblique axes. Let I_x, I_y, and J_{xy} represent moments and products of inertia for a pair of rectangular axes at a point of an area, I_u the moment of inertia for any oblique axis through that point and α its angle with the X axis; then, $I_u = I_x \cos^2\alpha + I_y \sin^2\alpha - J_{xy} \sin 2\,\alpha$. For principal axes, $\tan 2\,\alpha = 2\,J_{xy} \div (I_y - I_x)$.

The equation for I_u is interpreted by the inertia circle as follows: Suppose I_x, I_y, and J_{xy} given for the shaded area in Fig 124. To convenient scale, plot OX' and OY' to represent I_x and I_y, and $Y'A$ to represent J_{xy} (downward if negative and upward if positive). Center C is midway between X' and Y'. With CA as radius, describe inertia circle. To find I_u, draw chord AB parallel to axis OU; draw perpendicular BU'. OU' (to scale) $= I_u$, and BU' (to scale) $= J_{uv}$. OM, parallel to A 2, is axis of least I; and a parallel to A 1, through O, is axis of greatest I. O 2 (to scale) is the value of least $I = I_2$; and O 1, value of greatest $I = I_1$. Least radius of gyration is measured perpendicular to axis OM and $= \sqrt{I_2 \div \text{area}}$. If principal moments of inertia (greatest and least) at a point are equal, ($I_1 = I_2$), then I for any oblique axis through the point has same value; that is, $I_u = I_1 = I_2$.

Circular Segment	A = Area of segment $= r^2(\alpha - \sin\alpha\cdot\cos\alpha)$, α being expressed in radians $I_g = \frac{Ar^2}{4}\left(1 - \frac{2}{3}\,\frac{\sin^3\alpha\cdot\cos\alpha}{\alpha - \sin\alpha\cdot\cos\alpha}\right)$ $I_a = \frac{Ar^2}{4}\left(1 + \frac{2\sin^3\alpha\cdot\cos\alpha}{\alpha - \sin\alpha\cdot\cos\alpha}\right)$
 Fig 137. Ellipse	$I_d = \frac{\pi}{4}ab^3$ $\quad I_c = \frac{\pi}{4}ba^3$ $k_d = \frac{b}{2}$ $\quad k_c = \frac{a}{2}$

44. MASSES

Moment of inertia of a mass, with respect to an axis, is the algebraic sum of the products of each element of mass and the square of its distance from the axis. $I = \Sigma mr^2$, in which m is any element of mass and r its distance from the axis. The common engineer's unit is slug-ft^2 (Art 53).

Radius of gyration is the distance from the axis to a point at which, if the entire mass were concentrated, the moment of inertia would not be changed. If k is the radius of gyration, and M the total mass, then $I = Mk^2$; or $k = \sqrt{I \div M}$, and is measured in ft. Value of k is always between the least and greatest values of r.

Parallel axis theorem. Let $\bar{I}$ be the moment of inertia with respect to an axis through the center of gravity, and I the moment of inertia for any parallel axis at a distance d; then $I = \bar{I} + Md^2$, and $k^2 = \bar{k}^2 + d^2$.

Principal axes and moments of inertia. The integrals $\int yz\,dm$, $\int zx\,dm$, and $\int xy\,dm$ are called products of inertia. For an oblique axis, through the origin with direction angles, α, β, and γ,

$$I = I_x\cos^2\alpha + I_y\cos^2\beta + I_z\cos^2\gamma - 2J_{xy}\cos\alpha\cos\beta - 2J_{yz}\cos\beta\cos\gamma - 2I_{zx}\cos\gamma\cos\alpha.$$

At each origin, there is one set of rectangular axes for which the three products of inertia vanish, and with respect to two of which the moments of inertia are least and greatest of all moments of inertia with respect to axes at that origin. The axes are called principal axes, and the moments of inertia with respect to them are called principal moments of inertia. If a body has three planes of symmetry, at right angles to each other, their lines of intersection are principal axes at the point of intersection. If a body has two planes of symmetry, their intersection is a principal axis for every point on it as origin, and the other two axes are in the planes of symmetry. If a body has one plane of symmetry, any perpendicular to the plane is a principal axis at the point where the axis pierces the plane. At the origin, the x-axis is a principal axis if $J_{xy} = 0$ and $J_{zx} = 0$; the y-axis is a principal axis if $J_{xy} = 0$ and $J_y = 0$; and the z-axis is a principal axis if $J_{zx} = 0$ and $J_{yz} = 0$.

45. FORMULAS FOR MASSES

Thin circular lamina, of radius a and mass m, with respect to a diameter, $I = ma^2 \div 4$. For axis perpendicular to face of lamina at its center, $I = ma^2 \div 2$.

Solid of revolution of volume V and mass M, with respect to its axis,

$$I = \left[\pi M\int y^4\,dx\right] \div 2V$$

With respect to an axis at right angles to its geometrical axis,

$$I = \left[\pi M\int\left(\frac{y^4}{4} + x^2y^2\right)dx\right] \div V$$

Thin straight rod of length l and mass M. Axis perpendicular to rod at center, $I = Ml^2 \div 12$; at end, $I = Ml^2 \div 3$. Axis inclined to rod at angle α: at center, $I = Ml^2 \sin^2 \alpha \div 12$; at end, $I = Ml^2 \sin^2 \alpha \div 3$.

Rectangular prism of dimensions a, b, c. Axis through center of gravity, parallel to edge c, $I = M\ (a^2 + b^2) \div 12$. Axis through center of base bc and parallel to edge c, $I = M\ (4\ a^2 + b^2) \div 12$.

Right circular cylinder of length h and base radius a; for its geometrical axis, $I = Ma^2 \div 2$. Axis through center of gravity, parallel to base, $I = M\ (3\ a^2 + h^2) \div 12$. Axis coinciding with diameter of base, $I = M\ (3\ a^2 + 4\ h^2) \div 12$.

Hollow cylinder, of height h and radii R and r, about axis of cylinder, $I = M\ (R^2 + r^2) \div 2$. Axis through center of gravity, perpendicular to axis of cylinder, $I = M\ (3\ R^2 + 3\ r^2 + h^2) \div 12$.

Elliptical cylinder, length h and semi-axes a and b; for its geometrical axis, $I = M\ (a^2 + b^2) \div 4$. Axis through center of gravity, parallel to minor axis $2\ b$, of elliptical section, $I = M\ (3\ a^2 + h^2) \div 12$.

Sphere of radius a, about a diameter, $I = 2\ Ma^2 \div 5$.

Right circular cone, of height h and base radius a. About its axis, $I = 3\ Ma^2 \div 10$. Axis through vertex, perpendicular to geometrical axis, $I = 3\ M\ (a^2 + 4\ h^2) \div 20$.

Ellipsoid of axes $2\ a$, $2\ b$, and $2\ c$. About the axis $2\ b$, $I = M\ (a^2 + c^2) \div 5$.

Right rectangular pyramid, of height h and sides of base a and b, about geometrical axis, $I = M\ (a^2 + b^2) \div 20$. Axis through vertex perpendicular to geometrical axis and parallel to b side of base, $I = M\ (a^2 + 12\ h^2) \div 20$. Axis through center of gravity, parallel to b edge of base, $I = M\ (4\ a^2 + 3\ h^2) \div 80$.

Circular ring of circular section, radius of section $= r$, and center of section at distance R from axis of ring. About axis of ring, $I = M\ (4\ R^2 + 3\ r^2) \div 4$. About axis through center of gravity, perpendicular to axis of ring, $I = M\ (4\ R^2 + 5\ r^2) \div 8$.

KINEMATICS

46. RECTILINEAR MOTION

A particle is in motion with respect to surrounding objects if its position with respect to them is continually changing. If A is the position of a particle at a time t_1, and B its position at a later time t_2, its displacement in the time interval $t_2 - t_1 = \Delta t$ is the vector AB, no matter whether path is straight or curved. Velocity of a particle is its time rate of displacement. Acceleration of a particle is its time rate of change of velocity.

Rectilinear motion of a particle. Let s be distance measured along the path of a particle, s_1 the distance from origin at time t_1, s_2 the distance at a later time t_2, $\Delta s = s_2 - s_1$ = displacement in time interval $\Delta t = t_2 - t_1$. Then AVERAGE VELOCITY $= \Delta s \div \Delta t$. If the position changes at a uniform rate, actual velocity at any time $= \Delta s \div \Delta t$. For every case, INSTANTANEOUS VELOCITY $= v = \dfrac{ds}{dt} = \underset{\Delta t \doteq 0}{\text{limit}} \left(\dfrac{\Delta s}{\Delta t}\right)$. UNIT OF VELOCITY is any distance unit divided by any time unit. SPEED is the name for magnitude of velocity, and does not refer to its sense or linear direction. If s is not known in terms of t, but displacements for several time intervals, beginning or ending at the instant in question, are known, an approx value of v can be obtained from a consideration of average speeds.

For example, determine the speed at time $t = 2$ sec, having given the accompanying 4 sets of observed values for Δs and Δt. Column 3 is computed from the first two. As $\Delta t \doteq 0$, the value of aver velocity in last column appears to approach a limit of 3.6 ft per sec. A value of this limit may be determined graphically by platting time intervals along the horiz (Fig 138), and corresponding values of aver velocity vertically. The curve $ABCD$, "faired" to meet the ordinate through O at E (zero time interval), determines $v = OE = 3.6$ ft per sec.

$s_2 - s_1 = \Delta s$, feet	Δt, seconds	$\Delta s \div \Delta t$, ft per sec
28.8 − 3.73 = 25.07	2 to 6 = 4	6.27
20.83 − 3.73 = 17.10	2 to 5 = 3	5.70
13.87 − 3.73 = 10.14	2 to 4 = 2	5.07
8.1 − 3.73 = 4.37	2 to 3 = 1	4.37

Let v_1 = veloc at time t_1, v_2 = veloc at a later time t_2, $\Delta v = v_2 - v_1$, change in veloc in time interval Δt; then AVER ACCELERATION $= \Delta v \div \Delta t$. If veloc changes at a uniform rate, the actual acceleration at any time is $\Delta v \div \Delta t$. For every case, INSTANTANEOUS ACCELERATION $= a = \dfrac{dv}{dt} = \dfrac{d^2s}{dt^2} = \underset{\Delta t \doteq 0}{\text{limit}} \left(\dfrac{\Delta v}{\Delta t}\right)$. UNIT OF ACCELERATION is any veloc unit

divided by any time unit. The unit used herein is feet per second per second, or ft per sec². If s or v are not known in terms of t, but the displacements or veloc records are available, an approx value for a can be obtained from a consideration of average accelerations. If the displacement record only is available, values of v must first be obtained as in the accompanying table.

t, sec	v, ft per sec	Δt, sec	Δv, ft per sec	$\Delta v \div \Delta t$, ft per sec²
2	3.6	2 to 6 = 4	4.8	1.2
3	5.1	2 to 5 = 3	3.9	1.3
4	6.4	2 to 4 = 2	2.8	1.4
5	7.5	2 to 3 = 1	1.5	1.5
6	8.4			

For example, determine the acceleration at time $t = 2$ sec, having given the five sets of values for t and v as shown in first two columns of table. Columns 3 and 4 are computed from the first two. Values in last column are computed from third and fourth. As $\Delta t \doteq 0$, the value of aver acceleration appears to approach 1.6 ft per sec² as a limit. A value of this limit may be determined graphically by platting time intervals along the horizontal (Fig 139), and corresponding values of aver acceleration vertically. The curve $ABCD$, "faired" to meet the ordinate through O at E (zero time interval), determines $a = OE = 1.6$ ft per sec².

If s is given in terms of t, v and a are determined by differentiation as indicated above. If a is given in terms of t, v and s are determined by integration. The formulas are

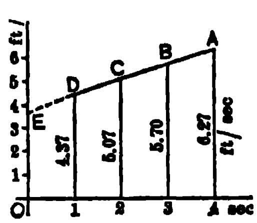

Fig 138

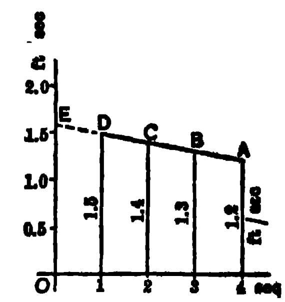

Fig 139

$$\int_{v_1}^{v_2} dv = \int_{t_1}^{t_2} a\,dt;\quad \int_{s_1}^{s_2} ds = \int_{t_1}^{t_2} v\,dt;\quad \int_{v_1}^{v_2} v\,dv = \int_{s_1}^{s_2} a\,ds;\quad \int_{t_1}^{t_2} dt = \int_{v_1}^{v_2} \frac{1}{a}\,dv = \int_{s_1}^{s_2} \frac{1}{v}\,ds$$

in which s_1, v_1, t_1, are simultaneous values. For uniform acceleration, a = constant, $v = at + v_o$, $s = {}^1/_2\,at^2 + v_o t + s_o$, v_o being initial velocity and s_o initial distance. For bodies falling from rest in vacuum, $v_o = 0$, $s_o = 0$, and $a = g$ = about 32.2 ft per sec², $s = {}^1/_2\,gt^2$, $v = gt = \sqrt{2gs}$.

47. MOTION GRAPHS

Motion graphs. DISTANCE-TIME (s-t) GRAPH (Fig 140). Any ordinate represents value of s at corresponding time. Slope of tangent represents speed $= \dfrac{ds}{dt}\cdot$ CB must be read to distance scale and AB to time scale; then speed $v = CB \div AB$. SPEED-TIME (v-t) GRAPH (Fig 141). Any ordinate represents value of v at corresponding time. Slope of tangent represents $a = \dfrac{dv}{dt}\cdot$ FE is read to speed scale and DE to time scale; then $a = FE \div DE$. Area between curve and time axis, limited by any two ordinates, represents

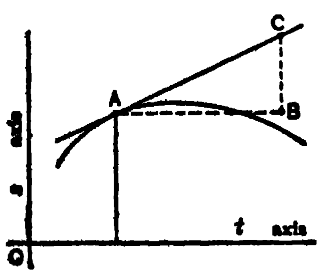

Fig 140

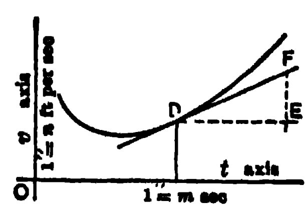

Fig 141

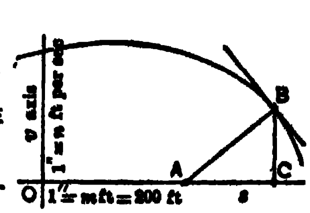

Fig 142

displacement in corresponding time interval. Δs = sq in of area × product of scale numbers = area × m × n. If area is below time axis it is considered minus. ACCELERATION-TIME (a-t) GRAPH. Any ordinate represents value of a at corresponding time. Area between curve and time axis, limited by any two ordinates, represents change in speed in corresponding time interval, Δv = sq in of area × product of scale numbers. SPEED-DISTANCE (v-s) GRAPH (Fig 142), for rectilinear or curved path. The subnormal at any point B (line AC) represents tangential component of acceleration at corresponding instant.

If m = distance scale number and n = speed scale number, then $a = AC$ (in) $\times m^2 \div n$. (In Fig 142, $m = 200$, $n = 30$.)

Simple harmonic motion. If a point P moves in a circular path of radius r at uniform speed, its projection on any diameter has simple harmonic motion. Radius r is called AMPLITUDE. PERIOD is time required for the projection to go from one end of diameter to other and back. FREQUENCY is number of periods per unit time.

When $t = 0$, let P be at P_0 (Fig 143). ϵ is called the load angle (lag, if negative). For simple harmonic motion (S H M) of V in the vertical diam, $y = r \sin (\theta + \epsilon) = r \sin (\omega t + \epsilon)$, in which $\omega = \dfrac{d\theta}{dt}$ = radians per unit time.

$$v_y = r\omega \cos (\theta + \epsilon) = r\omega \cos (\omega t + \epsilon) = \omega x$$
$$a_y = -r\omega^2 \sin (\theta + \epsilon) = -r\omega^2 \sin (\omega t + \epsilon) = -\omega^2 y$$

For S H M of H in horiz diam:

$x = r \cos (\theta + \epsilon) = r \cos (\omega t + \epsilon)$; $v_x = -r\omega \sin (\theta + \epsilon) = -r\omega \sin (\omega t + \epsilon) = -\omega y$; $a_x = -r\omega^2 \cos (\theta + \epsilon) = -r\omega^2 \cos (\omega t + \epsilon) = -\omega^2 x$

Crank and connecting-rod mechanism. Problem is to find expressions for the velocity and acceleration of any point in the crosshead, as A in Fig 144. Let $c = r \div l$, n = rev

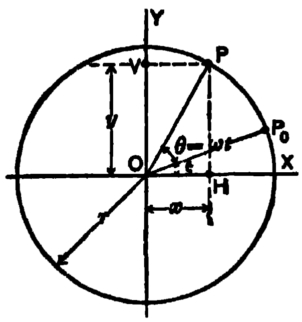

Fig 143

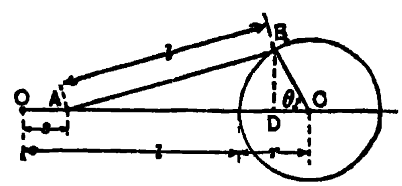

Fig 144

per sec (assumed constant), ω = radians of angle described by crank per second, and s = distance of A from its extreme left position, all distances expressed in ft. Then,

$$s = (l + r) - l\,(1 - c^2 \sin^2 \theta)^{1/2} - r \cos \theta$$

$$v = r\omega \left(\sin \theta + \frac{c \sin 2\theta}{2\,(1 - c^2 \sin^2 \theta)^{1/2}} \right); \quad a = r\omega^2 \left(\cos \theta + \frac{c \cos 2\theta + c^3 \sin^4 \theta}{(1 - c^2 \sin^2 \theta)^{3/2}} \right)$$

The above formulas are exact; close approximations are:

$s = r\,(1 - \cos \theta) + {}^1/_4\, cr\,(1 - \cos 2\theta)$; $\quad v = r\omega\,(\sin \theta + {}^1/_2\, c \sin 2\theta)$; $a = r\omega^2 \cos \theta + c \cos 2\theta)$

Exact and approximate formulas for a give same values for extreme right and left positions of point A.

48. CURVILINEAR MOTION

Curvilinear motion of a particle. The definitions of displacement and velocity, given at the beginning of article 47, apply to curvilinear motion. Velocity is a vector quantity. If s is distance measured along the curved path, the magnitude of velocity (speed) at an instant $= \dfrac{ds}{dt}$; the linear direction of the velocity is tangent to the path at the instantaneous position of the particle; and the sense of velocity corresponds to the direction of motion of the particle at the instant.

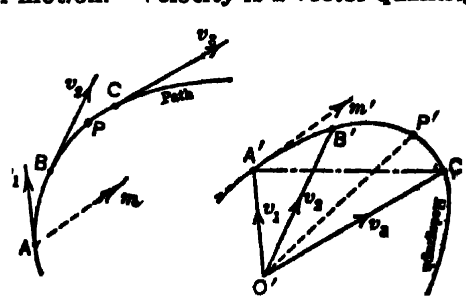

Fig 145

Acceleration for curvilinear motion is time rate of change of velocity and is a vector quantity. The velocity vector changes in magnitude and direction. In Fig 145, let A, B, C represent positions of particle P in its curved path, s, distance along the path, and v_1, v_2, v_3, velocity vectors at A, B, C. Plat velocity vectors $O'A'$, $O'B'$, $O'C'$, etc, from any origin O' to represent the velocities at A, B, C, etc. The curve $A'B'C'$, drawn through the ends of the vectors, is called a hodograph for the motion. For every position of P in

its path, there is a corresponding position P' in the hodograph; and P' describes distance s' on hodograph, while P describes distance s on path. Vector $O'P'$ represents the velocity of P. In time Δt, P moves from A to C, its velocity changes from $O'A'$ to $O'C'$, and the velocity change is $A'C'$. AVERAGE ACCELERATION for interval Δt = vector $A'C' \div \Delta t$, and it has the direction of the chord $A'C'$. INSTANTANEOUS ACCELERATION of P at $A = a$ = limit of aver acceleration as Δt approaches zero.

$$a = \lim_{\Delta t \doteq 0} \left(\frac{\text{vector } A'C'}{\Delta t}\right) = \lim_{\Delta t = 0} \left(\frac{\text{arc } A'B'C'}{\Delta t}\right) = \frac{ds'}{dt} = \text{speed of } P'$$

on hodograph. The direction of a is along the tangent $A'm'$, and as P' is moving clockwise, the sense is as indicated by arrow at m'. Hence acceleration at A is Am, parallel to $A'M'$ and $= \dfrac{ds'}{dt}$. Unit is any velocity unit divided by any time unit.

Motion graphs. Speed may be computed from a distance-time graph in the same way as for rectilinear motion. Tangential component (see Art 49) of acceleration may be computed from the speed-time graph; and the distance Δs may be obtained from the area under the curve.

49. COMPONENTS OF VELOCITY AND ACCELERATION

Components of velocity and acceleration of a particle for any curved path (not a plane curve). The position of the particle P, being defined by its coordinates x, y, z, the axial components of velocity are $v_x = \dfrac{dx}{dt}$, $v_y = \dfrac{dy}{dt}$, $v_z = \dfrac{dz}{dt}$. Resultant velocity $v = \sqrt{v_x^2 + v_y^2 + v_z^2}$, and its direction cosines are $\cos\theta_x = \dfrac{v_x}{v}$, $\cos\theta_y = \dfrac{v_y}{v}$, $\cos\theta_z = \dfrac{v_z}{v}$. Axial components of acceleration are:

$$a_x = \frac{dv_x}{dt} = \frac{d^2x}{dt^2}; \qquad a_y = \frac{dv_y}{dt} = \frac{d^2y}{dt^2}; \qquad a_z = \frac{dv_z}{dt} = \frac{d^2z}{dt^2}.$$

Resultant acceleration $a = \sqrt{a_x^2 + a_y^2 + a_z^2}$; and its direction cosines are:

$$\cos\phi_x = \frac{a_x}{a}; \qquad \cos\phi_y = \frac{a_y}{a}; \qquad \cos\phi_z = \frac{a_z}{a}$$

If the path is a plane curve, $v_z = 0$, $a_z = 0$. The tangential and normal components of acceleration are $a_t = \dfrac{dv}{dt} = \dfrac{d^2s}{dt^2}$, and $a_n = \dfrac{v^2}{\rho}$, ρ being the radius of curvature. Resultant acceleration is $a = \sqrt{a_t^2 + a_n^2} =$

50. TRANSLATION

Translation of a rigid body is a motion such that each straight line in it remains fixed in direction. The paths of all particles of the body are exactly alike, straight or curved (not necessarily plane curves); the velocities of all particles at an instant are the same, and their accelerations at an instant are the same. For these reasons, it is customary to use the expressions, "velocity of the body" and "acceleration of the body."

51. ROTATION

Rotation of a rigid body is a motion such that one line of the body, or of its extension, remains fixed. The fixed line is the axis. The plane through the mass center perpendicular to the axis is the plane of rotation. The paths of all particles are circles with centers on the axis. Since all lines of the body parallel to plane of rotation sweep through equal angles in equal times, it is customary to describe rotation by the behavior of one radial line. In Fig 146 let θ be the angle from the x-axis to the radial line OP. $\Delta\theta = \theta_2 - \theta_1$ is the ANGULAR DISPLACEMENT of the body in the time $\Delta t = t_2 - t_1$, and is expressed in any angular unit. ANGULAR VELOCITY is the time rate of angular displacement. Average angular velocity $= \dfrac{\theta_2 - \theta_1}{t_2 - t_1} = \dfrac{\Delta\theta}{\Delta t}$. The limit of this average, as Δt approaches zero, is the instantaneous angular velocity. The symbol for angular velocity is ω, and $\omega = \lim_{\Delta t \doteq 0}\left(\dfrac{\Delta\theta}{\Delta t}\right) = \dfrac{d\theta}{dt}$. The unit is any angular unit divided by any time unit, such as

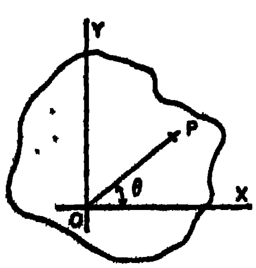

Fig 146

radians per sec, radians per min, rev per sec, or rev per min. The sign depends on the numerator of the fraction, or the way in which θ is changing. ANGULAR ACCELERATION is the time rate of angular velocity. Average angular acceleration $= \frac{\omega_2 - \omega_1}{t_2 - t_1} = \frac{\Delta\omega}{\Delta t}$. The limit of this average, as Δt approaches zero, is instantaneous angular acceleration. The symbol for angular acceleration is α, and $\alpha = \lim_{\Delta t \doteq 0} \left(\frac{\Delta\omega}{\Delta t}\right) = \frac{d\omega}{dt} = \frac{d^2\theta}{dt^2}$. The sign of α depends on the numerator of the fraction, or on the way in which ω is changing.

Relations between v and a of any point P, of a rotating body and ω and α of the body. Let r = radius of path of P. Then $v = r\omega$, $a_t = r\alpha$, $a_n = r\omega^2$, $a = r\sqrt{\alpha^2 + \omega^4}$.

Sense of v must agree with sense of ω. Sense of a_t must agree with sense of α. Sense of a_n is always toward the axis.

52. PLANE MOTION

Plane motion of a rigid body is a motion such that each particle of the body moves in a plane at a constant distance from a fixed plane, through the center of gravity, called the plane of motion. Each line of the body parallel to plane of motion turns through the same angle θ in the same time interval. ANGULAR DISPLACEMENT of the body in time interval Δt is change of angular position of any line in the plane of motion. ANGULAR VELOCITY is time-rate of angular displacement. ANGULAR ACCELERATION is time-rate of angular velocity. The expressions, units, and rules of signs for plane motion are the same as those for rotation about a fixed axis (Art 51). Angular displacement is $\Delta\theta = \theta_2 - \theta_1$; angular velocity is $\omega = \frac{d\theta}{dt}$; angular acceleration is $\alpha = \frac{d\omega}{dt} = \frac{d^2\theta}{dt^2}$.

A plane motion may be traced by giving the history of the movement of one point of the body (called a base point) in its own curved path, and a description of the rotation of

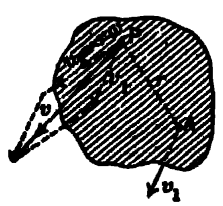

Fig 147

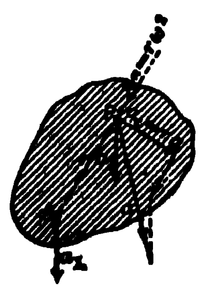

Fig 148

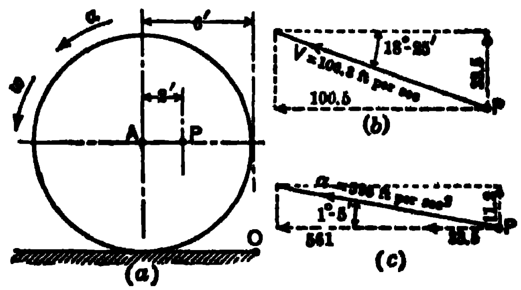

Fig 149

the body about the selected base point. The point selected as base should be one for which the motion is readily specified. In the case of a wheel rolling along a straight path, the center would be selected as a base point. VELOCITY OF ANY POINT P of the body, at an instant, with respect to a fixed point O, is the vector sum of the velocity of base point A, with respect to O, and of velocity of P with respect to A due to rotation about A. Thus (Fig 147) O is fixed point, A the moving base point, and P any other point of the body at distance r from A; v_1 is velocity of A with respect to O, and $v_2 = r\omega$ is velocity of P with respect to A. Resultant velocity of P with respect to $O = v$; or

$$v_P \text{ to } O = v_P \text{ to } A + v_A \text{ to } O$$

ACCELERATION OF ANY POINT P, with respect to a fixed point O, at an instant, has two components; one is that of the base point A with respect to O, and the other that of P with respect to base A. Acceleration of P with respect to A is rotational, and is conveniently replaced by its tangential and normal components, $a_t = r\alpha$ and $a_n = r\omega^2$. Then resultant acceleration of P, with respect to O, is the vector sum of $r\alpha$, $r\omega^2$, and acceleration of A with respect to O. Thus (Fig 148) a_1 is acceleration of A to O, and acceleration of P to A is resultant of a_t and a_n. Acceleration of P to O is a = vector sum of a_1, a_t, and a_n.

Example. A wheel of 6 ft radius rolls along a straight horiz path, and at a certain instant the point P, 2 ft from center of wheel, is in the position shown in Fig 149a. At this instant $\omega = 16.75$ radians per sec and $\alpha = 5.6$ radians per sec². Determine the velocity and acceleration of point P with respect to fixed point O at the specified instant.

SOLUTION. Select center A as base point. From relation between v and a of any point of a rotating body, and ω and α of the body (Art 51),

v_P to $A = r\omega = 2 \times 16.75 = 33.5$ ft per sec, vertically upward.

v_A to $O = r\omega = 6 \times 16.75 = 100.5$ ft per sec, horizontally toward left.

Therefore, v_P to $O = 106.3$ ft per sec, upward to left, at 18° 25′ to horizontal (Fig 149b).

a_A to $O = r\alpha = 6 \times 5.6 = 33.5$ ft per sec², horizontally toward left.

$a_t = r\alpha = 2 \times 5.6 = 11.2$ ft per sec², vertically upward.

$a_n = r\omega^2 = 2 \times (16.75)^2 = 561$ ft per sec², horizontally toward left.

Therefore, a_P to $O = 595$ ft per sec², upward to left, at 1° 5′ to horizontal (Fig 149c).

Instantaneous axis. For a body having plane motion, there is always one point in it (or in its extension), at each instant, for which the velocity with respect to A is equal and opposite to velocity of A with respect to O, that is, its velocity is zero at the instant. This point Q is called the INSTANTANEOUS (or instant) CENTER of rotation, and a line through Q, perpendicular to the plane of motion, is called the INSTANTANEOUS AXIS. Since Q is at rest for the instant, the resultant velocities of all points at the instant are purely rotational about the instant axis. The instant center is the intersection of two lines drawn from any two points, C and D, in the plane of the motion, perpendicular to their velocities. If the velocity of the point C is known, ω for the body is determined by dividing v_c by the distance of C from Q, or by r_c. The velocity of any other point E is $\omega \times r_E$, perpendicular to the radius r_E.

The position of Q in the body (or in its extension) is continually changing; its locus is a line (usually curved) fixed in the body and moving with it, called the BODY CENTRODE. The locus of the positions of Q in the fixed plane of motion is a line (usually curved) called the SPACE CENTRODE. The plane motion may be considered as produced by the rolling, without slipping, of the body centrode upon the space centrode.

KINETICS

53. FORCE AND MASS UNITS

Mass is the quantity of matter in a body; it means substance as measured by a beam scale. Standards of mass are the pound and kilogram; they are certain pieces of metal preserved in London and Paris. The mass of a body does not change with locality.

A force F acting on a particle of mass m gives it an acceleration a parallel to the force, and the relation between the quantities is given by the equation $F = Kma$, in which K is a constant. It is customary to use a KINETIC SYSTEM OF UNITS, one for which $K = 1$. For such a system, unit force gives to unit mass unit acceleration. The c g s system of units is a kinetic system; in it, force is measured in dynes, mass in gm, and acceleration in cm per sec². The system is called an absolute system, because the units are constant.

Units. The English-speaking engineers' unit of force is the pull of the earth on 1 lb of mass. This amount of pull is called ONE POUND OF FORCE. As this EARTH PULL varies with the elevation of the pound of mass, POUND FORCE is not an absolute unit. But, the range of variation is so slight, that the error involved by assuming it constant is negligible in most computations. The engineers' corresponding mass unit has no standard name, but will here be called a SLUG; it is the mass in which an acceleration of 1 ft per sec² is produced by a force of 1 lb. 1 slug of mass = about 32.2 lb of mass. In any computation that involves mass with pounds force, feet distance, and seconds time, mass should be reduced to slugs. Slugs of mass = wt of body (lb) ÷ 32.2 (approx value of acceleration due to gravity. In the following problems, the numerical value of this accel is taken as 32).

54. MOTION OF MASS CENTER AND TRANSLATION

For any particle of mass m

$$\Sigma\begin{pmatrix}\text{components in any } x \text{ direction of}\\ \text{all forces acting on the particle}\end{pmatrix} = \begin{pmatrix}\text{mass of particle times its } x \text{ component}\\ \text{of acceleration}\end{pmatrix}$$

or more briefly, if R_x represents the component of the resultant in the x direction,

$$R_x = \Sigma F_x = ma_x \qquad (A)$$

For any body, rigid or non-rigid,

$$\Sigma\left(\begin{array}{l}\text{components in any } x \text{ direction of all}\\ \text{external forces, pairs of internal}\\ \text{forces excluded}\end{array}\right) = \left(\begin{array}{l}\text{total mass of system times } x \text{ compo-}\\ \text{nent of acceleration of mass center}\end{array}\right)$$

or, more briefly, $$\Sigma F_x = M\bar{a}_x \qquad (B)$$

This is the equation of the motion of the mass center of a body or system of bodies.

Rigid body having motion of translation. Velocities of all particles are the same, and accelerations of all particles are the same. Resultant of all applied forces is a single force $R = Ma$, acting through the mass center, parallel to the acceleration,

$$\Sigma\left(\begin{array}{l}\text{components in any } x \text{ direction of}\\ \text{applied forces, including weight}\\ \text{of body}\end{array}\right) = \left(\begin{array}{l}\text{mass of body times the } x \text{ component}\\ \text{of acceleration}\end{array}\right)$$

or, more briefly, $$R_x = \Sigma F_x = Ma_x \qquad (C)$$

Also,

$$\Sigma\left(\begin{array}{l}\text{moments about any } x\text{-axis of ap-}\\ \text{plied forces, including weight of}\\ \text{body}\end{array}\right) = \left(\begin{array}{l}\text{moment of resultant about same}\\ x\text{-axis}\end{array}\right)$$

or, $$\Sigma M_x = Ma_x \times arm \qquad (D)$$

Following method of procedure is advisable in solving a problem: (*a*) Make a sketch of the body and place arrows upon it to represent all forces (including resultant at mass center), indicating unknown forces or distances by letters. Do same for each body if a system of bodies is under discussion. (*b*) Write as many resolution equations (*C*) and moment equations (*D*) as there are unknown quantities. (*c*) Solve the simultaneous equations to determine unknown quantities.

Example 1. A rectangular box (Fig 150), 2 by 2 by 8 ft high, weighing 480 lb, is placed upon a rough flat-car. If the car is running on a straight level track, what acceleration will cause the box to tip? If coeff of friction = 0.22, will the box slip or tip first? Solution. If tipping about edge O is impending, normal reaction is in position shown by N. By equation (*D*), $\Sigma M_0 = -480 \times 1 = -{}^{480}/_{32} \times a \times 4$; hence $a = 8$ ft per sec². If slipping impends, N acts through some point O' at distance x from center line. $a_y = 0$; hence $\Sigma F_y = 0 = N - 480$, shows $N = 480$ lb. Limiting friction = 0.22 N = 105.6 lb. By equation (*C*), $\Sigma F_x = 105.6 = {}^{480}/_{32} \times a$; hence, $a = 7.04$ ft per sec² to cause slipping. As this value of a is smaller than the first one, slipping will occur before tipping. x may be found from $\Sigma M_{o'} = -4 \times Ma$.

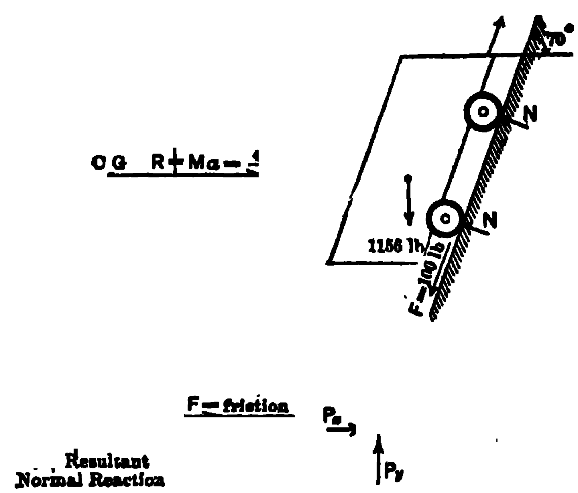

Fig 150 Fig 151

Example 2. A mine car (Fig 151), weighing 960 lb starts up a 70° slope, with an acceleration of 6 ft per sec, and is stopped at top with an acceleration of 4 ft per sec². A 196-lb man stands in the car. Determine starting and stopping tensions in the cable, if the frictional resistance amounts to 100 lb parallel to track. Also find reaction of car on man's feet for starting and stopping. Solution:

For starting, man and car: $\Sigma F_x = T - 100 - 1\,156 \sin 70° = {}^{1156}/_{32} \times 6 = 216.9$; hence, $T = 1\,402.9$ lb.

For stopping, man and car: $\Sigma F_x = T - 100 - 1\,156 \sin 70° = {}^{1156}/_{32} \times (-4) = -144.5$; hence, $T = 1\,041.5$ lb.

Man only, starting: $\Sigma F_x = P_x = {}^{196}/_{32} \times 6 \cos 70° = 12.57$ lb to right. $\Sigma F_y = P_y - 196 = {}^{196}/_{32} \times 6 \sin 70° = 34.55$ lb; hence, $P_y = 230.55$ lb up. $P = 231$ lb up to right, at angle of 3° 7′ to vertical.

Man only, stopping: $\Sigma F_x = -P_x = {}^{196}/_{32} \times (-4) \cos 70° = 8.38$ lb to left. $\Sigma F_y = +P_y - 196 = {}^{196}/_{32} \times (-4) \sin 70° = 23$ lb; hence, $P_y = 196 - 23 = 173$ lb up. $P = 173.1$ lb up to left, at angle of 2° 46′ to vertical.

55. ROTATION AND PLANE MOTION

Rigid body having motion of rotation about a fixed axis. Angular velocity $= \omega$, angular acceleration $= \alpha$, and moment of inertia of body about axis of rotation $= I$. The usual equation of motion is

$$\Sigma\begin{pmatrix}\text{moments about axis of rotation}\\ \text{of all external forces, including}\\ \text{weight of body}\end{pmatrix} = \begin{pmatrix}\text{moment of inertia about axis of rota-}\\ \text{tion times angular acceleration}\end{pmatrix}$$

or, more briefly,

$$\Sigma M = I\alpha \qquad (E)$$

Equation (E) is used to determine one unknown quantity, as a force, an arm, α, or I, according to the problem. In solving problems dealing with a connected system, in which certain bodies have motion of translation and others rotation, (C) and (E) may be used as simultaneous equations.

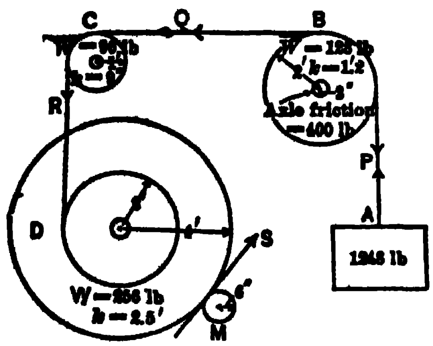

Fig 152

Example 3. Motor M (Fig 152) is geared to hoisting drum D to raise and lower weight A. Assume A descending at speed of 15 ft per sec, and determine tangential force S, exerted by motor, that will stop A in 30 ft at a uniform rate. Also, determine tensions P, Q, and R during the motion. Neglect mass of motor armature, and neglect all friction except that of axle on B (weights and sizes are not selected to conform to practice, but to illustrate the method of writing and using equations). SOLUTION. Determine acceleration of A by formulas given under Rectilinear motion (Art 46).

$$\int_{v_1}^{v_2} v\,dv = \int_{s_1}^{s_2} a\,ds;\quad \left[\frac{v^2}{2}\right]_{15}^{0} = a\left[s\right]_{0}^{30};\quad -\frac{(15)^2}{2} = a \times 30;\quad a = 3.75 \text{ ft per sec}^2 \text{ upward.}$$

By equations given under Angular acceleration (Art 51), $3.75 = a_A = 2\,\alpha_B = a_C = 2\,a_D$. By ($C$) and ($E$) of this Art, equations of motion for each body are:

$$P - 1\,248 = \frac{1\,248}{32} \times 3.75 = 146.25$$

$$2 \times Q - 2 \times P + 400 \times \frac{1}{4} = \frac{128}{32}(1.2)^2 \times \frac{3.75}{2} = 10.8$$

$$1 \times R - 1 \times Q = \frac{96}{32}\left(\frac{3}{4}\right)^2 \times 3.75 = 6.33$$

$$4 \times S - 2 \times R = \frac{256}{32}(2.5)^2 \times \frac{3.75}{2} = 93.75$$

Solution of these simultaneous equations determines $S = 701.4$ lb, $P = 1\,394.3$ lb, $Q = 1\,349.7$ lb and $R = 1\,356$ lb. The required motor torque is $S \times r = 701.4 \times 0.5 = 351$ ft-lb.

An axis of rotation which does not pass through the mass center must be held by forces (exerted by bearings) to keep it from shifting position. These bearing reactions depend upon the weight of the body, the manner in which the mass of body is distributed about the axis, the applied forces, the angular velocity ω, and the angular acceleration α. Generally, the resultant of the applied forces for such a body is not a single force, but a single force at a selected origin and a couple. Selecting the origin on the axis of rotation, the axial components of the single force and axial components of the couple are given by the following six equations:

$$\left.\begin{array}{ll}\Sigma F_x = M\bar{z}\alpha - M\bar{x}\omega^2 & \Sigma M_x = -\alpha\int xy\,dm - \omega^2\int yz\,dm\\ \Sigma F_y = 0 & \Sigma M_y = I_y\alpha\\ \Sigma F_z = -M\bar{x}\alpha - M\bar{z}\omega^2 & \Sigma M_z = -\alpha\int yz\,dm + \omega^2\int xy\,dm\end{array}\right\} \qquad (H)$$

In these equations, the axis of rotation is fundamentally the Y-axis; $\bar{x}$, $\bar{y}$, and $\bar{z}$ are the instantaneous coordinates of the mass center; ΣF_x, ΣF_y, ΣF_z are the sums of components of all applied forces in the axial directions; ΣM_x, ΣM_y, ΣM_z are the sums of moments of all applied forces about the axes; and the convention of signs for moments of forces, sense of ω, and measurement of θ $\left(\alpha = \frac{d^2\theta}{dt^2}\right)$ is as follows:

rotation about Z-axis from $+X$ to $+Y$ is positive,
rotation about X-axis from $+Y$ to $+Z$ is positive,
rotation about Y-axis from $+Z$ to $+X$ is positive.

Equations (H) are simultaneous at each instant. They are used more often to determine the forces exerted by the bearings on the axle, than to determine the resultant.

Special case (Fig 153). Choose the X-axis through the mass center and let XZ be a plane of symmetry of a homogeneous body. The resultant is a single force in the plane of symmetry having the Z component $-M\bar{x}\alpha$ and the X component $-M\bar{x}\omega^2$ acting at point C. $\overline{OC} = \dfrac{k^2_y}{\bar{x}}$, k_y being radius of gyration about Y-axis. If $\bar{x} = 0$, the resultant becomes a couple, in the XZ-plane, of moment $= \Sigma M_y = I_y\alpha$. If $\alpha = 0$ and $\bar{x} \neq 0$, the resultant $= -M\bar{x}\omega^2$, in the sense CO. If $\alpha = 0$ and $\bar{x} = 0$, the resultant vanishes.

Centrifugal force, body rotating about fixed Y-axis. Any particle of mass m moves in a circular path of radius r. The resultant of all forces acting on the particle has a normal component $= mr\omega^2$ and a tangential component $= mr\alpha$. The component $mr\alpha$ increases or decreases the speed of the particle; the component $mr\omega^2$ continually changes the direction of the linear velocity. The resultant of such forces for all the particles of the body is equivalent to the resultant specified by equations (H). If ω is constant and $\alpha = 0$, the resultant force acting on a particle to make it rotate in its circular path is $mr\omega^2$ toward the axis, and is called CENTRIPETAL FORCE. CENTRIFUGAL FORCE for the particle is equal and opposite to centripetal force, and is exerted by the particle upon its neighboring particles, or upon the axis of rotation. CENTRIFUGAL RESULTANT for a body is the resultant of centrifugal forces of all its particles. Generally, this resultant is not a single force; it may be computed from equations (H) by making $\alpha = 0$ and reversing senses of resultant force and couple.

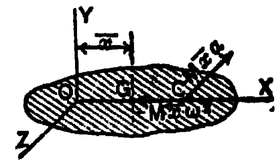

Fig 153

In the three following cases the centrifugal resultant is a single force: Case (a) Fig 154. Body has a plane of symmetry, XY, containing axis of rotation and mass center. Centrifugal resultant is a single force $= M\bar{x}\omega^2$, in XY plane, perpendicular to Y-axis, at a distance $y' = \left(\int xy\, dm\right) \div M\bar{x}$ from the XZ plane, and having sense EG. Case (b). Body has an axis of symmetry parallel to axis of rotation. Case (c). Body has plane of symmetry perpendicular to axis of rotation. In cases (b) and (c), centrifugal resultant is a single force $= M\bar{x}\omega^2$, acting through mass center outward and perpendicular to axis of rotation ($\bar{x}$ specified in Fig 154).

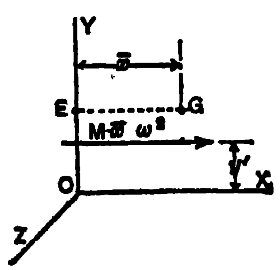

Fig 154

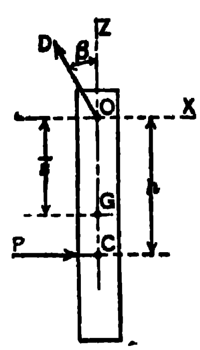

Fig 155

Center of percussion. Let Fig 155 represent a prismatic bar suspended on a horizontal Y-axis at O. G is the mass center. If a force P, parallel to X-axis, is applied to the body, the axle reaction at OD will generally be inclined to the Z-axis at some angle $\pm\beta$, the angle depending on the distance h of P from the axis of rotation. If $h = k_z^2 \div \bar{z}$, in which k_z is radius of gyration about Z-axis, P will cause no x component of axle reaction, that is β will be zero, and the point C, where the action line of P intersects OG, is the center of percussion. In impact testing machines, heavy pendulums are used to deliver blows, and proper design requires the striking point to coincide with the center of percussion, in order to avoid shock to the axle and detrimental vibration of the pendulum itself.

Body having plane motion. This motion has been described as translation of a base point in the plane of motion, and rotation about the base point (Art 52). Choose the mass center as base point and origin of coordinates, and the XY plane as plane of motion. Resultant of all applied forces may be described as a single force and a couple in the plane of motion. The couple is computed from the equation $\Sigma M_z = I_z\alpha = Mk_z^2\alpha$, in which ΣM_z represents sum of moments of applied forces about Z-axis. I_z and k_z are moment of inertia and radius of gyration about the Z-axis. The single force acts through the mass center, and its components are given by $R_x = \Sigma F_x = M\bar{a}_x$, $R_y = \Sigma F_y = M\bar{a}_y$, $R_z = \Sigma F_z = 0$. ΣF_x, ΣF_y, and ΣF_z, are sums of components of all applied forces, and $\bar{a}_x$, $\bar{a}_y$ are components of acceleration of mass center.

56. WORK, ENERGY AND POWER

Work of a constant force is the product of the force and the effective displacement of its application point. Effective displacement of application point is the component of the displacement parallel to the force. In Fig 156, the work of force F as application point describes path $AB = F \times AC$. Since $F\ (AB \cos \alpha) = (F \cos \alpha)\ AB$, the work is also equal to displacement of application point times component of force parallel to the displacement. Work of a variable force is $\int_{s_1}^{s_2} F \cos \alpha \, ds = \int_{s_1}^{s_2} F_t \, ds$, in which F is the variable force, ds is the elementary length of path, α is angle between force and element ds, and F_t is tangential component of force. The SIGN OF WORK is plus if force and effective displacement have same sense, and the sign is negative if they differ in sense.

Unit of work is unit force times unit distance 1 erg = 1 dyne cm. Work done by a body against a force is equal and opposite to work done by the force on the body.

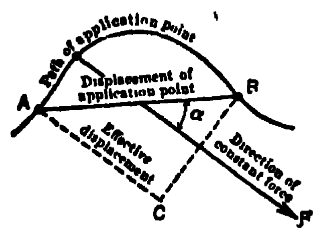

Fig 156

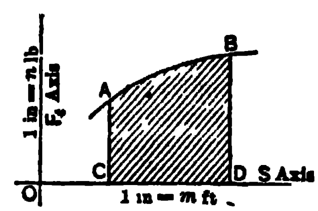

Fig 157

Work diagram (Fig 157). Plot values of F_t as ordinates, corresponding values of s as abscissas; draw curve AB through ends of ordinates. Area $ABDC$ times mn equals work, in ft-lb, done by F_t over distance $s_2 - s_1$.

Work of gravity on a body in any motion equals product of weight and change in height of the center of gravity. Work of a central force F (one always directed toward a fixed point), in any displacement of its application point, is $-\int_{r_1}^{r_2} F \, dr$, in which r_1 and r_2 are the distances of the application point from the center at the beginning and end of the displacement.

Work done by a pair of equal, opposite and colinear forces, for any motion of their application points, A and B. If force on A acts from B toward A, work of the pair $= \int_{r_1}^{r_2} F \, dr$; if force on A acts from A toward B, work of the pair $= -\int_{r_1}^{r_2} F \, dr$. In these formulas, r_1 and r_2 are the initial and final distances between A and B. Work of a torque T on a body for an angular displacement of θ radians $= T\theta$.

Power is time-rate of doing work. Let P = power and w = work; $w = \int F_t \, ds$, and $P = \frac{dw}{dt} = F_t \frac{ds}{dt} = F_t\, v$, v being speed of application point of force F. If P equals power (rate of doing work) of the steam in a locomotive, R = total resistance (grade, air, rolling, etc), M, v, and a_t being mass, speed, and acceleration of train respectively, then $P = Rv + Mva_t$; $P = 0$, for $v = 0$. Power of a torque $T = T\omega$, ω being angular velocity of rotating body. UNIT OF POWER is any work unit divided by time unit, such as ft-lb per sec, ft-lb per min, or erg per sec. (10^7 ergs per sec = 1 watt). One horsepower = 550 ft-lb per sec = 33 000 ft-lb per min.

Energy. A body possesses energy when it can do work against forces applied to it. The amount of energy possessed at any instant is the amount of work the body can do in changing to some standard state. KINETIC ENERGY (K E) of a body is energy possessed by virtue of its velocity, and the standard state is zero velocity. K E of a particle is one-half its mass times square of its velocity. K E of a body in translation $= 0.5\ Mv^2$. K E of a rotating body $= 0.5\ I\omega^2 = 0.5\ Mk^2\omega^2$, I, k, and ω being moment of inertia, radius of gyration, and angular velocity about axis of rotation. K E of a body having plane motion $= 0.5\ I\omega^2 = 0.5\ Mk^2\omega^2 = 0.5\ M\bar{v}^2 + 0.5\ \bar{I}\omega^2$, in which I and k refer to instantaneous axis, $\bar{v}$ = velocity of mass center and $\bar{I}$ is moment of inertia about axis through mass center perpendicular to plane of motion. UNIT of K E is same as unit of work, usually ft-lb. In computing K E, engineers use mass in slugs, v in ft per sec, ω in radians per sec, and k in ft.

Principle of work and kinetic energy. Total work of the applied forces acting on any body, or on any system of connected bodies, equals the change in the kinetic energy of

the body, or bodies. Work done = Δ K E. Change in energy in translation = 0.5 M $(v_2^2 - v_1^2)$, v_1 and v_2 being initial and final velocities. Change in energy in rotation = 0.5 I $(\omega_2^2 - \omega_1^2)$ = 0.5 Mk^2 $(\omega_2^2 - \omega_1^2)$, ω_1 and ω_2 being initial and final angular velocities. In plane motion, change in K E is

$$\Delta \text{ K E} = 0.5\, I\, (\omega_2^2 - \omega_1^2) = 0.5\, Mk^2\, (\omega_2^2 - \omega_1^2)$$

$$= 0.5\, M\, (\bar{v}_2^2 - \bar{v}_1^2) + 0.5\, \bar{I}\, (\omega_2^2 - \omega_1^2) = 0.5\, M\, (\bar{v}_2^2 - \bar{v}_1^2) + 0.5\, M\bar{k}^2\, (\omega_2^2 - \omega_1^2)$$

in which I and k refer to instantaneous axis, $\bar{I}$ and $\bar{k}$ to a parallel axis through mass center, and $\bar{v}$ is velocity of mass center.

Example. In example 3, Art 55 (Fig 152): (*a*) Use principle of work and K E to find constant torque M necessary to stop body A in 30 ft, from a downward veloc of 15 ft per sec; (*b*) Find tension in cord P; (*c*) Find power of motor for above value of torque, when veloc of A is 10 ft per sec. Solution:

Work of gravity is positive = 1 248 × 30 = +37 440 ft-lb
Work of axle friction is negative = −400 × $^{30}/_{2}$ × $^{1}/_{4}$ = −1 500 ft-lb
Work of motor is negative = $-M\theta = -M$ × 60 × 0.5 = −120 M ft-lb
Total work = −120 M + 35 940
Final K E = 0, and change is a loss, or negative.

For D, Δ K E = $^1/_2\, Mk^2\, (\omega_2^2 - \omega_1^2) = -^1/_2 \times {}^{256}/_{32} \times {}^{25}/_4 \times ({}^{15}/_2)^2$ = −1 408 ft-lb
For C, Δ K E = $^1/_2\, Mk^2\, (\omega_2^2 - \omega_1^2) = -^1/_2 \times {}^{96}/_{32} \times {}^{9}/_{16} \times (15)^2$ = −189.8 ft-lb
For B, Δ K E = $^1/_2\, Mk^2\, (\omega_2^2 - \omega_1^2) = -^1/_2 \times {}^{128}/_{32} \times (1.2)^2 \times ({}^{15}/_2)^2$ = −162 ft-lb
For A, Δ K E = $^1/_2\, M\, (v_2^2 - v_1^2) = -^1/_2 \times {}^{1248}/_{32} \times (15)^2$ = −4 387.5 ft-lb

Total Δ K E = −6 147.3 ft-lb

(*a*) Since W = Δ K E, −120 M + 35 940 = −6 147.3; hence, M = 351 ft-lb
(*b*) When v_A = 10 ft per sec, ω of motor = 40 radians per sec

Power = torque × ω = 351 × 40 ft-lb per sec = 351 × 40 ÷ 550 = 25.5 hp

(*c*) To find tension P, apply principle of work and K E to body A alone.

Work = (−P + 1 280) 30 = −30 P + 37 440
Δ K E = $^1/_2\, M\, (v_2^2 - v_1^2) = {}^1/_2\, {}^{1248}/_{32}\, (0 - 15^2)$ = −4 387.5 ft-lb
Then, −30 P + 37 440 = −4 387.5; hence, P = 1 394.3 lb

57. IMPULSE AND MOMENTUM

Linear impulse of a constant force F for time $t = F \times t$. If the force varies in magnitude and direction, the impulse is computed from axial components of impulse, which are found by taking the time integrals of axial components of the force. The three axial component impulses are $\int_{t_1}^{t_2} F_x dt$, $\int_{t_1}^{t_2} F_y dt$, $\int_{t_1}^{t_2} F_z dt$; the resultant of these is the impulse of the force F. Impulse is a vector quantity; hence the impulse of the force equals the square root of the sum of the squares of the components. The direction cosines of the resultant vector are determined in the usual manner (see resultant of noncoplanar concurrent forces or resultant velocity in curvilinear motion). Unit of impulse is unit force times unit time, or lb-sec in engineers' units.

Angular impulse of a force about a line for a time interval dt is the product of the moment of the force about the line and the time dt. If T represents the moment or torque of the force, the angular impulse for the time interval $t_2 - t_1 = \int_{t_1}^{t_2} T\, dt$. Unit of angular impulse is unit moment times unit time, or ft-lb-sec in engineers' units.

Sign of impulse. Impulse of a force tending to increase velocity of the body to which the force is applied is positive; that which tends to decrease velocity is negative.

Linear momentum of a particle is the product of its mass and velocity. It is a vector quantity and has the sense and direction of the velocity. Unit of momentum is unit mass times unit velocity and is equivalent to unit of impulse. Linear momentum of a body is the resultant, or vector sum, of the momentums of its particles. In any motion the linear momentum of a body is $M\bar{v}$, M being mass of the body and $\bar{v}$ the velocity of its mass center. In engineers' units this is expressed in slug-ft per sec or lb (force)-sec.

Angular momentum of a particle about an axis is the moment of its momentum about that axis. In Fig 158, let mv = momentum of particle P. Resolve the momentum into components parallel and perpendicular to the axis. DE is perpendicular distance from

axis to line AP. The momentum of $P = mv \cos \alpha \times DE$. The angular momentum of a body about an axis is the algebraic sum of the angular momentums of its particles. The angular momentum of a rotating body about the axis of rotation is $I\omega = Mk^2\omega$, I and k being moment of inertia and radius of gyration about the axis of rotation and ω the angular velocity. Engineers use I in slug ft^2, ω in radians per sec, M in slugs and k in ft; the unit of the quantity is slug ft^2 per sec or lb (force)-ft-sec.

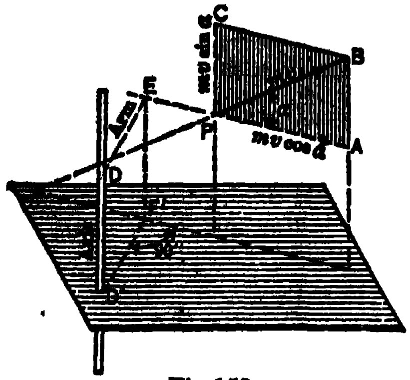

Fig 158

Principle of impulse and momentum for a body. The change in the component of linear momentum parallel to any axis x in the time $t_2 - t_1$ equals the algebraic sum of the components of the impulses of the applied forces parallel to the axis in the same time, or, more briefly, $\Delta\,(M\bar{v}_x) = \sum\int_{t_1}^{t_2} F_x\,dt$. The change in the angular momentum about any axis y in the time $t_2 - t_1$ equals the algebraic sum of the angular impulses of the applied forces about the axis in the same time, or $\Delta\,(I_y\,\omega) = \sum\int_{t_1}^{t_2} T_y\,dt$. This component of linear momentum and the angular momentum remain constant if no forces are applied.

Example. In example 3, Art 55 (Fig 152), assume the time required to stop A is 4 sec. Use principle of impulse and momentum to determine tensions P and Q. Solution:

For A,
$$\Delta\,(M\bar{v}_x) = \sum\int_{t_1=0}^{t_2=4} F_x\,dt$$
$$^{1248}/_{32}\,(0 - 15) = -585 = +1\,248 \times 4 - P \times 4; \quad \text{hence, } P = 1\,394.3 \text{ lb}$$

For B,
$$\Delta\,(I_y\omega) = \sum\int_{t_1=0}^{t_2=4} T_y\,dt$$
$$^{128}/_{32}\,(1.2)^2\,(0 - 7.5) = -43.2 = -Q \times 2 \times 4 + 1\,394.3 \times 4 - 400 \times {}^{8}/_{12} \times 4;$$
hence,
$$Q = 1\,349.7 \text{ lb}$$

EDWARD K. JUDD AND ROBERT PEELE

CHEMICAL AND PHYSICAL NOTES AND TABLES

Table 1. The Chemical Elements, 1934 (a)

Element	Symbol	Atom wt (b)	Valence	Element	Symbol	Atom wt (b)	Valence
Aluminium	Al	26.97	*iii*	Mercury	Hg	200.6	*i, ii*
Antimony	Sb	121.76	*iii, v*	Molybdenum	Mo	96.0	*iv, vi*
Argon	A	39.94	*o*	Nickel	Ni	58.69	*ii, iii*
Arsenic	As	74.91	*iii, v*	Nitrogen	N	14.01	*iii, v*
Barium	Ba	137.37	*ii*	Osmium	Os	191.5	*iv, viii*
Bismuth	Bi	209.0	*iii, v*	Oxygen	O	16.0	*ii*
Boron	B	10.82	*iii*	Palladium	Pd	106.7	*ii, iv*
Bromine	Br	79.92	*i*	Phosphorus	P	31.027	*iii, v*
Cadmium	Cd	112.41	*ii*	Platinum	Pt	195.23	*ii, iv*
Calcium	Ca	40.07	*ii*	Potassium	K	39.09	*i*
Carbon	C	12.00	*iv*	Radium	Ra	225.97	*ii*
Cerium	Ce	140.13	*iii, iv*	Selenium	Se	78.9	*ii, iv, vi*
Chlorine	Cl	35.457	*i*	Silicon	Si	28.06	*iv*
Chromium	Cr	52.01	*iii, vi*	Silver	Ag	107.88	*i*
Cobalt	Co	58.94	*ii, iii*	Sodium	Na	23.0	*i*
Columbium	Cb	93.3	*iii, v*	Strontium	Sr	87.63	*ii*
Copper	Cu	63.57	*i, ii*	Sulphur	S	32.06	*ii, iv, vi*
Fluorine	F	19.0	*i*	Tantalum	Ta	181.4	*iii, v*
Glucinum	Gl	9.2	*ii*	Tellurium	Te	127.6	*ii, iv, vi*
Gold	Au	197.2	*i, iii*	Thallium	Tl	204.4	*iii*
Helium	He	4.0	*o*	Thorium	Th	232.15	*iv*
Hydrogen	H	1.008	*i*	Tin	Sn	118.7	*ii, iv*
Iodine	I	126.92	*i*	Titanium	Ti	47.9	*iii, iv*
Iridium	Ir	193.1	*iv, viii*	Tungsten	W	184.0	*ii, iv, vi*
Iron	Fe	55.84	*ii, iii*	Uranium	U	238.14	*iv, vi*
Lanthanum	La	138.92	*iii*	Vanadium	V	50.96	*iii, v*
Lead	Pb	207.2	*ii, iv*	Ytterbium	Yb	173.04	*iv*
Lithium	Li	6.94	*i*	Yttrium	Yt	88.9	*iv*
Magnesium	Mg	24.32	*ii*	Zinc	Zn	65.38	*ii*
Manganese	Mn	54.93	*ii, iv*	Zirconium	Zr	91.22	*iv*

(*a*) Omitting 33 elements of small interest to engineers. For atomic weights of all elements, see *Jour Amer Chem Soc.* The Society publishes, from time to time, such changes as may be due to further investigation. (*b*) Figures for 1934; based on oxygen = 16.

Grouping of elements based on similarity in chemical properties (same omissions as in Table 1):

1. Hydrogen
2. Chlorine, bromine, iodine, fluorine
3. Oxygen, sulphur, selenium, tellurium
4. Nitrogen, phosphorus, arsenic, antimony, bismuth
5. Carbon, silicon
6. Boron
7. Alkalies: lithium, sodium, potassium, ammonium (NH_4)
8. Alkaline earths: barium, strontium, calcium
9. Magnesium, glucinum, zinc, cadmium, mercury
10. Silver, copper, gold
11. Aluminum, yttrium, lanthanum, ytterbium, thallium
12. Iron, nickel, cobalt
13. Manganese
14. Chromium, molybdenum, tungsten, uranium
15. Tin, lead, titanium, zirconium, cerium, thorium
16. Vanadium, tantalum
17. Platinum, palladium, osmium, iridium

To compute percentage composition from a formula. Two examples:

CALCIUM PHOSPHATE

$Ca_3(PO_4)_2$

Ca....3 × 40.07	= 120.21	=	38.7%
P.....2 × 31.027	= 62.054	=	20.0
O.....2 × 4 × 16	= 128.00	=	41.3
Formula-weight	= 310.264	=	100.0

KAOLIN

$H_2Al_2(SiO_4)_2, H_2O$

H......2 × 1.008	= 2.016	=	0.8%
Al......2 × 26.97	= 53.94	=	20.9
Si......2 × 28.06	= 56.12	=	21.8
O.......2 × 4 × 16	= 128.0	=	49.5
H_2O....2.016 + 16	= 18.016	=	7.0
Formula-weight	= 258.092	=	100.0

To determine formula from analysis: divide percentage of each element by its atomic weight, and reduce quotients to least common denominator. Example:

Phosphorus.........	21.82% ÷ 31.027 = 0.703 = 1	
Hydrogen...........	0.71% ÷ 1.008 = 0.703 = 1	= Na_2HPO_4
Sodium.............	32.43% ÷ 23.00 = 1.407 = 2	
Oxygen.............	45.02% ÷ 16.00 = 2.814 = 4	
	99.98%	

Computations from analysis will not always work out with mathematical precision, but small errors can be compensated according to the fundamental law that elements always combine in simple proportions represented by whole numbers.

Determining formula of a mineral from its analysis is complicated by fact that few natural substances are "chemically pure"; certain constituents of a mineral from one locality may be found, in same mineral from a different locality, to be replaced wholly or partly by another element. First convert percentage of minor element to equivalent percentage of preponderating element of same group, equivalents being directly proportional to atomic weights; then compute ratio of elements (or molecules) in same manner as above. Example:

Analysis of a garnet:	
SiO_2.....	39.85%
Al_2O_3....	22.07
Fe_2O_3...	1.13
MgO....	0.68
CaO....	36.31
	100.04

$Fe_2O_3 : Al_2O_3$ = (2 × 55.84 + 3 × 16 = 159.68) :: (2 × 27.0 + 3 × 16 = 102.0) = 1.13 : x. x = 0.72; that is, 1.13% of Fe_2O_3 is equivalent to 0.72% of Al_2O_3. Similarly, MgO : CaO = (24.32 + 16 = 40.32) :: (40.07 + 16 = 56.07) = 0.68 : x. x = 0.94% CaO.

SiO_2............	39.85 ÷ (28.06 + 32) = 0.660 = 3
Al_2O_3...........	(22.07 + 0.72) ÷ 102.2 = 0.223 = 1
CaO............	(36.31 + 0.94) ÷ 56.07 = 0.664 = 3

Type formula: $3\,CaO \cdot Al_2O_3 \cdot 3\,SiO_2$

Table 3. Composition, etc, of More Important Industrial Compounds

(For composition of minerals, see Sec 1, Tables I–VIII. For gases, see Sec 39, Art 7–10. For additional organic and inorganic compounds, see Van Nostrand's "Chemical Annual," Merck's "Index," or U S Pharmacopœia.)

Name	Formula	Mol wt	Sp gr

The upper figure of each pair is the number of grams of the anhydrous salt held in solution by 100 c c of water; the lower is the molar solubility, *i e*, the number of moles (molecular weight expressed as grams) contained in 1 liter of saturated solution. The numbers for small solubilities have been abbreviated; thus $0.0_64 = 0.0000004$.

Table 4. Specific Gravity of Sulphuric Acid at 15° C*

ELEMENTS OF HYDRAULICS

BY

J. K. FINCH

RENWICK PROFESSOR OF CIVIL ENGINEERING, COLUMBIA UNIVERSITY

ELEMENTS OF HYDRAULICS

1. DEFINITIONS

Hydromechanics deals with the mechanics of fluids. Fluids embrace LIQUIDS (practically incompressible and the molecules of which are not fixed in position) and GASES (compressible and expand spontaneously, volume depends on press and temp, and molecules are free). Hydromechanics comprises HYDROSTATICS, dealing with fluids at rest and HYDRODYNAMICS, with fluids in motion. HYDRAULICS treats of the hydrostatics and hydrodynamics of water, but the term is often restricted to hydrodynamics only, or the mechanics of water in motion.

The principles of hydraulics are also applicable to other liquids, but hydrodynamic (not hydrostatic) phenomena are greatly influenced by internal frictional or shearing resistance as measured by viscosity and by inertia, which vitally affect motion. Viscosity, while often assumed constant for water, actually varies with the temp and is a controlling factor in flow of more viscous liquids, such as oils. The notion of velocity, basic in hydrodynamics, was clarified by Galileo, Torricelli and others in 17th century; the Bernoullis, Pitot, and Chésy pioneered in practical hydraulics in the 18th; and the determination of experimental coefficients occupied attention of Darcy, Basin, Francis and others during the 19th century. More recent work has reverted to fundamentals, to which the experiments of Reynolds have directed attention. See Art 2.

2. PHYSICAL PROPERTIES OF LIQUIDS

Compressibility. Liquids may generally be assumed incompressible; actually, water decreases about 1% in vol under press of 3 000 lb per sq in.

Unit weight. Water is assumed to have a constant wt per unit of vol, designated by w; commonly taken as 62.5 lb per cu ft (8.355 lb per U S gal). Sea water averages 64 lb, while that of salt lakes may reach 75 lb or more. Similar approx values may be used for other liquids under static conditions, although density and wt vary with temp; while such variation is unimportant with water, it may be vital in dynamic problems involving other liquids.

Mass density and specific gravity. Liquid flow is affected by inertia and viscosity. Scientifically, inertia is expressed in terms of mass. Mass density, ρ (Greek rho) in

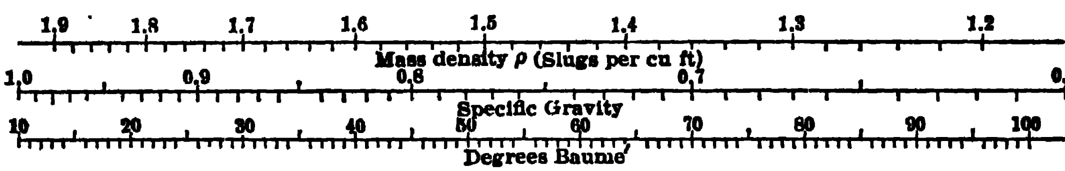

Fig 1. Density Conversion Scales

British units (SLUGS per cu ft) = w (lb per cu ft) ÷ g (ft per sec^2), where g is accel of gravity (aver value 32.16 ft per sec^2 or 980.7 dynes or cm per sec^2). Using aver values, ρ for water = 1.94, varying from 1.938 at 32° to 1.925 at 100° F.

For oils, wt is usually expressed in terms of specific gravity as measured by Baumé scale (Fig 1). With oils, sp gr is commonly determined at temp of 60° F (designated 60/60); this is not precise, though the error is usually negligible.

In flow problems, it is important to know ρ at existing temp, and charts are available for various oils. For heavy oils, with sp gr near unity, approx sp gr at any temp, t, = sp gr (60/60) − 0.00035t (°F). For lighter oils, with sp gr around 0.7, the last factor is about 0.00025t. ρ (approx) = 1.94 × (sp gr).

Viscosity. Liquids do not possess perfect fluidity; adjacent particles adhere, and a moving thread or layer of liquid tends to drag the particles with it. At low veloc, this drag constitutes a shearing resistance which is measured by the coeff of ABSOLUTE VISCOSITY, μ (Greek mu), defined as "the frictional resistance to motion, lb per sq ft, between 2 parallel

surfaces in a fluid, 1 ft apart and moving relatively to each other at rate of 1 ft per sec." In the metric system, the unit for μ is the POISE, expressed in dyne-sec per sq cm. To convert poises into lb-sec per sq ft, divide by 478.8

Viscosity is measured by viscometers of various types, and is usually expressed as time in secs required for a certain vol of liquid to pass through a small tube under a fixed head. Formulas and charts are available for converting viscosity measurements into absolute viscosity units. (See "The Viscosity of Liquids" by Emil Hatschek, London, 1928; also "The Mechanical Properties of Fluids," Van Nostrand, 1924).

Viscosity is independent of rate of change in velocity, but is affected to a small extent by press, and markedly by temp, diminishing as temp increases. For water, see table.

Temp, F°	μ (British) lb-sec per sq ft	Temp, C°	μ (Poises) dynes-sec per sq cm
32	0.000037	0	0.0179
68	0.000021	20	0.0100*
100	0.000014	56	0.0069

* Called "centipoise," one-hundredth of a poise.

Some viscosity-temp charts for oils (viscosity of which may be 50 to 300 or more times greater than that of water) have been published, but μ for the fluid in question should be known at the existing temp.

Kinematic viscosity. In flow phenomena, inertia (measured by ρ) tends to continue the existing state of motion, while viscosity (measured by μ) tends to retard such motion. Fluid flow is thus a compromise between inertia and viscosity, and the ratio $\mu \div \rho$ thus becomes a very vital characteristic of any fluid in motion. This ratio is the KINEMATIC VISCOSITY, designated by ν (Greek nu).

ν is expressed in a confusing number of units. In the British scientific system (followed here) ν is in lb-sec per sq ft $\div$ slugs per cu ft; that is, as absolute viscosity $\div$ mass density. In the metric system it is given in poises (or centipoises) $\div$ grams μ per cu cm. Since grams per cu cm = sp gr for all practical purposes, we may use poises $\div$ sp gr. Other variations are in use. To convert metric into British units, as above defined, divide former by 929. In most hydrodynamic problems, ν is simply an argument on which the friction factor depends, and no great degree of accuracy is usually required in determining its value. As viscometers actually depend upon ν for their data (rather than simply μ) viscometer readings can be directly converted into kinematic viscosity (Fig 2).

Reynolds number, *R*. Flow phenomena and coefficients vary with character of the liquid, as measured by μ and ρ, but the influence of these factors varies in turn with the scale and veloc of movement. Whereas viscous resistance varies with the first power of the veloc and of the scale of movement, the inertial forces (represented by ρ) vary with the squares of those factors. Hence, a variation must be expected in the proportionality between μlv and ρl^2v^2, where l is any linear dimension representing the scale of movement (as the diam of a pipe), and v = veloc. The formula is written:

$$\frac{\rho l^2 v^2}{\mu l v} = \frac{lv}{\nu} = R = \text{the "Reynolds number."}$$

It may be shown that R is dimensionless (containing no units of mass, length, or time) and thus it has the same value, irrespective of the units used in its calculation. *Example.* When water flowing in a pipe 1 ft diam at 4 ft per sec veloc, at 68° F, $\mu = 0.000021$, $\rho = 1.94$, and $R = 370\,000$. In metric units, at 20° C, $\mu = 0.01$ poise, $\rho = 1.0$, $d = 30.5$ cm, and $v = 122$ cm per sec, giving same value of R.

Recent studies have shown that many flow coefficients vary with R, which, as it includes general physical characteristics of the liquid, makes it possible to correlate data applying to air, oil, water, and other fluids of varying density and viscosity, and in movements on different scales.

Atmospheric pressure. At 30 in barometer (14.7 lb per sq in or 1 atmos) a water column stands 34 ft high, and water boils at 212.2° F. Boiling point is lowered about 1.8° F per in of mercury; for barom press of 20 in (= 192.4° F), water column is 22.7 ft. Roughly, the mercury barometer drops 1 in per 1 000 ft of elevation.

Water carries an amount of dissolved air varying with temp. At 60° F there are about 1 part oxygen and 4.4 parts air by wt in 100 000 of water.

Constants. Following are convenient units and constants for hydraulic computations:

1 cu ft water = 7.48 U S gal = 28.32 liter = 62.5 lb.

1 U S gal = 231 cu in = 3.78 liters = 8.355 lb.

g = acceleration due to gravity = 32.16 ft per sec; $\sqrt{2g} = 8.02$; $1 \div 2g = 0.01555$.

1 ft head = 0.434 lb per sq in; 1 lb per sq in = 2.304 ft head.

Area circle 1 ft (= 12 in) diam = 0.785 sq ft.

Area circle 3 in (=0.25 ft) diam = 0.785 ÷ 16 = 0.049 sq ft, etc.

1 acre ft = 1 ft depth over 1 acre = 43 560 cu ft = a flow of 1 cu ft per sec for 12 hr and 6 min.

1 cu ft per sec = 646 300 gal per day.

1 in of rain = 2 323 200 cu ft per sq mile.

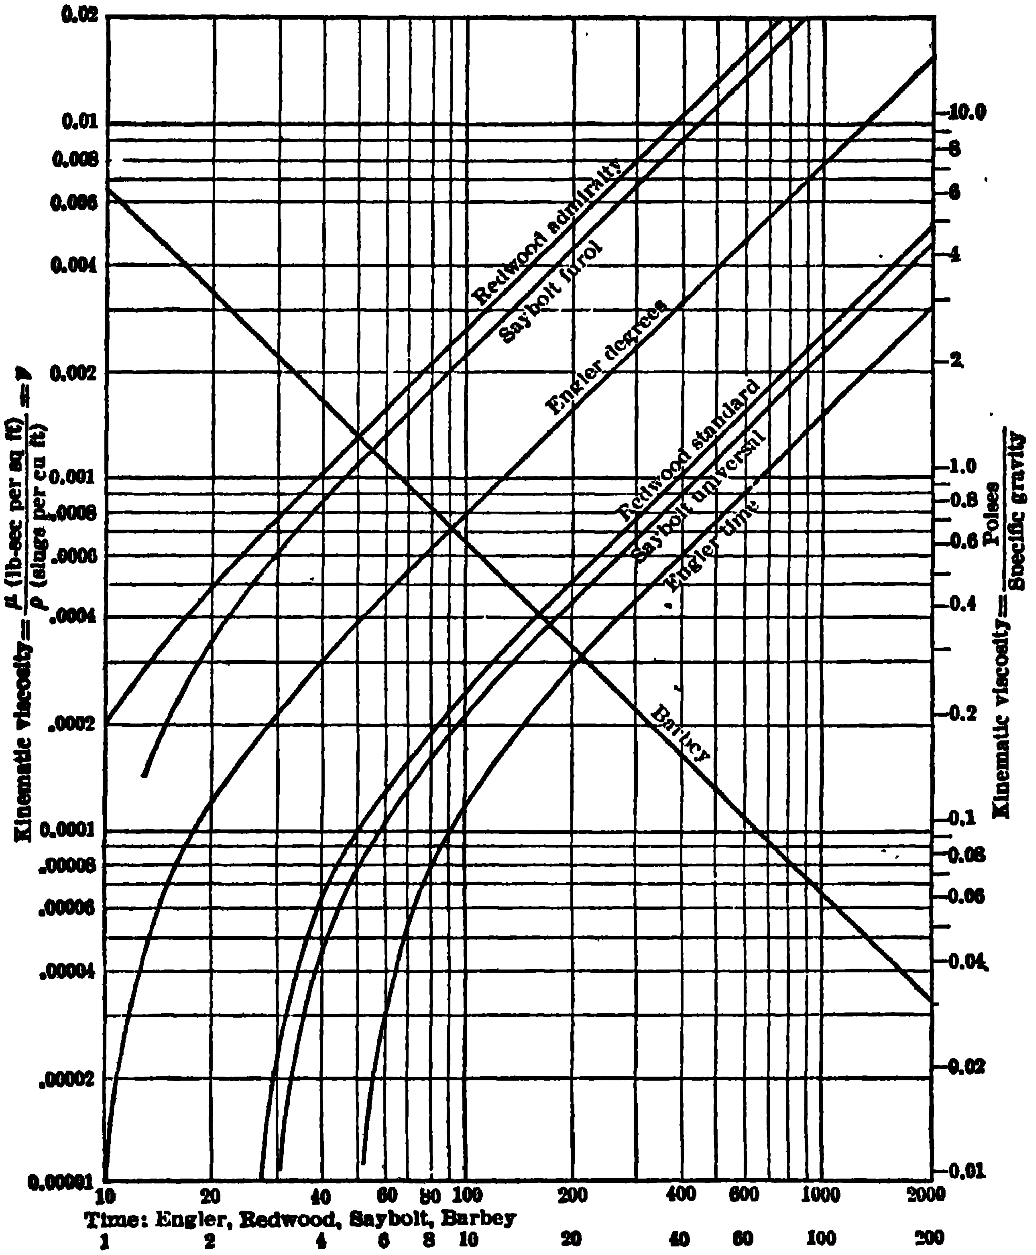

Fig 2. Viscosity Conversion Chart

HYDROSTATICS

3. TRANSMISSION OF PRESSURE

Pascal's law (1646). In a perfect fluid, neglecting effect of gravity, press exerted anywhere on the fluid is transmitted undiminished in all directions (at speed of 4 670 ft per sec = velocity of sound in water), and acts with the same force on all equal areas and at right angles to the surface.

Pascal noted that great forces could thus be produced, and that the total press increases in proportion to the surface area. A light press exerted on the water in a small tube inserted in a barrel may burst the barrel. This principle was applied by Bramah (1796) in the first successful HYDRAULIC PRESS (Fig 3), which consists of 2 cylinders, large and small, fitted with pistons and connected by a pipe through which water passes from one cylinder to other. A force P, applied to the small piston, is transmitted through the liquid and produces an equal unit press p on the large piston. Thus $W : P :: D^2 : d^2$, or $W = PD^2 \div d^2$. This is reduced by the frictional resistance of the packing, which, depending upon the type, condition and adjustment of same, may amount to as much as 10% of the applied load per cylinder.

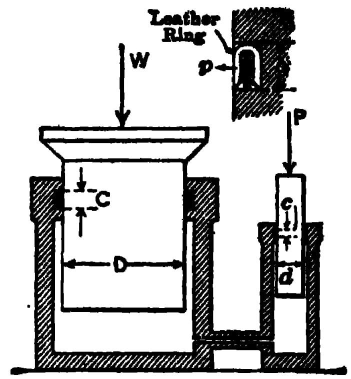

Fig 3. Hydraulic Press

4. PRESSURE PRODUCED BY GRAVITY

Considering a liquid divided into layers, the press in each layer is: (*a*) proportional to its depth, (*b*) proportional to wt of the liquid, (*c*) the same at all points in each layer, (*d*) same in all directions at any depth, (*e*) independent of size and shape of containing vessel. Also, water surface is normal to the resultant of the forces acting. Cases (*a*) and (*b*) are practically self-evident. $P = wAh$, where P = total press, lb; w = wt of 1 cu ft of water, lb; A = area, sq ft; h = head, ft. If $p = P \div A$ = unit press, then p in lb per sq ft $= wh = 62.5\ h$, or in lb per sq in $= 0.434\ h$, or h in ft $= 2.30$ times p in lb per

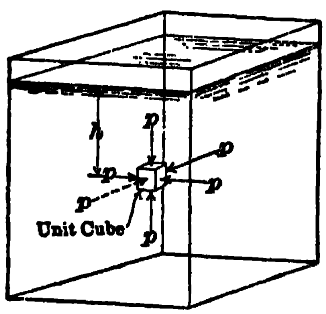

Fig 4

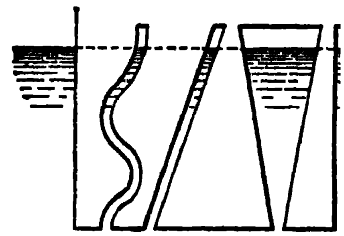

Fig 5

sq in. (*c*) and (*d*) follow from Pascal's law (see Fig 4). (*e*) is shown in Fig 5, where the bottoms of vessels are at same level, and unit pressures must be same or flow would occur.

5. TOTAL NORMAL PRESSURE AND CENTER OF PRESSURE

Total normal press, or press acting at right angles to surface $= P_n = wAh_{cg} =$ 62.5 × area of surface × distance of center of gravity of the surface below water level. This applies to any surface, plane, curved or warped. Thus the total normal press against the back face of dam shown in Fig 7 is $P_n = 62.5 \times 1 \times h\ (h \div 2) = {}^1/_2\ wh^2$ lb per lin ft.

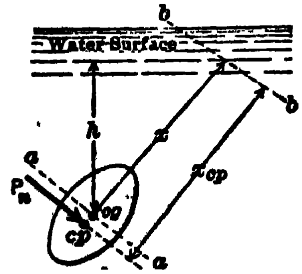

Fig 6

Component total pressure in any direction $= P' = P_n \cos\theta = wA'h_{cg}$, where θ = angle between normal and the given direction. That is, the total press in any direction = total normal press on a projection (= A') perpendicular to that direction. In Fig 7*d*, total horiz press $= P_h = wh^2 \div 2$, the same as the normal press against a vertical projection (Fig 7*a*).

Center of pressure (*cp*) of a submerged surface is the point of application of the resultant press. For a submerged rectangle, the center of press is ${}^2/_3\ h$ below the water surface, when the top of the rectangle is at the surface (Fig 7*a*). In general, the distance $x_{cp} = I \div S$, where I is the moment of inertia of the surface and S its statical moment (= area × distance of *cg* from axis) both with reference to an axis situated at intersection of the plane of the surface with the water level. x_{cp} is the perpendicular distance from this axis to the *cp*.

In applying this formula, use is made of the well known relation $I = I' + Ax^2$, where I = moment of inertia about any axis, I' = that about an axis through *cg* of surface, A = area of surface, and x = distance between axes. Thus for a circular area, Fig 6, *aa*

is axis through cg, bb is water surface axis, $A = \pi r^2$, $I' = \pi r^4 \div 4$; hence $x_{cp} = (\pi r^4 \div 4 + \pi r^2 x^2) \div \pi r^2 x = (r^2 \div 4x) + x$, or when the circle is vertical $= (r^2 \div 4h) + h$.

It is seen that the center of press is lower than the center of gravity, and that the distance between them decreases as the head increases. Practically they may be taken as coincident, when the head exceeds 3 or 4 times the vertical dimension of the surface.

6. PRESSURE AGAINST DAMS AND GATES

Fig 7 shows graphically the variation in normal, horiz, and vertical press, total press and centers of press for rectangular surfaces of unit width. The press at water surface is

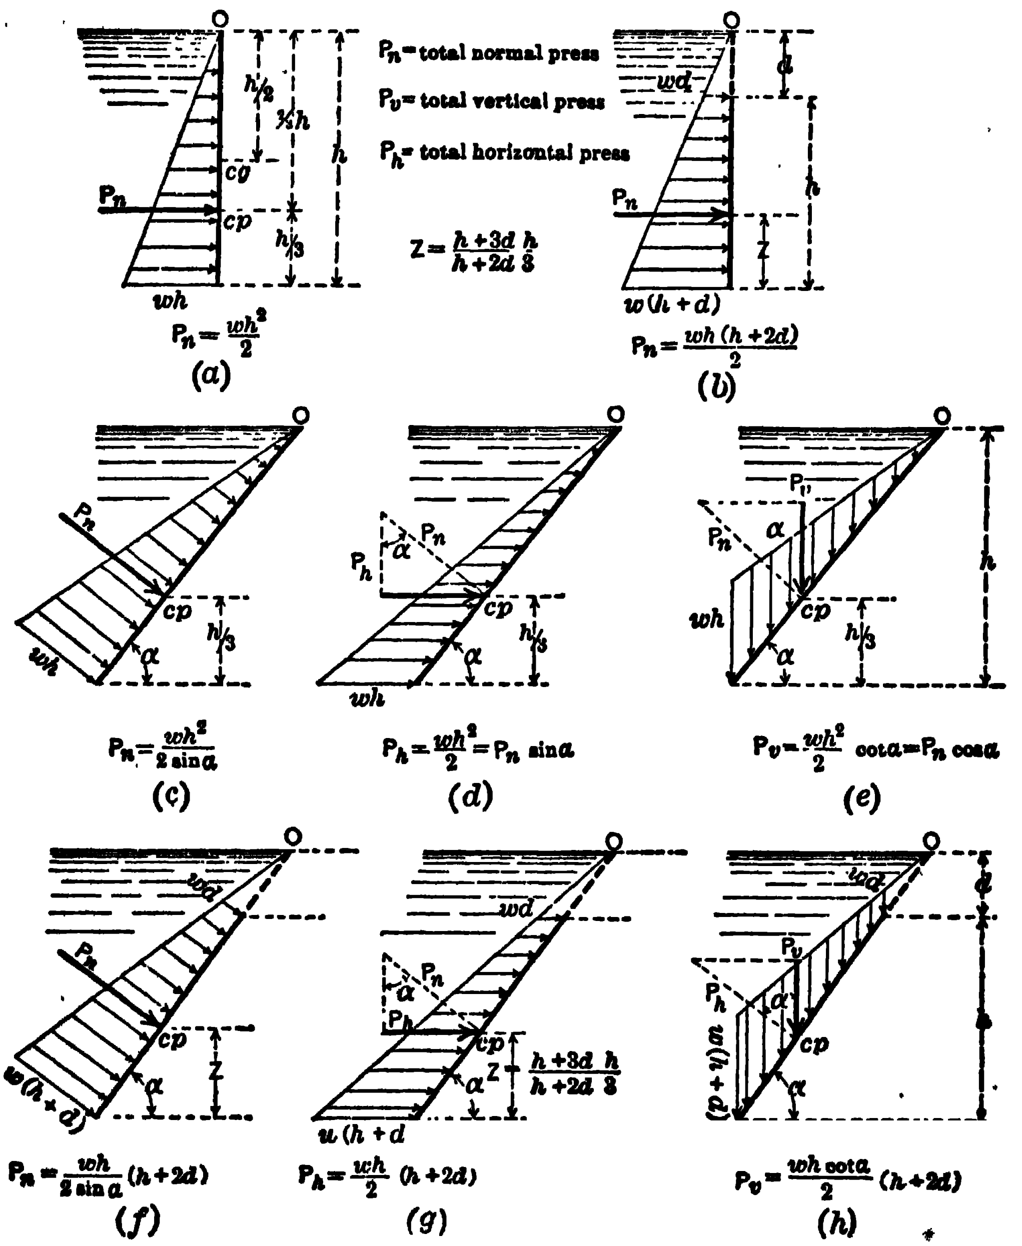

Fig 7. Water-pressure Diagrams

0, and at depth $h = wh$ in all directions; hence the variation is uniform and resultant press acts through the cg of the pressure figure.

In case of press from both sides (Fig 8), the resultant press, represented by arrows and ... by drawing the 2 press triangles, is uniform in intensity and $= wh$ for any depth at right an[gles] water surface a. It depends only on the difference in levels h. Thus a gate

anywhere between a and b would be subjected to the same resultant press, independent of its depth below a. The point of application of the total resultant press against the gate is best found by taking the difference in moments of the 2 press triangles about b.

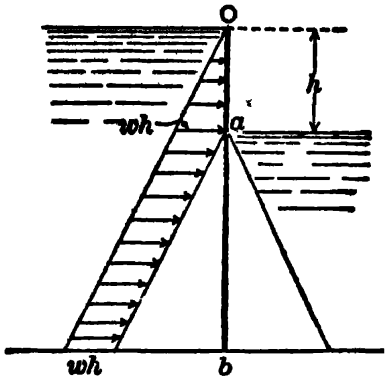

Fig 8

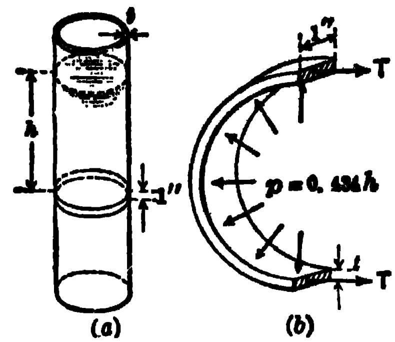

Fig 9. Pressure in Pipes and Tanks

7. PRESSURE IN PIPES AND TANKS

Hoop tension. Considering the vertical section of pipe in Fig 9a as a unit (1 in) in height, subjected to a uniform internal press of p lb per sq in, this press produces tension in the pipe $= T$ (Fig 9b), which tends to rupture the pipe longitudinally. From the principle that the total press in any direction = total normal press on a projection perpendicular to that direction, $2\ T = pd$, or T (lb per lin in of pipe) $= p$ (lb per sq in) $\times\ r$ (radius of pipe, in). If s = allowable stress in shell, lb per sq in, then required thickness t (in) $= pr \div s = 0.434\ hr \div s$, where h = head in ft.

Example. Head, 400 ft; diam, 3 ft; riveted steel pipe; joint efficiency, 70% s = 14 000 lb per sq in. $t = 0.434 \times 400 \times 18 \div (14\,000 \times 0.70) = 0.32$, or $3/8$ in. This formula holds only for thin shells. The limit is usually put at $t = 1/30\ d$. For thick shells, see *Proc* Am Soc Mech Engrs, 1912. Also the press p will be uniform only for a vert pipe, but may be so taken for a small pipe under a large head. For large pipes, besides the allowance for internal press, other factors must be taken into account (Art 14). This principle is used in designing the hoops or bands for wood-stave pipes or water tanks, or for the reinforcing steel in reinforced concrete tanks (Art 13).

8. FLOTATION AND LOSS OF WEIGHT IN WATER

(See Merriman, Treatise on Hydraulics; also Sec 1, Art 3.)

HYDRODYNAMICS

9. FLOW THROUGH ORIFICES AND NOZZLES

Torricelli's theorem (1644). The theoretical veloc of flow from an orifice is the same as that acquired by a body falling freely through a height equal to the head of water on the orifice. That is, theoretically, the veloc of flow in ft per sec from an orifice $= \sqrt{2\ gh}$, where g = accel of gravity, ft per sec per sec, and h = head on orifice, ft. This formula represents a theoretical limit which can not be exceeded by the actual veloc.

Fig 10 shows the STANDARD OR SHARP-EDGED ORIFICE. The contracted vein, or VENA CONTRACTA, of a jet issuing from a standard orifice, is due to the fact that the particles of water converge as they approach the orifice and so continue for a short distance beyond it. The contracted section occurs at a distance from the orifice of about 0.5 the diam of the orifice. Its diam is about 0.785 and its area about 0.62 that of the orifice, this latter figure being the coeff of contraction $= c'$. Experiments show that the aver veloc at the contracted section is about 0.98 ($= c_1$ = coeff of veloc) times the theoretical velocity; hence the veloc in ft per sec in the contracted section $= c_1\sqrt{2\ gh}$, the aver being $0.98\sqrt{2\ gh}$.

Since the discharge, in cu ft per sec, flowing from the orifice $= Q$ = area $\times$ veloc, the theoretical discharge $= av = a\sqrt{2\ gh}$, where a = area of orifice in sq ft. Practically $Q = c'ac_1\sqrt{2\ gh} = ca\sqrt{2\ gh}$, where $c = c'c_1$ = COEFFICIENT OF DISCHARGE, the aver

value of which is 0.605. Theoretically the shape of or head on the orifice has no effect. But experiments show that c is greater for low heads than for high, greater for rectangles than for squares, and greater for squares than for circles, and varies from 0.59 to 0.63 or more. Averages: for rectangular orifice 0.604, for circular 0.597. These averages are for water and, unless otherwise noted, coeffs given herein are for water at aver temp. For fluids in general, $c = 0.592 + 51.6 \div R_0^{0.74}$, where R_0 is a number of the Reynolds type, namely, $d\sqrt{2\,gh} \div \nu$, the $\sqrt{2\,gh}$ being substituted for v, to which it is proportional. Knowing ν for the liquid in question, this equation gives the aver coeff for a standard orifice.

The preceding figures apply also to the contracted section only. A fundamental law of hydrodynamics, the EQUATION OF CONTINUITY, is that for steady flow equal masses or weights of a fluid must pass all cross-sections in equal times. This reduces to equal volumes of liquids, since liquids are practically incompressible. Hence, the discharge in the plane of the orifice must equal that at the contracted section $= ca\sqrt{2\,gh}$, or since $v = Q \div a$, the veloc in the plane of the orifice $= v_0 = ca\sqrt{2\,gh} \div a = c\sqrt{2\,gh} = c'v$. In these formulas the HEAD ON THE ORIFICE should be taken as the head on the center of press,

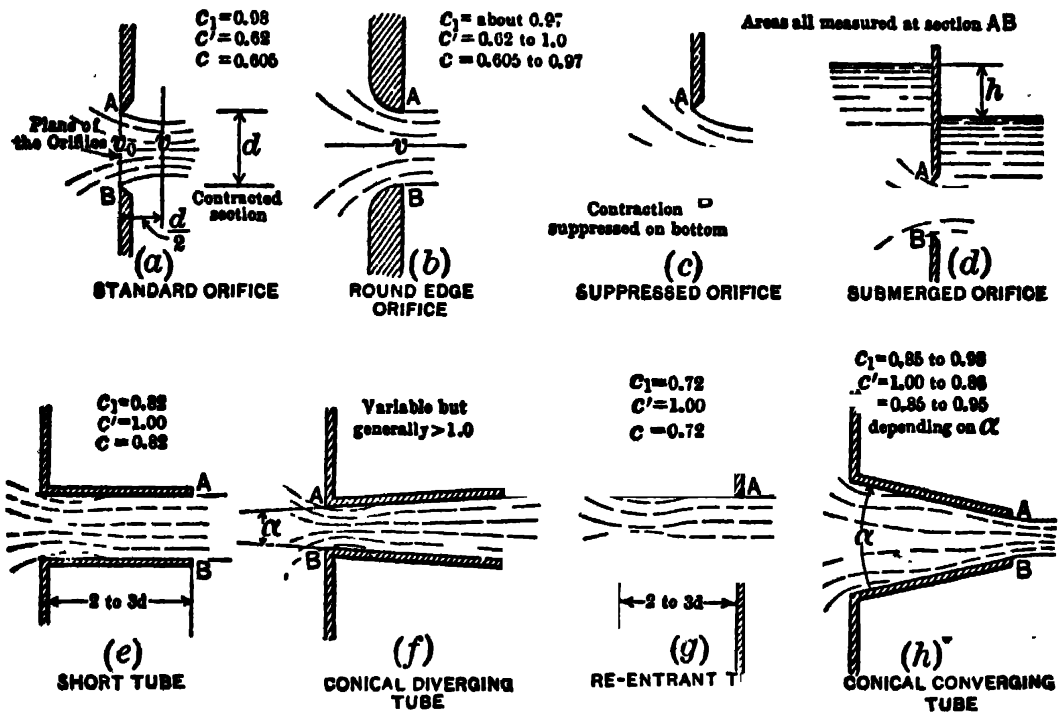

Fig 10. Orifices and Short Tubes

but if the head is greater than 2 or 3 times the vert dimension of the orifice, the head on the center of gravity of the orifice may be used. For a circular orifice the head on the center of press $= (r^2 \div 4\,h) + h$, where r = radius and h = head on cg. For rectangular orifices a convenient formula for small heads is $Q = c\,{}^2\!/_3\,b\sqrt{2\,g}\,(h_2^{3/2} - h_1^{3/2})$, where b = breadth, h_2 = depth to bottom and h_1 = depth to top of orifice. This allows for difference between cp and cg.

Loss of head in an orifice $= h' = (1 - c_1^2)\,h = (1 \div c_1^2 - 1)\,v^2 \div 2\,g = (1 \div c_1^2 - 1)v_0^2 \div c'^2\,2\,g$. For water and with a standard orifice, $c_1 = 0.98$, $c' = 0.62$ and $h' = 0.04$. Also, $h = 0.041\,v^2 \div 2\,g = 0.11\,v_0^2 \div 2\,g$.

Rounded-edge orifices (Fig 10*b*). By rounding the inner edge of an orifice, c' may have any value between 0.62 and 1.0, depending on how closely the rounding corresponds to the contour of the jet. An orifice for measuring discharge should not be round-edged, because of uncertainty in its value of c, but the increase in Q due to rounding may often be turned to advantage.

Suppression of contraction occurs when the orifice edges are nearer than 3 times the least dimension of the orifice from sides or bottom of tank. Preventing the jet from contracting increases c' and hence the discharge.

Submerged orifices. EFFECTIVE HEAD is the difference in level between the 2 water surfaces, and the action of the orifice is independent of its depth below the lower water

surface. In such case, c is slightly smaller than for free discharge into air and is usually taken as 0.60.

Velocity of approach. In above formulas h is taken as constant, but this can occur only when the inflow Q is constant. The water then approaches the orifice with an initial veloc, and the effective head is $H = h + h_v$, where $h_v = v_a^2 + 2g$ and v_a = veloc of approach. For a standard orifice,

$$v = c_1 \sqrt{\frac{2gh}{1 - c^2(a/A)^2}} \text{ and } Q = a \sqrt{\frac{2gh}{(1/c)^2 - (a/A)^2}}$$

where a = area of orifice and A = that of tank. When $a + A$ is 0.2 or less, the error due to neglecting v_a is negligible. In the case of water approaching a large orifice in a canal or conduit, the formula for a rectangular orifice under small head is $Q = c\,^2/_3\, b \sqrt{2g}\,[(h_2 + h_v)^{3/2} - (h_1 + h_v)^{3/2}]$, which is the basis for the Francis weir formulas with v_a.

Time required to empty any vessel of uniform horiz cross-sec is t (sec) $= [2A(\sqrt{H} - \sqrt{h})] + [ca\sqrt{2g}]$, where A = cross-sec area of vessel, a = orifice area, and H = initial and h = final head on orifice.

Flow under pressure may be estimated by the same formulas given above, the press being first reduced to equivalent head.

Example. Find Q when an orifice 3 in diam is first opened in a tank containing 3 ft water with 50 lb per sq in gage air press on top. Effective head $= 3 + 50 \times 144 + 62.5 = 118$ ft. $Q = 0.60 \times (0.785 + 16) \times 8.02 \times \sqrt{118} = 2.52$ cu ft per sec.

For fluids other than water the corresponding wt per cu ft is used to determine the effective head, and c must also be modified. Thus, in preceding example, if the fluid is mercury, $c = 0.62$ and wt $= 850$ lb per cu ft, or $h = 3 + 50 \times 144 + 850 = 11.5$, and $Q = 0.80$ cu ft sec. Same formula is used to find the discharge of air from an orifice, the coeff being about 0.60.

Short tubes are short sections of cylindrical or tapering pipe, used for connecting two vessels or other special purposes. Fig 10 shows some common forms, with their coeffs.

Nozzles are of the smooth or ring type. The former is the commoner. The discharge is given by $q = 29.83\, D^2 \sqrt{\dfrac{p}{\left(\frac{1}{c}\right)^2 - \left(\frac{D}{d}\right)^4}}$, where q = discharge, gal per min, p = press at the nozzle, lb per sq in, c = coeff of discharge $= c_1$ for a smooth nozzle, since there is no contraction, and $c' = 1$. (For smooth nozzle, c varies from 0.990 for a 1-in to 0.997 for a 6-in nozzle.) D = diam of nozzle, in, and d diam of pipe. If q is required in cu ft per sec, use 0.0665 instead of 29.83. This formula allows for velocity of approach, which is sometimes considerable. If p is measured by a Pitot gage held in the nozzle (Art 20), $q = 29.83\, cd^2 \sqrt{p_1}$, where p_1 = press recorded on gage in lb.

10. FLOW OVER WEIRS AND DAMS

Contracted weir (Fig 11) with end contractions is a rectangular notch in the upper edge of a vertical wall. The length of notch is less than that of the channel, and, that the end contraction may be complete, there should be a clearance of not less than 3 h on the sides, and the crest should be at least 3 h from bottom of channel. If the weir is the full width of the channel, contraction is suppressed on the ends and it is known as a SUPPRESSED WEIR, having no end contractions. There are many weir formulas. The rational formula is $Q = c\,^2/_3\, b \sqrt{2g}\, h^{3/2}$, where c is a constant or coeff of discharge, b = breadth, and h = head in ft. It is derived from the orifice formula by letting the head on the top of the orifice = 0. Francis uses $Q = 3.33\, bh^{3/2}$ for a suppressed weir (Table 1), and for a contracted weir, considering the effect of end contractions as reducing effective length of the weir by 0.1 h on each end, $Q = 3.33\,(b - 0.2\,h)\,h^{3/2}$. For Miner's Inch, see Art 20. The coeffs c for weirs do not appear to follow closely a Reynolds Number relationship, being affected also by gravity and surface-tension effects. Data on liquids other than water are lacking.

Velocity of approach affects weir discharge, and for accurate work should be kept below 1 or 2 ft per sec. The effect of v_a can be allowed for by adding to the actual head h on the weir 1.5 h_v, which is obtained from Table 2, using the aver veloc of approach v_a as an argument.

Table 2. Head h_v Due to Velocity of Approach v_a

0.4	0.6	0.8	1.0	1.2	1.4	1.6	1.8	2.0	2.2
0.002	0.005	0.010	0.015	0.022	0.030	0.040	0.050	0.062	0.075
2.4	2.6	2.8	3.0	3.2	3.4	3.6	3.8	4.0	
0.089	0.105	0.122	0.140	0.150	0.179	0.201	0.213	0.248	

Examples. (*a*) Suppressed weir, no veloc of approach, $b = 4$ ft, $h = 1.73$ ft. Find Q. From Table 1, Q per ft of length $= 7.577$ and total $= 7.577 \times 4 = 30.31$ cu ft per sec.

(*b*) Contracted weir, same as above. Q per ft of length $= 7.577$, but effective length $= b - 0.2\,h = 4 - 0.35 = 3.65$ ft, and total $Q = 27.65$ cu ft per sec.

(*c*) Contracted weir as above, with aver veloc of approach of 2 ft per sec. From Table 2, $h_v = 0.062$ and $1.73 + 1.5 \times 0.062 = 1.82$, which from Table 1 gives 8.176 per lin ft, or a total of $8.176 \times 3.65 = 29.80$ cu ft per sec.

To obtain accurate results, the weir must be constructed in a standard manner, similar to that used in obtaining the experimental coefficients: the notch must have sharp edges as for a standard orifice; crest must be level and sides vert; length should be between 4 and 8 h; veloc of approach should be small (area of cross-sec of channel of approach should be at least 6 bh); sides and crest should be 3 h from sides and bottom of channel; head should be measured accurately, 4 to 6 ft upstream, to eliminate effect of slope in the water surface toward the weir (for common work a stake may be driven in the bed of the channel of approach, Fig 12, and cut off level with the weir crest, h being obtained by measuring the water level on a graduated rod held on this stake. For accurate work a hook gage should be used); for suppressed weirs there must be free access of air to the under side of the overflowing sheet of water or NAPPE.

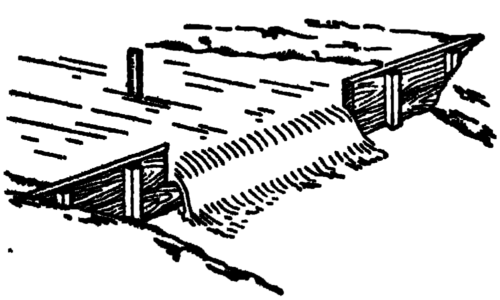

Fig 12. Measuring Flow over Weir

Example. Design a contracted weir to measure the flow of a stream 6 ft wide by 2 ft deep, the aver veloc of which, obtained roughly by a float, was 3 ft per sec. Q = approx 36 cu ft per sec. For a depth of 1 ft, Q (Table 1) $= 3.33$ cu ft per sec per ft of length, and the required length would be $36 \div 3.33$, or 11 ft, which is too long (see above). By further trial, using Table 2, it is found that a weir 8 ft long, with $h = 1.25$ ft, will give the required Q (ratio about 1 : 6.4). Crest of the weir must be about 4 ft ($3\,h = 3.75$) above bottom of stream and width of channel of approach at least 16 ft, as shown by $8 + (2 \times 3 \times 1.25) = 15.5$. If the channel is narrower when flooded, it should be widened or a suppressed weir used.

Triangular weir (Fig 13) is convenient for small quantities of water. It should have sharp inner corners, sides of equal slope, and bottom angle should be a right angle. For this weir $Q = 2.53h^{5/2}$, h being measured from bottom of notch.

Trapezoidal or Cippoletti weir (Fig 14) saves time in computations, as a table may be made or a stick graduated to read the discharge directly, as for a rectangular suppressed

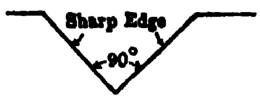

Fig 13. Triangular Weir

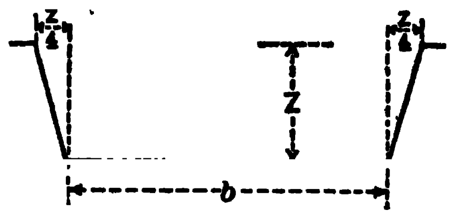

Fig 14. Trapezoidal Weir

weir. Sides are sloped to make the discharge through the triangular end portions equal to the loss due to end contractions ($3.33 \times 0.2 \times h \times h^{3/2}$). End slopes should be 1 on 4, as shown. Formula $Q = 3.367\,bh^{3/2}$ is then used, b being the bottom width. Fig 15 shows a stick graduated to read discharge directly for a trapezoidal weir 1 ft long ($b = 1$).

Spillway dams are a type of weir, but are seldom suited to flow measurement, except approximately, as the coeff in Francis formula (3.33 for standard weir) may vary from 2.5 to 4.2. A sloping upstream face on the dam generally increases the discharge, which is also modified by width and shape of crest and inclination of downstream face. In designing spillways, the flood flow Q is approx known, the breadth b is usually fixed by the flood width of channel below the dam, and the probable flood height h over the spillway may be computed from Francis formula. As it is difficult to determine flood discharge, an ample factor of safety is desirable, and the coeff used should be small enough to be on safe side (3 is a common coeff for masonry spillways).

11. FLOW IN PIPES

Bernoulli (1738) stated the law of steady flow: "At any section of a tube or pipe, under steady flow without friction, the press head plus the veloc head is equal to the hydrostatic head that obtains when there is no flow." This law, together with the equation of continuity (Art 9) and a formula for loss of head in friction, is fundamental in determining flow conditions in pipes.

Loss of head by friction in pipes is inconsiderable for short tubes, and is provided for in the coeff of discharge, but for long pipes it is important and as the length increases consumes most of the available head. The proposed formulas for loss of head in friction are so numerous, and some are so complicated, that the engineer may be at a loss which to use. All reduce practically to one of the two forms given below; their chief value is not in their form, but in the fact that coefficients have been determined from experiments on certain kinds of pipes with use of a particular form of equation, so that in designing a given pipe the equation for which the best coefficients are available should be used.

Hydraulic gradient and friction head. In a pipe of uniform diam the frictional loss is at a uniform rate and hydraulic conditions may be graphically represented as in Fig 16, which shows a uniform pipe leading from a reservoir or tank. With no flow, the static head at end $A = h$. With free flow at A, h is partly converted into veloc of flow (veloc head $h_v = v^2/2g$), but is largely consumed in overcoming frictional and other resistances. A small amount is thus lost at entrance into the pipe (h_e = approx $0.5\,v^2/2g$ for flush entrance), but most of it is frictional loss. Laying these values off to scale gives the construction shown and determine the line BA, or hydraulic gradient. This is the pressure line to which liquid in pressure tubes inserted in the pipe would rise during flow and is important in design.

Entrance loss and veloc head are usually small and, in practice, it is common to neglect them and assume entire head h, available for overcoming frictional resistance. Hence data on frictional losses become vitally important. For all practical purposes, therefore, the hydraulic gradient may be drawn from free water surface to free water surface. Note also that the entire head on end of pipe can seldom be used to produce flow alone. Some terminal press is usually required in connection with use of water, as for developing power, fire service, and hydraulic mining, and h is to be taken as head available for flow only (Fig 20, 27).

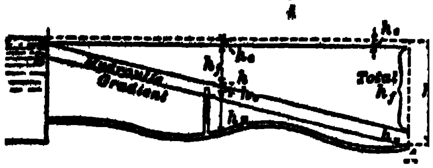

Fig 16. Hydraulic Gradient

Minor losses (usually neglected) also include: Curvature. Least for a 90° bend if the radius is about 3 d. For a 90° bend in 6-in pipe, the loss is nearly equal to that in an 8-ft length of straight pipe, and for 30-in pipe in a length of 40 ft. For intermediate sizes the loss varies roughly with diam. Loss in expansion from a small pipe with veloc v_1, to large pipe with veloc v_2, is $(v_1 - v_2)^2 \div 2g$. Loss in contraction from large to small pipe may be taken $= 0.5\,v^2 \div 2g$, where v = veloc in small pipe. Loss in gates and valves is uncertain, but for full gate is about the same as in a length of straight pipe of 6 d.

Loss of head in friction. Reynolds has shown that there are 2 major types of flow: stream-line or laminar, and turbulent. Underground flow in sands and gravels, and low-veloc flow of heavy oils in pipes, are usually stream-line, while the more rapid flow in pipes and open channels common in engineering practice is turbulent. Transition from one type to the other depends upon character of liquid and dimensions and veloc of flow. It is thus best expressed in terms of Reynolds number R (Art 2). Aver value of this number for pipes is about 2 000 or, for water at normal temps, the veloc × diam is 0.02 to 0.03.

Laminar flow. Experiments show that fluid flow is independent of press; also, it may be demonstrated that the head h_f lost (uselessly dissipated) in laminar flow in pipes $= 32\mu l v \div w d^2$, or (approx) $l^2 v \div Rd$; or the loss in press in lb per sq in per ft of pipe $= 32\mu v \div d^2$. Such flow is purely a viscous shearing phenomenon; veloc at pipe walls is zero, and loss is thus unaffected by the character (roughness or smoothness) of pipe. In porous materials, of flow V in time t in a cross-sectional area of flow A is $kAth \div l$ (Darcy's law), where k is a coeff of permeability depending upon the porosity, shape and grading of material, and the temp of flow.

Turbulent flow. Similar analysis and experiment show that h_f in turbulent flow varies: (a) directly with length of pipe, l; (b) inversely with diam d; (c) directly with the nth power of the veloc v; (d) coeff of friction f, which varies with R and with roughness of the pipe surface. As n appears to approach 2 as a limiting value, it is convenient to express this relationship in terms of the veloc head v_2, by dividing by the constant $2g$, thus: $h_f = f \cdot \frac{l}{d} \cdot \frac{v^2}{2g}$. For smooth pipe (as glass, brass, copper) the value of f is given by the experimentally determined "Blasius-Nikuradse" curve (Fig 17). In designing oil lines (Sec 44), for which steel tubing with usual couplings is employed, the "W M S" line (Wilson, McAdams & Seltzer, *Jour* Ind Eng & Chem, Feb, 1922, p 114) gives values often used. The "Ludin" line is for a "wavy-smooth" composition pipe. Note that the scale dimension used in R for pipes is the diam d; thus $R = vd \div \nu$.

Example. Determine the press drop in lb per sq in per 1 000 ft of line in pumping 500 gal per min of an oil of 29°.1 Baumé gravity and an absolute viscosity of 0.3 poises, at a temp of 50° F, through a smooth pipe of 6-in diam. From conversion chart (Fig 1) 29°.1 Baumé = 0.88 sp gr = 1.71 slugs per cu ft. Also 0.3 poises ÷ 478.8 = 0.00063 ft-lb-sec units. Hence kinematic viscosity = 0.00037. Also 500 gal per min ÷ (7.48 × 60) = 1.11 cu ft per sec. Since d = 0.5 ft, veloc = 5.7 ft per sec. Thus $R = 5.7 \times 0.5 \div 0.00037 = 7\,700$. With this value as argument, Fig 17 (WMS line) gives $f = 0.037$. Substituting in above equation, $hf = 0.037 \times 1\,000 \times (5.7)^2 \div (0.5 \times 64.4) = 37$ ft per 1 000 ft. Or, since $p = wh$, p(lb per sq in) $= 0.434 \times$ sp gr $\times h = 0.434 \times 0.88 \times 37 = 14$ lb per sq in per 1 000 ft.

Flow of water in pipes. Except under extreme conditions of temp, ν for water is fairly constant; hence $v \times d$ may be substituted for R as an argument in determining friction factor f. Conduits used for water frequently have rough surface or, in many cases, corrode or deteriorate with use, and become rough. The smooth-pipe data used for oil lines are thus seldom applicable in the design of water conduits. Such conduits are also often of large size, beyond the range of laboratory experiments. The most valuable data have thus been secured from tests of actual lines in use; they are often fragmentary and seldom cover a wide range of v or d. Yet, empirical formulas derived therefrom have long been used, and recently have been shown to correspond with laboratory tests.

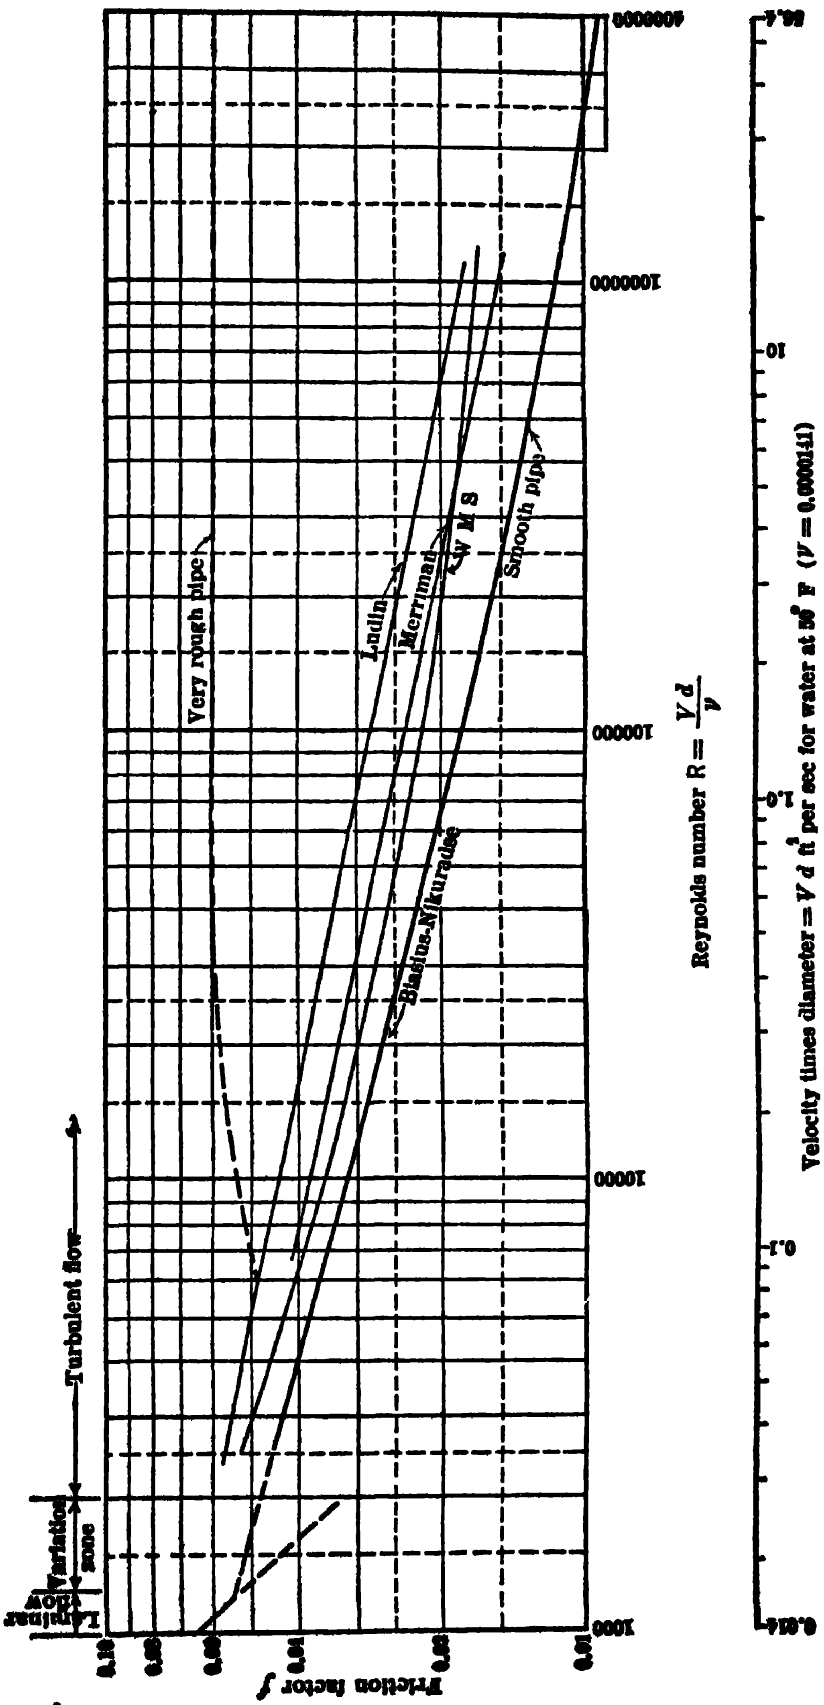

Fig 17 Design Data for "Smooth" Pipe

Chézy formula. For a uniform degree of roughness, the Chézy formula is most widely used for both pipes and open channels: $v = C\sqrt{RS}$, where v is aver veloc of flow, ft per sec. R is HYDRAULIC RADIUS, or hydraulic mean depth, a scale element of flow which, by definition = area a of flowing stream ÷ wetted perimeter p. Slope S is head available for flow, ft per ft = sine of slope of the hydraulic gradient, or practically = $h \div l$, the available head divided by the length of pipe or channel. It is sometimes expressed in ft per mile, per 1 000 ft, or in per cent. C is a coeff of smoothness, increasing with smoothness of surfaces and averaging 80–120 in value. Replacing d of the usual pipe formulas by R makes possible the application of the Chézy equation to any section of flow. For circular pipe, $R = \pi d^2/4 \div \pi d = d/4$. For rectangular flume, 6 ft wide and 3 ft deep, $a = 18$, $p = 12$, and $R = 1.5$ ft. By substituting $d \div 4$ for R, and $h \div l$ for S in the Chézy formula, this is found to be of same type as the pipe formula given above, except that $8g \div C^2$ is substituted for f. Therefore C will vary with R, as does f. This formula is applied, however, only to water, and C thus varies with the quality of the surface of channel n, and with v and d.

Simplest of the several empirical equations for C is the MANNING formula: $C = 1.486\ R^{1/6} \div n$, where n is a surface factor varying from 0.010 for smooth wood pipe, 0.012–0.015 for concrete surfaces, 0.016 for ordinary riveted steel pipes, 0.020–0.025 for good earth canals, to 0.03 for rock cut channels and 0.035–0.060 for rocky streams.

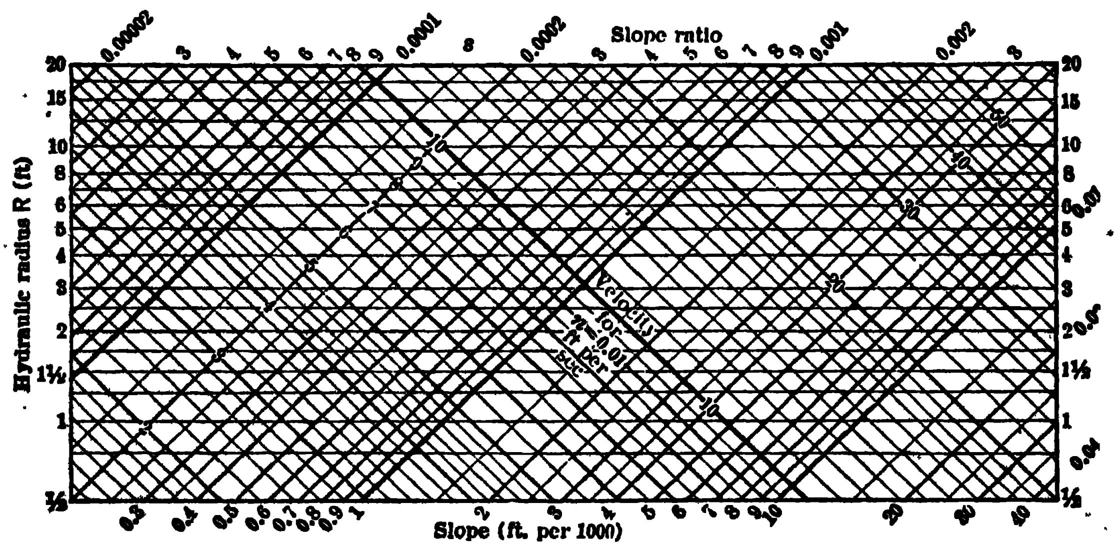

Fig 18. Graphic Solution of Chézy–Manning Formula

This equation makes C independent of v. Laboratory experiments show that for a uniform surface quality and large sizes of conduits, f and C tend to become constant. The relative effect of roughness of surface depends, however, upon the size of the channel; hence the form of the Manning equation.

Combining the Chézy and Manning formulas gives $v = 1.486\ R^{0.67}S^{0.5} \div n$, which, being exponential in form, is easily solved by a logarithmic diagram. Fig 18 shows the relationship of v, R, and S, for usual ranges in value and for $n = 0.01$. Since v varies inversely with n, the diagram may be used for any value of n by introducing a proportional factor.

Example 1. A wood-stave pipe is 6 ft diam and 2 miles long; available head, 10 ft. If $n = 0.011$, what are v and Q? $R = 6 \div 4 = 1.5$. $S = 0.95$ ft per 1 000. Enter diagram at slope 0.95 (interpolated between 0.90 and 1.0), following slope line to intersection with R value of 1.5. This point falls on v scale between 5 and 5.5 and v is estimated at 5.3 ft per sec. Since the diagram is made for $n = 0.01$, v for 0.011 would be $^{10}/_{11}$ of 5.3 or 4.9 ft per sec. Since $a = 28.2$ sq ft, $Q = a \times v = 138$ cu ft per sec. *Example 2.* A riveted steel pipe 4 ft diam and 5 000 ft long is to carry 60 cu ft per sec; $n = 0.016$. What head is required? $R = 1.0$ ft. $a = 12.6$ sq ft; hence $v = 60 \div 12.6$ or 4.8 ft per sec. Since diagram is for $n = 0.10$, whereas, here, $n = 0.016$, the v used in diagram should be $0.016 \div 0.01$ or $1.6 \times 4.8 = 7.7$ ft per sec. Enter diagram with $R = 1.0$ and run to intersection with interpolated line for $v = 7.7$. Position of this intersection on S scale gives $S = 2.7$ ft per 1 000 ft, or total h required $= 2.7 \times 5 = 13.5$ ft. For other problems, see Art 15.

Limits of application. Chézy formula is best used for velocities between 1 and 6 ft per sec, but is fairly reliable up to 10 ft. For hydraulic radii greater than 10 ft, velocities

greater than 10 ft per sec, or slopes flatter than 1 in 10 000, it should be used with caution. For R or v greater than 20, it is unreliable. Results from the formula must not be expected to be consistently closer than 5%. For values of n recommended for use in design see Art 14, 15. It can be shown that S varies as n^2 for values of R greater than 1 ft, and that v varies approximately inversely as n. An uncertainty of x% in selecting n will therefore result in an uncertainty in a computed slope of twice this amount, or 2 x%, and in a computed velocity of x%.

Exponential formulas. While the Chézy-Manning formula fits conditions for larger and rougher conduits, measurements of smaller pipes, of smoother surface, or of scattered roughness such as caused by pitting, indicate that f (or C) does not tend toward a constant value, but varies with changes in both diam and veloc.

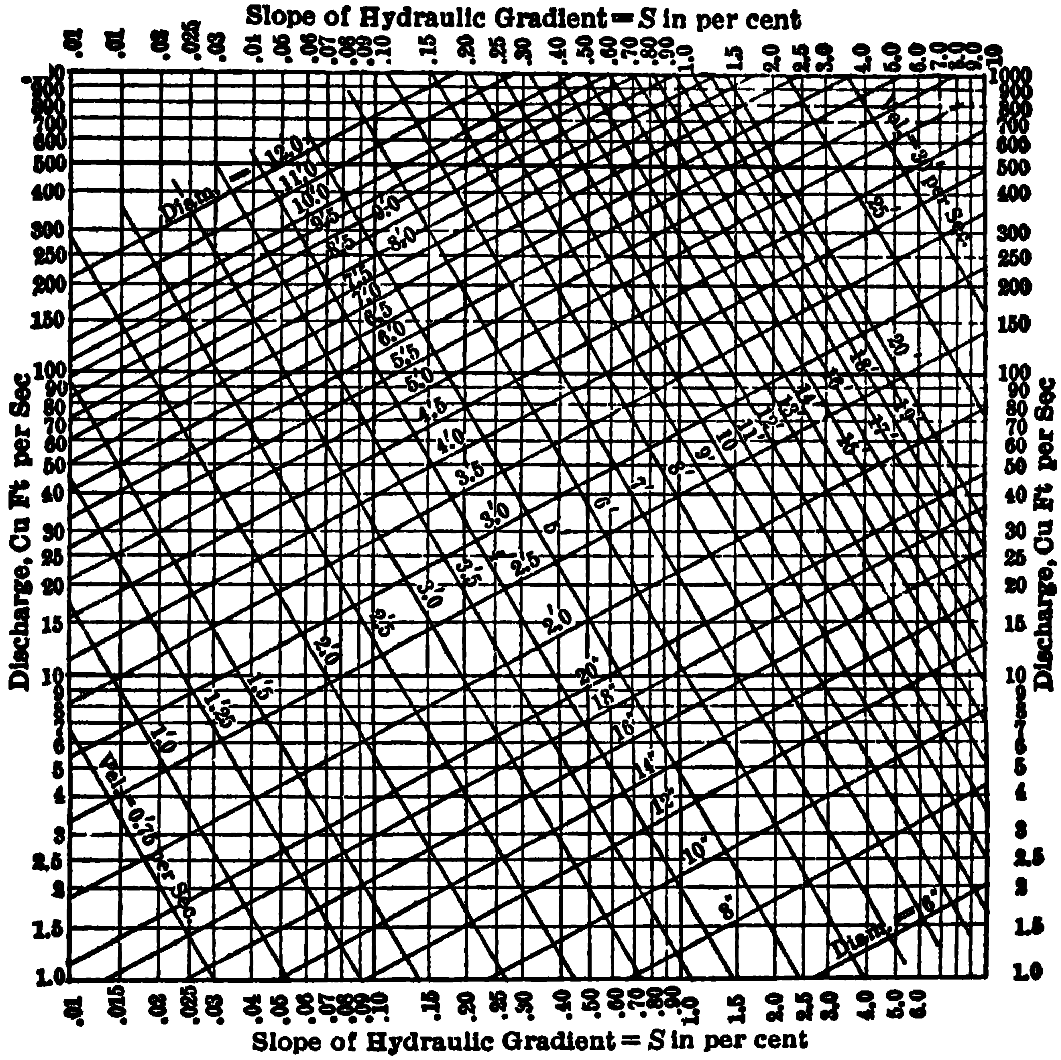

Fig 19. Diagram for Solving Hazen-Williams Formula

For example, the "Merriman" line in Fig 17 is an aver for smooth, new-coated, C-I pipe; a similar line with higher values of f and a different slope would represent older, pitted pipe. Thus, the "smooth pipe" line is the lower limit and a line such as the upper dotted "rough pipe" line of Fig 17 represents a typical upper limit in the range of f for pipes. (The Chézy-Manning equation applies to the horiz portion of this rough-pipe line and intermediate lines of similar form.) Intermediate types of pipe often appear to fall in a class giving data corresponding to the sloping "Merriman" curve, intermediate between these limits. An exact correlation of such data would require a special equation for each size of pipe, but aver data may be approximated by an exponential equation, like the Chézy-Manning, but with different constants and exponents.

Among the better known empirical equations designed to fit aver quality and range of v and d for smaller pipes is the Hazen-Williams formula, $v = 1.318cR^{0.63}S^{0.54}$ (Hydraulic Tables. Wiley, N Y, 1905.) The quantity 1.318 is introduced to make the value of c about the same as that of the Chézy constant C.

Hasen-Williams advise following values of c: for very best C-I pipe, 140; good new C-I pipe, 130; tuberculated C-I pipe, 80 to 110; designing C-I pipe, 100; new riveted steel pipe, 110; ordinary W-I pipe, 100; lead, brass, tin pipe, 140; smooth wood pipe, 120; vitrified pipe, 110; brick sewers, 100; smooth clean masonry, 140; slime-coated masonry, 130; ordinary good masonry, 120.

The diagram, Fig 19 (S. D. Bleich, *Eng Rec*, Nov 30, 1907), is convenient for solving Hasen-Williams formula. It is constructed for $c = 100$; for other values of c multiply the required discharge by $100 \div c$, and the resulting value of Q must be used to get the size of pipe and veloc. Then multiply this veloc by the ratio $c \div 100$ to get the true value.

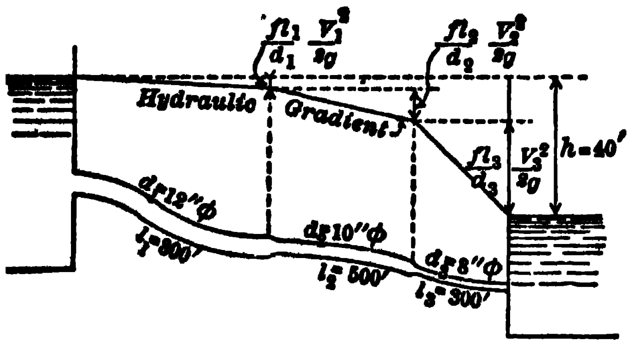

Fig 20. Hydraulic Gradient for Compound Pipe

Example 1. A C-I pipe is to carry 10 cu ft per sec, length 1 000 ft, available head 10 ft. Using $c = 100$, find required size. $S = 1$ ft per 100, and running vert from this slope in the diagram to the intersection with the horiz line representing a discharge of 10 cu ft per sec, the intersection is found to be slightly below the 18-in diam line, indicating that an 18-in pipe is needed, and the mean veloc is slightly less than 6 ft per sec. *Example 2.* A wood pipe is 4 000 ft long, and is to discharge 60 cu ft per sec with 20-ft available head. Find d and v. In this case $c = 120$. Multiply Q by $100 \div 120$, giving $Q = 50$, and enter the diagram with this value and a slope $S = 0.5$ ft per 100, as before. Hence, $d = 38$ in and $v = 6.5$ ft per sec. Actual v will be $6.5 \times 1.20 = 7.8$ ft per sec.

The Hasen-Williams formula was derived largely from a study of C-I pipe, and is best applied to design of this type. In general, however, the designer selects the nearest standard size of pipe and no great refinement in calculation is necessary. Similar formulas for other kinds of pipe have been derived by Scobey: for wood-stave, $v = 184R^{0.65}S^{0.55}$; concrete pipe, $v = 127R^{0.625}S^{0.5}$. See *Tech Bulletins* of U S Dept of Agriculture.

Compound pipes. Algebraic expressions can be derived, giving exact relations between discharge and head for compound pipes, but it is simpler to solve these problems by determining size of a single pipe that will be equivalent to the given combination; that is, such a size as will give same loss of head for a given discharge.

Example. Find the discharge from the compound pipe in Fig 20. Take $c = 100$ in Hasen-Williams formula. Assume any convenient and reasonable Q, say 3 cu ft per sec. From Hasen-Williams diagram find for the 8, 10, and 12-in pipes the required grades or loss of head in per cent, viz, 5, 1.8, and 0.7 for this Q, which, multiplied by the respective lengths, give 15, 9, and 5.6 ft, or a total of 29.6 ft necessary head. As the total length is 1 600 ft, this represents an aver loss of 1.85 ft per 100, and the uniform pipe which would give a discharge of 3 cu ft per sec with this hydraulic gradient would be (from diagram) about 9.8 in diam. Actual available head is 40 ft ($S = 2.5\%$), and Q for a 9.8-in pipe with this head is 3.5 cu ft per sec, the required value.

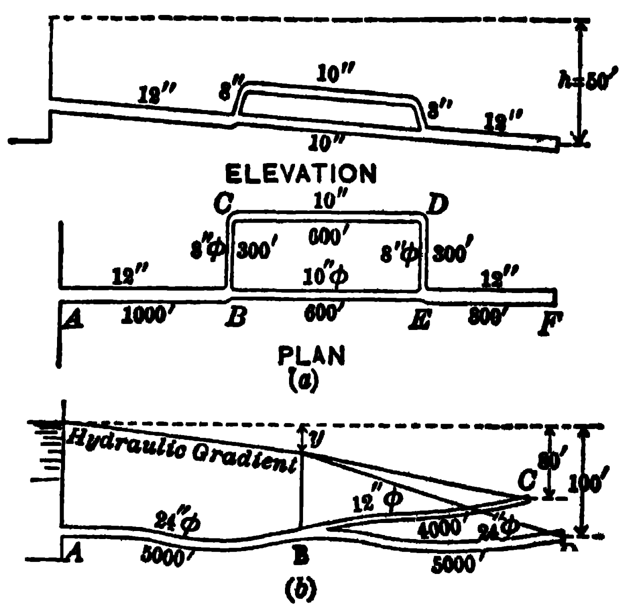

Fig 21. Branch Pipes

Branch pipes, as shown in Fig 21*a*, may be solved similarly. First find size of uniform pipe to replace *BCDE*, as above. This is found to be 8.8 in. Now the loss of head between *B* and *E* must be the same by both routes, *BE* and *BCDE*. Assume any reasonable loss of head, say 15 ft, and find discharge by each route. For the *BE* pipe (10 in, 600 ft long), $S = 2.5$ ft per 100, and from the diagram $Q = 3.7$ cu ft per sec. For 8.8-in

pipe 1 200 ft long, $S = 1.25$ and $Q = 1.8$. Total discharge = 5.5 cu ft per sec, and diam of pipe 600 ft long which will deliver 5.5 cu ft per sec under a head of 15 ft is found from the diagram to be 11.5 in. The problem is thus reduced to that in Fig 20, which when computed as above for compound pipes, assuming a Q of 6 cu ft per sec, gives uniform pipe of 11.9 in, the discharge for 2 400 ft of which under a 50-ft head is 5.2 cu ft per sec.

Fig 21b shows another problem in branch pipes. It may be solved algebraically, but more easily by trial. A certain portion y of the head up to the fork must be used up in causing a discharge through AB that will just equal the sum of the discharges through BC and BD under the remaining heads $80 - y$ and $100 - y$. Value of y is best found by trial. From Fig 21b, since lengths AB and BD are same, it is evident that y must be more than 50, and by a few trials it is found that $y = 58$ will give satisfactory results, the total discharge being 23 cu ft per sec ($BC = 2.6$ and $BD = 20.5$).

12. FLOW IN OPEN CHANNELS

In open channels, as canals or ditches, or in pipes, aqueducts or tunnels flowing part full and, hence, not under press, the hydraulic gradient coincides with water surface and slope S is slope of this surface. The Chézy formula is commonly used in design (Art 16).

Earlier practice used the Kutter rather than the simpler Manning formula for C, and in legal cases in West, this is still widely recognized in courts. (Flow of Water in Rivers and other Channels. Transl by Hering and Trautwine, Wiley & Sons.) The KUTTER FORMULA is:

$$C = \frac{\dfrac{1.811}{n} + 41.65 + \dfrac{0.00281}{S}}{1 + \dfrac{n}{\sqrt{R}}\left(41.65 + \dfrac{0.00281}{S}\right)}$$

where n, R, and S are defined as in the Chézy-Manning formula.

Usual problems in non-pressure, or open channel flow, deal with steady, established, *uniform flow*, that is, constant flow in channels of uniform slope and cross-sec. The surface and bottom slopes of the channel are the same, and S is utilized entirely for overcoming frictional resistances. Thus the "energy of flow," $E = d^2 + v^2 + 2g$ is constant, where d is depth of the channel and v the veloc of flow. This requirement may be met by two depths or stages (levels or elevations) of flow. Thus, for 50 cu ft per sec discharge, a d of 9.6 ft with an aver v of 5.2 ft per sec, or a d of 2.2 ft with $v = 22.7$ ft per sec are possible. The former is known as the TRANQUIL STAGE OF FLOW and commonly occurs in slow flowing, low-slope streams, canals and other conduits. The latter, TORRENTIAL FLOW, requires steep slopes and is found in the overflow, or spillway, sections of dams, in inclined chutes, or in the escape from partially opened sluices. The slope required to maintain such flow is generally lacking and a sudden rise in water surface, known as the HYDRAULIC JUMP, occurs when flow changes from torrential to tranquil stage. This phenomenon is important in the design of spillway dams and outlets.

Occasionally, problems in steady NON-UNIFORM FLOW are encountered, as constant flow in channels of varying cross-sec. Then, E is not constant, but energy may be added to or taken from the flowing stream. The water surface may form a BACKWATER CURVE, where veloc is retarded as depth increases, or a DROP-DOWN CURVE, where reverse conditions hold. The CRITICAL DEPTH, or depth for minimum E, is an important criterion in determining whether the flow will form a jump or a backwater curve, a drop or a drop-down curve. For these special problems of non-pressure flow, see "Hydraulics of Open Channels," B. A. Bakhmeteff, McGraw-Hill, 1932.

DESIGN

13. KINDS OF PIPE

Standard sizes. In computing the necessary diam for a pipe no great degree of refinement is ordinarily necessary, as it reduces to a question of selecting a standard size. The relative discharge capac of pipes varies as the $^5/_2$ power of the diam (about) and is shown below, using a 4-in pipe as 1. An 8-in pipe will carry 6.5 + 3, or over twice as much as a 6-in pipe; hence no very accurate computations are necessary to determine which is required.

Diam..................	4	6	8	10	11	14	16	20	24	30	36
Relative capacity......	1	3	6.5	12	20	30	43	80	130	235	390

Cast-iron pipe. Standard sizes are 4, 6, 8, 10, 12, 14, 16, 18, 20, 24, 30, 36, 42, 48, 54, and 60 in, usually made in 12-ft lengths, with bell and spigot or flanged joints (Sec 41).

The latter is used for pump connections, or wherever it may be occasionally necessary to remove sections of pipe. Bell and spigot is common for water and gas mains. The joint is made by first packing with oakum, then pouring a collar of lead around the bell, which is afterwards calked tight (Table 3). Cement joints are commonly used for gas mains. Pipe is made in standard sizes and thicknesses (Table 3); for large orders, any desired thickness is obtainable.

C-I pipe is usually in 12-ft lengths, cast with bell down, and cleaned and dipped in hot tar and linseed oil for a protective coating. In recent years, spun or centrifugally cast pipe has become the predominating type, and length has been increased, reducing number of joints. This process gives a denser, stronger metal, and thicknesses given in Table 3 can be correspondingly reduced (see catalogues of makers).

C-I pipe is subject to formation of tubercles of rust (particularly when used for impure water or water containing free CO_2), which seriously affects its carrying capac, but usually without greatly impairing its strength. Probably Hazen-Williams formula (Art 11) is the best to use in design, and while the value of c may reach 140 for new pipe, about 100 must be used if the carrying capac is to be maintained over a period of years. In laying C-I pipe, "bell holes" should be dug for the joints, so that the pipe will have a firm support over its entire length and not rest on the ends; for large sizes the back fill should be well tamped around the pipe and for a depth of 2 or 3 ft over it, to relieve the pipe from excessive external loading. C-I pipe has an aver life of 40 to 80 years or more. Cost varies considerably, averaging between $45 and $60 a ton. Special shapes, as Ys, Ts, curves and blow-off branches, aver $100 a ton. See Sec 41.

W-I pipe was formerly made in considerable quantities, but has been practically replaced by mild steel (frequently sold as wrt iron). The relative durability of the two materials has long been a matter of dispute, but since 1916 only 1 or 2 firms in U S make a real W-I pipe, so that there is seldom opportunity to choose between them.

Steel pipe is welded, ordinary riveted, spiral riveted, and lock bar. BUTT or LAP-WELDED PIPE is of mild steel, from $^1/_8$ to 15 in nominal diam (actual internal diam varies, Sec 41). It is used for steam and water connections in mechanical work, for interior piping in water supply, gas and heating, and for supply pipe lines and pumping. It is standard for most service, when the required size is 10 or 12 in or less. Quite recently the making of lap-welded pipe of larger sizes has been developed; it is now made to 72 in diam, and is used in water-power work for high heads, where the saving in metal due to its greater joint strength and perfectly smooth interior make it more economical than riveted pipe.

Riveted steel pipe is used chiefly in large sizes and for high heads. It is made of curved sheets, the longit edges of which are joined usually by a double-riveted lap joint, although in the larger sizes butt joints double or triple-riveted with single or double cover plates are used. Sizes to 30 in diam are sometimes made of single sheets in 12- or 15-ft lengths. Larger sizes are made with single-riveted lap transverse joints. Field joints between the lengths are made in several ways. For low press and pipes to 40 in diam, a slip joint may be used. A sleeve is placed inside and attached to one end of the pipe, which is covered with burlap or canvas coated with red lead or asphaltum and then driven into the end of the next length and held by wire ties. For higher press, the pipe ends are riveted to forged steel flanges, connected by bolts and gaskets. Fig 22 shows several joints. Bolted joints are also used, which not only act as expansion joints but also allow a slight deflection and permit straight pipe to be laid on easy curves. Lengths of large pipe are riveted or welded together in the field. For design of riveted joints see Sec 43.

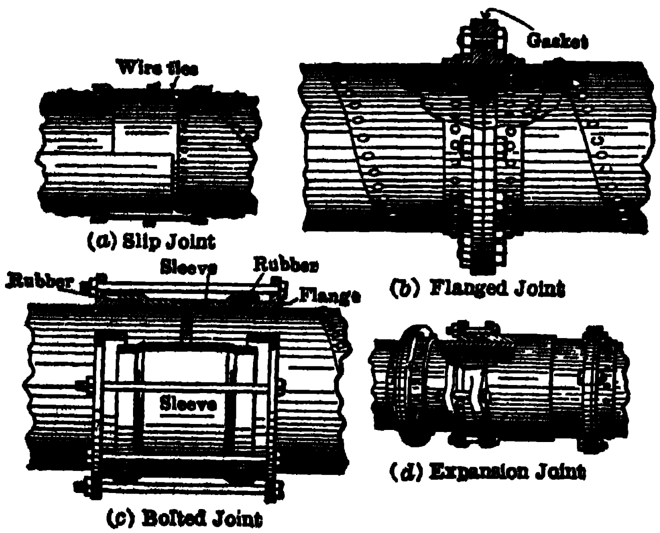

Fig 22. Steel-pipe Joints

Spiral-riveted pipe is frequently used for smaller heads and in sizes to 42 in (Sec 43). It is made in 15-ft lengths galvanized, and 30 or 40 ft, asphalt coated. Each length is of a single sheet, rolled with overlapping edges forming a single-riveted spiral seam. This gives an effic joint against bursting, and the seam is said to be the strongest part of the pipe. In large sizes it is not thicker than 0.25 in, and though used for ordinary water or

low-head pipe lines, is best for construction work where its great strength as a beam saves necessity of frequent supports. Also, for its strength, it is the lightest steel pipe made.

Lock-bar pipe is a form of steel pipe in which a 100% efficient joint is obtained by bending a steel plate to the proper form. The edges, first upset, are inserted in the open grooves of a "lock bar" or small H-section, which is closed over the upset edges by a hydraulic press.

Life of steel pipe depends on so many factors that it can be given only in general terms. Unlike CI, which rusts more or less uniformly, steel often pits through in places. Thin steel pipes, $^1/_8$ in or even less in thickness, have lasted 15 or 20 years. A thickness not less than 0.25 in should give a useful life of 25 years or more.

Carrying capac of small sizes of steel pipe may be found by the Hazen-Williams formula (Art 11). For large, riveted pipe, with rivet heads and seams projecting on inside, the Chésy formula is often used with $n = 0.016$. Formula $V = 1.34\ D^{0.7}H^{0.555}$ is also used, where V = veloc, ft per sec, D = diam, ft, and H = loss of head, ft per 1 000.

Wood pipe has 2 forms: continuous-stave, built in place, and machine-banded made in lengths in factories.

Continuous-stave pipe has been built up to 14 ft diam; it is rarely made less than 2 ft diam. It is best adapted to moderate pressures, from a min of 20 ft head (considered necessary to keep the wood saturated and prevent decay) to a max of 200 to 250 ft. Advantages for large diam pipe: low cost, great carrying capac (n = 0.009 to 0.011 in Chésy's formula); easy transport of material, curves of moderate radius readily made, less liable to freeze than steel, greater strength against deformation than thin steel. Staves are milled with radial edges, to form true circular inside and outside surfaces. They have a length of 10 ft and upward, aver 16 ft, and are placed so as to break

joint by 2 ft. Joints between ends of staves are made by metal tongues inserted in saw kerfs (Fig 23). Hoops are usually of round, mild steel, in one piece for pipes to 54 in diam. They have button head on one end, and cold-rolled threads for 5 in or more on other end, which is often upset to make thread as strong as body of bar. Ends of hoop rest in a malleable iron shoe, and the band is cinched up by a hex nut. All metal work is heated and dipped in a mixture of asphalt and linseed oil, and touched up after placing. Pipe is built by using an outside form for lower half, building up both sides at same time, and an inside form for upper half resting on lower half. Sharp curves are to be avoided. A radius of 60 times the diam is the usual minimum, but this has been exceeded. MATERIAL FOR STAVES is usually Redwood, Douglas fir or Oregon yellow pine. Redwood is considered by many to be too soft. Staves are milled from standard thickness of lumber for each diam.

Diameter of pipe		Nominal thickness of staves	
10 to 14 in	54 in	1.5 in thick, 4 in wide	2.5 in thick, 8 in wide
16 to 48 in	60 to 72 in	2 in thick, 6 in wide	3 in thick, 8 in wide

Actual dimensions of staves vary with each diam. The only computation made is for size and spacing of bands. BANDS. If safe strength of band (lb) = s, then $s = s\pi r^2$, where s = safe tensile strength, usually 15 000 lb per sq in, and r = radius of band, in. Bands may cause failure by breaking in tension, or by crushing the wood fibers. The safe crushing load on wood can in this case be taken as 650 lb per sq in. Width of bearing of band on wood = r, and some specifications require that band be hammered into the wood until this bearing is secured. Hence, safe load on band would be $s = (R + t)\ 650\ r$, where R = radius and t = thickness of pipe, in. For economical design, diam of band should be such that values of s figured from either formula are equal, or $r = 0.0138\ (R + t)$. Diams of $^3/_8$, $^7/_{16}$, $^1/_2$, $^5/_8$, $^3/_4$, and $^7/_8$ in are used. SPACING OF BANDS is determined by the hoop tension due to water press, and by the tension produced by swelling of the wood. Using the minimum s (see above) the spacing of bands, in = $s \div (pR \times et)$, where p = water press, lb per sq in, and e = swelling force of the bands, which can not exceed the compressive strength of wet wood and may be taken as 100–125 lb per sq in. LIFE OF WOOD PIPE is very variable, depending on conditions under which it is used. A buried pipe line, with a cover of 2 ft or more of clean soil free from alkali or vegetable matter and maintained under a head of 20 ft or more, will have a longer life (25–50 years) than a line above ground. Under less favorable conditions, life is 6–15 years, and the pipe is best supported on cradles or sills. Connections are made by inserting steel Ts or branches in the line, to which the wood pipe is firmly secured.

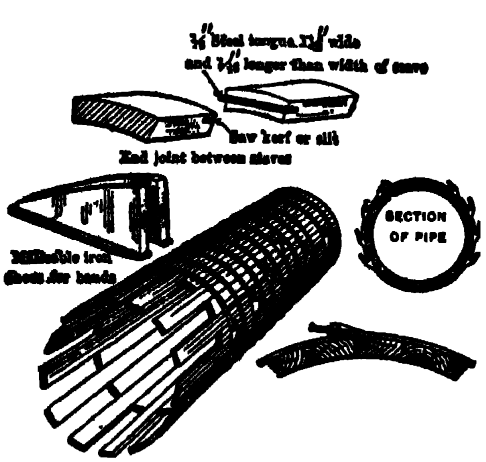

Fig 23. Continuous Wood-stave Pipe

Machine-banded pipe is built in the factory in lengths of 8–20 ft and diam ranging from 6–48 in, usually not over 24 in. Pipe is of staves with edges milled to form tongue and groove joints, banded with double galvanised steel wire, wound spirally by machine under high tension. Wire is No 8–0, size and spacing being regulated according to the press. Flat steel bands are also used. The outside of the pipe is heavily coated with hot asphalt and tar, and rolled in sawdust to make it better to handle and ship. The inserted joint (Fig 24) is for pipes to 14 in diam. A wooden collar or wood-sleeve coupling is used on larger sizes. This form has been used for water-supply pipes, instead of cast iron, also in hydraulic mining, and is useful for same service as continuous pipe, but where smaller sizes are required.

Concrete pipe has been used for drains, culverts, and for distributing water under heads of less than 15 or 20 ft. The mixture is 1 : 3 or 4 Portland cement and fine pit or bank gravel, cast in metal molds. A thin interior coating of neat cement is advisable to make the pipe less pervious. Joints are made tapering (Fig 25a). The bell end is well cleaned and filled with 1 : 2 cement mortar, and is then jammed against the taper end of previous length. Surplus mortar is removed, and a mortar band 3 in wide by 0.5 in thick is formed on outside of pipe.

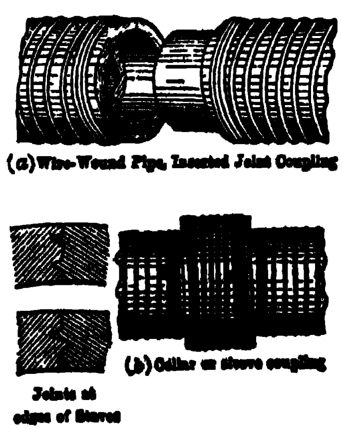

Fig 24. Machine-banded Wood Pipe

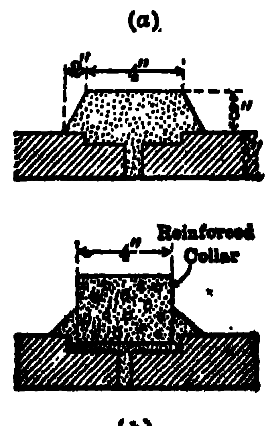

Fig 25. Concrete Pipes

Reinforced-concrete pipe for very large diam is built in place in the trench. Ordinary sizes are made in metal forms. It has been built to stand a press of 100 ft head, but the limit is generally

smaller. U S Reclamation Service has used it for upper part of wood-stave lines, where the head is 20 ft or less and wood pipe undesirable. The pipe is usually of 3 to 6 or 8-ft lengths, of 1 : 1.5 : 3 or 1 : 2 : 4 concrete, the thickness being 1 in for each ft of diam. Spiral reinforcing, held at proper pitch by spacing bars, takes the entire hoop tension. Plain wire is used, computed for a stress of 12 000 lb per sq in, and a size that gives a pitch not over 1.5 or 2 in. For joints, see Fig 25b.

Vitrified tile pipe is the commonest for sewers and drains to 36 in, but is usually 24 in and under. It is made in 24, 30, and 36-in lengths, with bell joints like C-I pipe, filled with jute packing and cement mortar. As it is never under press, only the external loading is important, and the standard thicknesses ($1/16$ to $1/12$ of the diam) are satisfactory if properly backfilled. Standard sizes, 4, 6, 8, 10, 12, 15, 18, 21, 24, 27, 30, 33, and 36 in.

14. STRESSES IN PIPES

Hoop tension is important in pressure pipes, and is the principal stress for which they are designed. Based on Art 7, the general formula is $t = \frac{(p + p')r}{s} + K$, where t = necessary thickness of shell, in, p = static press, lb per sq in (= 0.434 times head in ft), p' = allowance for water hammer, lb per sq in, r = radius of pipe, in, s = allowable stress in shell, lb per sq in, K = constant, added to the thickness determined by press considerations alone, to allow for deterioration, safety in handling, eccentricity, etc. Wood-stave pipe requires special design (Art 13).

The values of s and K depend on the material of which the pipe is made. For C I, s has been taken from 3 500–6 000 lb per sq in and K usually at 0.25 or 0.3 in. For steel pipe, s is taken at 14 000–16 000 lb or more and K at $1/16$–0.1 in. For permanent construction, thickness is usually $1/8$ in minimum for small pipes, and 0.25 in for diam over 2 or 3 ft.

Water-hammer is caused by suddenly stopping the flow in a pipe, as by quick closing of a valve at the lower end. The value of p' depends on length l (ft), veloc of flow v (ft per sec), and the time t (sec) of closing the valve. The press p_1, lb per sq in, above the normal press of the flowing water p_0, = $0.027\ lv \div t$, or = $63\ v$; the former expression to be used when t exceeds 0.000428 l, and the latter when t equals or is less than this value (Merriman). p' will then equal $p_1 + p_0 - p$. To make $p' = 0$, the time of closing is $t = 0.027\ lv \div (p - p_0)$. In water-power penstocks, relief valves, standpipes or surge tanks, are used to relieve the press caused by water-hammer. On long lines, valves are so arranged that they can not be closed quickly, and it is generally assumed that the water ram caused by closing a gate valve will not exceed 0.5 p. In designing C-I water pipes, values of p' are usually 100 to 120 lb per sq in for 4 to 10-in pipes, to 70 lb for 42 to 60-in pipes.

Backfill pressure may be important where pipe is laid in a deep trench. Steel pipe is seldom placed under deep cover. Cast iron usually has sufficient thickness, when in standard sizes or designed as above, to resist bending due to earth covering up to 20 ft or more in depth. Tile pipe is made only in standard thicknesses and must be carefully backfilled with selected material free from large stones, and well tamped around and for 2 or 3 ft over the pipe. Careful backfilling of trenches in any case is always wise. Concrete pipe is sometimes designed to withstand external loading.

Formula $t = 1/2 d\sqrt{h \div s}$ may be used in design as a rough check, t, d, and s, in, being same as for hoop tension, and h = depth of fill, ft. Wt of fill is say 100 lb per cu ft, and h is usually taken at 0.5 to $2/3$ the total depth, to allow for arch action. The amount and distribution of load is uncertain. Formula assumes the load to be uniformly distributed over the upper half of the pipe, and that it is resisted by uniform press over the lower half. This produces a moment in the shell M, in-lb per in of length = $1/16\ Wd$; where W = total load per linear in of pipe and d = diam, in. A concentrated load produces a positive moment $M = 0.159\ Wd$ at top and a negative moment = $0.091\ Wd$ at sides. Careless backfill may cause some other mode of loading (*Bull* No 22, Univ of Ill Expt Sta, 1908).

External atmospheric pressure, due to the pipe being placed above the hydraulic gradient, or to lack of or inadequate air valves, has often caused collapse of thin steel and wood-stave pipes. It is important only in lines of this kind. When the internal press becomes less than atmospheric, the shell is subjected to a uniform external press = p = difference between atmospheric (14.7 lb per sq in) and the absolute internal press; this causes circumferential compression in the pipe shell. The collapsing pressure for steel pipe, lb per sq in = p = about 50 200 000 $(t \div d)^3$. Air valves of too small a size may require a greater suction head than this amount, in order to supply air fast enough to fill the pipe when it is emptied quickly, intentionally, or due to a break. It is generally more economical to provide one or several air valves of ample area at all summits, than to increase the pipe thickness or to provide flanges to increase its collapsing strength.

Bending stresses due to wt of pipe and water are important in large steel pipes under low heads. They are usually provided for, not by increasing the thickness of shell, which

is uneconomical, but by placing a concrete saddle under the pipe, or by riveting to the pipe at short intervals curved hoops made of angles with an outstanding edge.

Maximum moment occurs at bottom of the pipe, and is due to the water load. M, ft-lb per lin ft of pipe $= CwR^3$, where C depends on angular length of the saddle (the angle at center of pipe subtended by the saddle) and has the following approx values: for $\alpha = 0°$, $C = 0.75$; $\alpha = 15°$, $C = 0.56$; $\alpha = 30°$, $C = 0.42$; $\alpha = 45°$, $C = 0.32$. W = wt of water, lb per cu ft ($= 62.5$) and R = radius of pipe. Knowing R and α, it is possible to test a pipe for bending due to this cause, the fiber stress in the shell being found by the usual formula (Sec 43), and if necessary the size and spacing required for angle stiffeners are computed.

Temperature range of a pipe depends on whether it is covered, and on its size. A short steel pipe of large diam full of water has a temp range nearly equal to that of the water (usually 32° to about 80° F); a long covered pipe line of small diam has a temp range about that of the soil, which depends on depth of cover and seldom exceeds 40° F for a 2-ft cover. If uncovered and with low flow, a small pipe may have a range almost equal to that of an empty pipe. Variations in temp produce longit stresses in a pipe that is fixed, so as neither to contract nor expand, the direction (tension or compression) and amount of which depend on the temp at which the pipe was laid. These stresses may cause buckling, and in many exposed pipes EXPANSION JOINTS are provided at intervals and the tops of saddles are made smooth to allow expansion and contraction without excessive friction. Fig 22d shows a common expansion joint. These joints are usually placed just below the anchorages on exposed pipe lines, and as anchorages occur at all bends at least one expansion joint is required on each straight portion of the pipe, and intermediate expansion joints are desirable on long stretches of straight pipe.

15. DESIGN OF PIPE LINES. VALVES AND ANCHORAGES

In general, pipe lines should be kept below the hydraulic gradient (Art 11). If they rise above it siphon action is created, which is undesirable because: (*a*) it interferes with the action of the pipe line and usually causes decreased or uncertain discharge; (*b*) the pipe at high points is under external press and liable to collapse. A profile of the proposed line should therefore be carefully studied respecting the hydraulic gradient.

Fig 26 shows profile of a pipe line. If a uniform diam is used from E to B, laid on surface of the ground (ECB), and the pipe discharges freely at B, the hydraulic gradient will run from A to B, provided the pipe is first filled and then a valve at B opened. Part of the pipe near C will be above the hydraulic gradient, and therefore subject to what is termed negative press, but which is really negative only in the sense of its being less than atmospheric, not less than zero. As long as CF is not over about 25 ft, the pipe will act as a siphon, discharging under the head h. But it is almost impossible to make the pipe tight, and air will collect at C and finally break the suction action. The pipe will then discharge at C, under the head h' (the hydraulic gradient running from A to C) and a certain quantity of water Q, less than the remaining portion CB could discharge under the head $h - h'$. The portion CB will therefore carry off this Q, flowing only partly full.

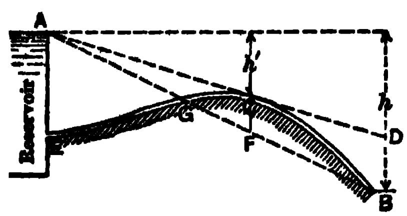

Fig 26. Profile of a Pipe Line

This action may be avoided in several ways: (*a*) Valve at B may be partly closed, causing the gradient to rise to D and acting as an orifice, the discharge of which under head DB just equals the discharge of pipe under head $h - DB$. This does away with negative press at C, but the discharge of the line is less than with siphon action. Also sudden opening of the valve at B, even if it is not opened more than the necessary amount stated above, may cause the "accelerating gradient" to fall below C until the water gets in motion and normal conditions are reached, so that air valves should be placed at C if there is danger of collapse; (*b*) if constant operation is unnecessary and negative press not liable to cause collapse, the valve at B may be closed at intervals, which puts the pipe at C under static press equal to head h'. A valve at C may then be opened and air allowed to escape. It would be advisable in this case to place a large air receiver at C, to collect the air in this tank above the pipe and not decrease the pipe section at this point; (*c*) a trench can be dug from G to B, to keep the pipe below the gradient, but this may be costly; (*d*) a compound pipe may be used, and this is usually the most satisfactory method. A large size is used from E to C, to deliver say 10% more water under the head h' than a smaller size, running from C to B, will deliver under the head $h - h'$.

Example (Fig 27). Pipe line from A to C is to deliver 2 cu ft per sec at C, with a terminal press of 25 lb per sq in ($= 25 \times 2.30 = 57.5$ ft head). If the pipe delivers this quantity when reservoir is empty, available head causing flow $= 130 - 6 - 57.5 = 66.5$ ft. For a uniform pipe, with slope 1.75 per 100, and $c = 100$, $d = 8.6$ in (Fig 19b); hence, use a 9 or 10-in pipe. With

this, the gradient will be AC', with siphon action present. Also, a uniform 14-in pipe is required to keep gradient above B, and flow at C must be throttled. Using a compound pipe for BC, the available head $= 130 - 11 - 57.5 = 61.5$ ft (slope 3.4 ft per 100) and nearest standard size (Fig 19) is 8 in. With this head an 8-in pipe will discharge 2.4 cu ft per sec. For the AB section the available slope (reservoir empty) is 0.25 ft per 100, and a 14-in pipe gives 2.5 cu ft per sec.

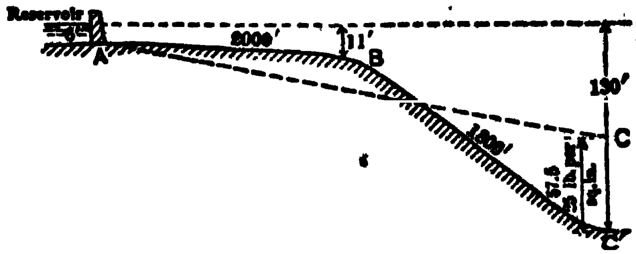

Fig 27. Profile of a Pipe Line

Fig 28 shows hydraulic gradient for conditions arising in pumping through pipes. Case *a* shows conditions in pumping from A to B against static head AC, and that the pump works under total head AD. In a pipe line for pumping it is usually economical to keep velocity (and hence friction head) low; say between 1.5 and 3 ft per sec, depending on cost of pipe and of pumping. In designing line AB, an economical velocity is computed or assumed, and area and diam of pipe found for required discharge. Friction head is then found from diagram.

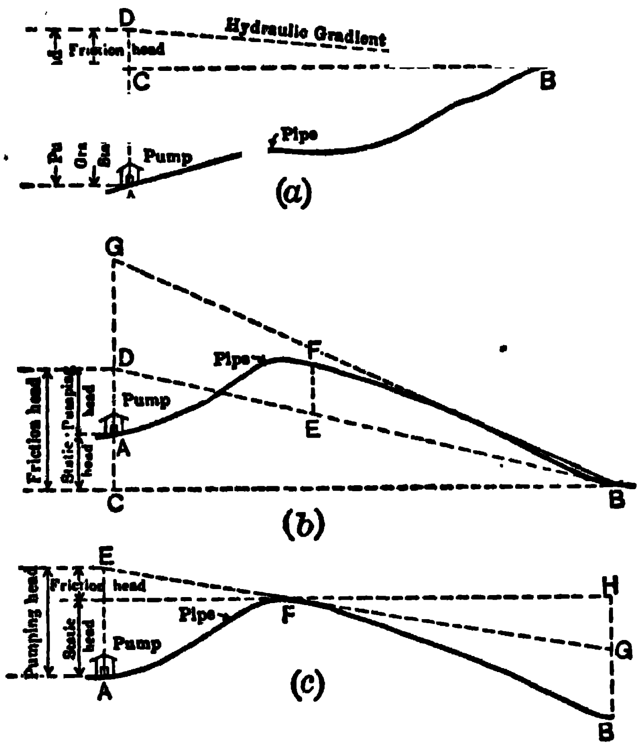

Fig 28. Examples of Hydraulic Gradient

In case *b*, if pipe AFB is once filled it would discharge under head AC, as in Fig 26, the hydraulic gradient running from A to B, provided distance EF does not exceed about 25 ft. If water is pumped through pipe AFB, the friction head is DC and the pump acts against head $DC - AC$, provided FE is as stated above. If FE be greater, the hydraulic gradient changes to that shown in case *c*, the pump then acting under head AE, and the pipe between F and B carrying off the discharge at F and flowing only partly full.

If negative press is not permissible at F, the hydraulic gradient must be kept above F. This can be done: I, by increasing the head against which the pump is working to head AG (case *b*), which involves a smaller pipe, with increase of veloc and friction head for the same discharge; II, by designing a pipe between A and F that will give an economical veloc and using a size from F to B that will just carry off this discharge under head BH; III, by placing a valve at B and throttling the flow as in case *c*. Here the gradient may be raised to line EG and kept above F. In this case air valves should be placed at F. If it is desired to take advantage of gradient DB (case *b*), steel pipe is necessary for the part above the gradient, made thick enough to withstand the difference in press (Art 14), or C-I pipe might be used. There must be a valve at B, to prime the siphon.

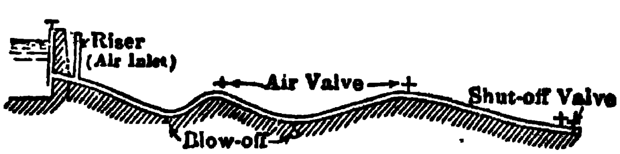

Fig 29. Profile of a Pipe Line

Valves. Fig 29 shows the profile of a pipe line, with location of valves. AIR VALVES, to permit escape of air on filling, and entrance of air on emptying, are placed at every summit and at shut-off valves. For a shallow reservoir, best type of air inlet is a simple standpipe, rising above water level in reservoir. Air valves are often automatic; float valves have been used, automatically permitting escape of air collecting at summits. Air collects at all summits, and must be removed, as by ordinary gate-valves operated by hand. The necessity of ample air valves to prevent formation of vacuum in steel pipe lines has been discussed. BLOW-OFF VALVES are placed at low points in pipe lines for emptying the pipe when necessary and for removal of sediment. These are gate-valves,

placed on a waste pipe (about 1/3 the diam of main pipe) leading to discharge in a stream or waste channel. SHUT-OFF OR STOP VALVES (ordinary gate-valves) are placed at end of pipe, and, in long pipes, at intervals of 1 to 2 miles along the line. This permits inspection and repair of any section, without emptying the entire line, and in case of breakage water may be shut off at nearest valve, thus preventing wastage and serious damage. These valves are usually placed at summits, with air valves on each side. A lock and chain are put on all valves to prevent tampering; on large lines the valves are in covered manholes with locks. For large diam lines, a small by-pass pipe with separate valve is added; it is left open to relieve the press while the large valve is being closed. Cost of gate-valves increases rapidly with the size; a saving in cost at a slight loss in head may be obtained by decreasing the diam of pipe at points where valves are placed by using suitable reducers and tapering increases. CHECK-VALVES are used mainly on pump lines, at points where breakage would permit large backward flow of water, as at foot of inclines (at A, Fig 28a, b and c), and on inlet pipe just outside tanks or standpipes. For small sizes a flap valve is used. For pipes larger than 24 in, a diaphragm or valve plate is cast in an enlarged section of the pipe, and a number of small valves attached to holes in the plate. A small by-pass is sometimes used to avoid heavy water-hammer, caused by sudden closing of valve with pulsations of pump. RELIEF (SAFETY) VALVES are occasionally used at ends of long pipe lines, or wherever water-hammer is especially to be feared. They are simple disk valves, opening outwards and held in place by springs adjusted to the press.

Freezing in pipes seldom gives trouble when there is continual flow. To prevent freezing in steel pipes, Bouche's formula is sometimes used to find necessary discharge in cu ft per sec: $q = 0.000045\ TA$, where A = exposed area of pipe and T = air temp in degrees F below 32°. Where velocities are very low at times, as in water-supply mains, pipes must be buried (3 to 5 ft, according to climate) or else protected by packing.

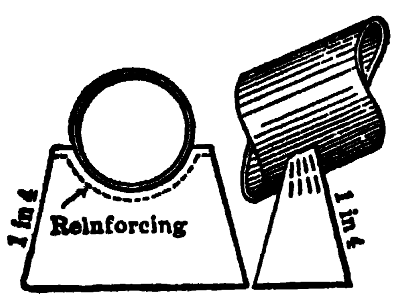

Fig 30. Concrete Pipe Support

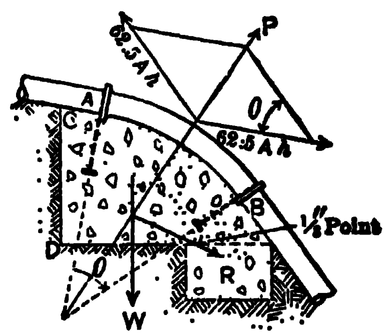

Fig 31. Concrete Anchorage

Pipe supports are required where pipe is placed above ground surface. Wood supports are common for wood pipe; for steel, concrete supports (Fig 30) are usual. Distance between supports is roughly estimated by considering the pipe as a continuous beam, loaded with its own wt plus wt of water, and using a low fiber stress.

Anchorages are necessary for exposed pipe at all bends where the resultant press may throw it out of line, at valves subjected to heavy static or water-hammer press, and on steep slopes.

On steep slopes, the pipe is usually anchored by wire or metal ties, carried to a deadman (heavy buried timber or a mass of concrete). Fig 31 shows a concrete anchorage on a bend. Anchors are at A and B. Pressures on the pipe at A and B are equal, producing an outward thrust $P = 125\ Ah\ \sin\ (\theta + 2)$, where A = area of pipe and h = static head. There is also the centrifugal force acting outward, $F = Wv^2 + 2\ gR$, where W = wt in lb of water contained in the bend between the 2 end faces A and B, v = veloc, ft per sec, g = 32.2, and R = radius of curvature of bend, ft. It may also be necessary to take into account pull produced by temp, sliding force caused by tendency of pipe to slide down hill, and earth press against the face CD. The resultant of all these forces, combined with wt of concrete acting through its center of gravity, should strike within middle third of base (Sec 43)

16. DESIGN OF DITCHES AND CANALS

(In what follows, the word "ditch" is used to include "canals.")

Hydraulic radius. When the cross-sec area of a channel and its grade are fixed, the form of cross-sec having the greatest hydraulic radius (least wetted perimeter, Art 12) will give greatest velocity and discharge. For this result, the proportions are such that the hydraulic radius = 0.5 the depth. For a rectangular section (flume or rock-cut) these considerations indicate that depth should be 0.5 the breadth, as this gives the least wetted perimeter (and hence least cost for a flume); it also gives least area for a given discharge, and hence least cost for a rock cut). For a trapezoidal section the most economical form is half of a hexagon; or, if side slopes are assumed, the best section is found by drawing

tangents to a half circle having a radius equal to the depth (Fig 32). Other practical considerations, however, result in marked variations from these sections in usual designs (see later notes).

Unlined ditches in earth. The CROSS-SECTIONAL PROPORTIONS in Fig 32 are not used, because they give sections that are too narrow and deep. Such sections are unstable; they will widen out on the sides and silt up in the center, and are seldom economical to

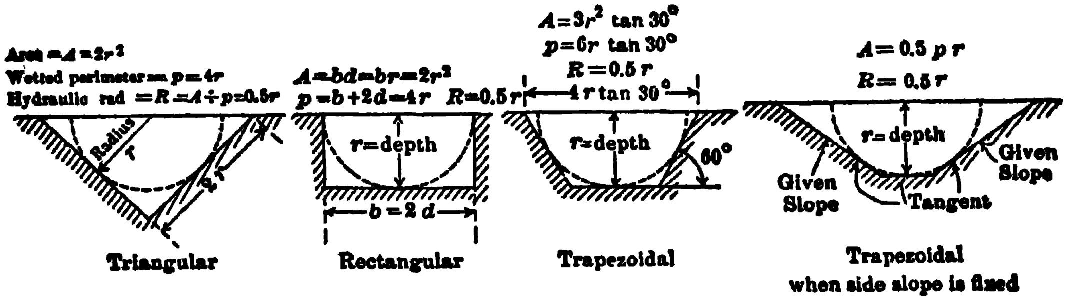

Fig 32. Cross-sections having Most Advantageous Elements

dig, as scrapers are generally used and a shallow cut is necessary. Deep narrow ditches require shoveling.

Proper proportions are largely a matter of judgment, depending on character of soil and mode of excavation. Average U S practice is to make $d = 0.5\sqrt{A}$, where d = depth, ft, and A = area, sq ft. This rule gives following depths:

Area, sq ft......	5	10	25	50	75	100	200	400
Depth, ft........	1.1	1.5	2.5	3.4	4.3	5.0	7.1	10

These values are exceeded for special conditions, as on steep hill sides where a narrow, deep section (with lining for stability if necessary) is often economical in excavation. Where water carries much silt the section may be shallower. Usual SIDE SLOPES are 1 : 1, 1.5 : 1, and 2 : 1. On steep hillsides in firm soil a 1 : 1 slope both for ditch section and outer side slope of bank is used. Any section gradually becomes rounded, the lower parts of the slopes becoming flatter, the upper parts steeper. For aver loam or gravelly loam, a slope 1.5 : 1 is used; for loose sandy loam, 2 : 1. About 1 ft freeboard is common for small, and a max of 3 ft for large ditches. Safe rule: make the freeboard $^1/_3\, d$. TOP WIDTH of ditch bank may be fixed by what is required for its use as a road (10 to 12 ft); it ranges from about 2 ft for small, to a max of 10 ft for large ditches, and is usually about equal to depth of water (Fig 33).

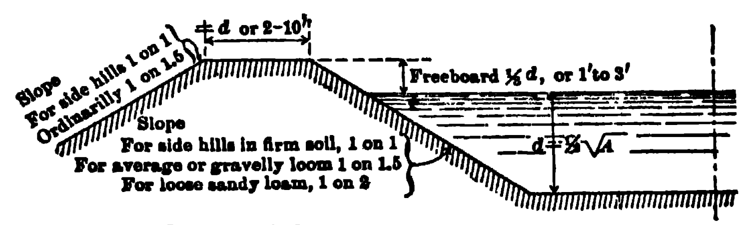

Fig 33. Side Slopes for Ditch or Canal

Velocity of water must not be high enough to erode the bottom, thus deepening the cut and making it difficult to divert water. But, there should be a certain minimum, to prevent deposit of silt and excessive growth of water plants. Experience in U S is that a veloc over 2 ft per sec will prevent deposit, and the following max mean velocities are safe against erosion. (Note.—Bottom veloc is generally about 75% of the mean.)

	Ft per sec		Ft per sec
Very light loose sand.............	1.0 to 1.5	Conglomerate, cemented gravel, soft rock......................	6.0 to 8.0
Average sandy soil...............	2.0 to 2.5	Hard rock......................	10.0 to 15.0
Average loam or alluvial soil......	2.75 to 3.0	Concrete, water carrying coarse sand	7.0 to 12.0
Stiff clay or ordinary gravel.......	4.0 to 5.0	Concrete, water carrying fine sand.	15.0 to 20.0
Coarse gravel or cobbles..........	5.0 to 6.0		

The above figures show that for ditches in earth the usual veloc is 2 to 3 ft per sec, which generally requires a slope of 4 to 7 ft per mile. A section may be designed as in the example following, and located to have the required slope; or, if the slope is fixed and small, it may be necessary to line the ditch to obtain the required discharge. On the other hand, if a large slope is available, the ditch may be excavated at the max desirable slope, and the extra head used up by constructing CHUTE DROPS, commonly designed as water-cushion

or baffle spillways (Fig 34). In some cases where no supporting ground is available, the ditch must be constructed on the given slope and lined to prevent erosion.

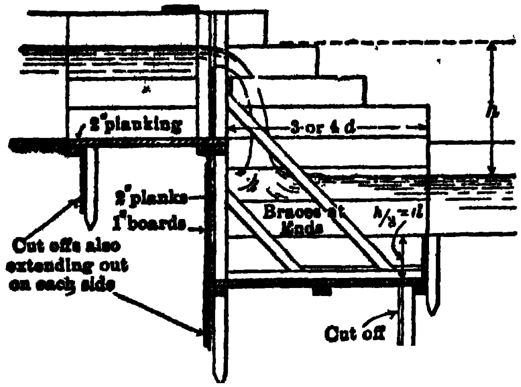

Fig 34. Vertical Drop in a Ditch

Chésy formula, with C determined from Manning (or Kutter) formula, is generally used for ditches and flumes. Most engineers take $n = 0.025$ for aver earth, n actually ranges from 0.02 for firm soil, trimmed smooth with a shovel, to 0.03 for rough gravelly surfaces, the aver for most irrigating ditches in Western U S being 0.0225.

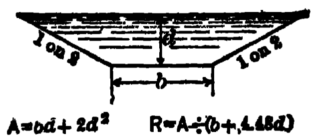

Fig 35. Cross-section of a Ditch

Example. Design a ditch in earth to carry 2 500 miner's inches of water, and compute the required slope. Assume $n = 0.025$ and safe velocity $= 2.5$ ft per sec. Discharge is $2\,500 \div 40. = 62.5$ cu ft per sec, and required area $= 62.5 \div 2.5 = 25$ sq ft. Desirable depth $= 0.5\sqrt{A} = 2.5$ ft. With 1 : 2 side slopes, area will be $bd + 2\,d^2$ (Fig 35), and $b = (25 - 12.5) \div 2.5 = 5$ ft. Hydraulic radius $R = A \div (b + 4.48\,d) = 25 \div 16.2 = 1.54$ ft. Using the diagram (Art 11, Fig 19), the required slope is found to be 1.0 ft per 1 000 ft.

The center line of the ditch should be so located that the cut will make the required fill plus the shrinkage, except where it is advisable to keep the water section entirely in cut because of danger from breaks. Breaks are especially to be feared on steep hillsides, even when the sod under the fill is furrowed with a plow to give a good bond between the fill and original ground surface.

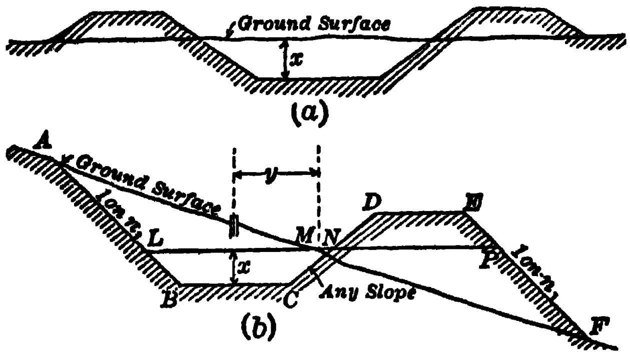

Fig 36. Balancing Cut and Fill

For level cuttings with 2 banks the economic cut x is computed to balance the section (Fig 36*a*). For side-hill work, 1 bank only is generally required, and the "pivot-point" method of locating the center line is used (Fig 36*b*). The section $ABCDEF$ being designed, a horiz line LP is drawn through the section, so that cut $LBCN$ makes the fill $NDEP$ plus shrinkage (usually 10%). Line LP is then divided into 2 parts by point M, equal if no allowance is made for shrinkage, or for 10% shrinkage such that $LM : MP :: \sqrt{100} : \sqrt{90}$. M is the pivot point, and for any slope as AF drawn through N the cut will balance the fill. M must thus be located on the ground as a point on a grade contour x ft above the bottom of the ditch, and center line will be a distance y up hill from M; x and y are independent of slope of side hill, and remain the same for any given cross-sec.

17. LOSSES IN DITCHES AND CANALS, DITCH STRUCTURES, FLUMES

Seepage losses often amount to 25% or more of the water delivered at the upper end of a ditch, and must be allowed for in computing the carrying capacity. The loss depends on the character of the material in which the ditch is excavated, whether it is or is not lined, on the relation of the water level in the ditch to the water level of the adjacent ground, and on the age of the ditch. If the ditch is below groundwater level, there will be inflow from the adjoining land and vice versa. In many cases the ditch is above groundwater influence, and the seepage loss in cu ft may be computed from the following table (Etcheverry):

Material	Loss, cu ft per 24 hr, per sq ft wetted perimeter	Material	Loss, cu ft per 24 hr, per sq ft wetted perimeter
Impervious clay loam	0.25–0.35	Sandy loam	1.00–1.50
Ordinary clay loam, silt, or lava ash loam	0.50–0.75	Loose sandy soils	1.50–1.75
Gravelly clay loam, sandy clay loam or cemented gravel	0.75–1.00	Gravelly sandy soils	2.00–2.50
		Porous gravelly soils	2.50–3.00
		Very gravelly soils	3.00–6.00

Ditch linings are to prevent excessive seepage losses, or to permit higher veloc than is permissible in earthy soils. Higher veloc is advisable in some cases for economy, the cross-sec and seepage loss being smaller; and also in cases where topography is such that supporting ground is not available for a combination of earth ditch and vertical drops or chutes to use up excessive head.

Details. About 3 gal heated heavy asphalt road oil per sq yd, applied in 2 or 3 light doses and raked into the upper 2 or 3 in of the soil, will reduce seepage loss to about 40% of value for untreated. It also prevents growth of vegetation and allows increase in veloc to about 5 ft per sec, but is not permanent, requiring renewal every 2 to 4 years. CLAY PUDDLE, consisting of a 3 to 4-in layer of well-tamped clay, is as effective stopping seepage as oiling, but does not allow any higher veloc or prevent growth of vegetation. WOOD planking, nailed to sills set in sides and bottom of ditch is effective, but due to high cost and short life is seldom as economical cement or concrete. CEMENT MORTAR lining, 1 cement to 4 sand, 1 in thick, will prevent 75% of the seepage. CONCRETE lining, 1 : 2 : 4, 2 to 4 in thick, will stop 95% of the loss. The concrete is placed with or without forms. On slopes of 1 to 1 or less, no forms are used, the lining being placed like cement sidewalks, grooved every 8 or 12 ft to reduce width of contraction joints by making them form at frequent intervals. For steeper side slopes heavier side linings are required and forms are used. Instead of trimming the bank to correct slope, it is best to use an outside form, filling in with wetted earth up to this form, and using an inner form for the concrete. A solid foundation is important, as the concrete has little strength and will crack if foundation settles or pockets are washed out under it. Proper drainage is essential to keep material compact and dry, and prevent heaving due to frost.

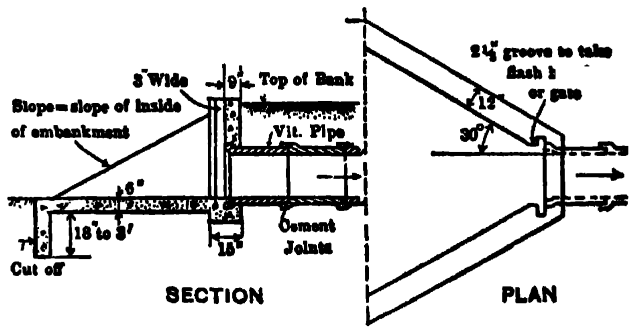

Fig 37. Turnout from Ditch

Ditch structures. TURNOUTS are to distribute water from main ditch to laterals. For small ditches, a wooden box will answer; for larger, where repairs would be costly, a permanent vitrified or cement pipe culvert is desirable (Fig 37). Connections of siphons, culverts, flumes and turnouts, to an earth ditch must be carefully made, to prevent leakage at these points, with danger of washout. CHECKS are to hold flow-back, so as to supply a turnout with proper amount of water. They are sometimes also used as small DROPS (Fig 34) to decrease the grade. CHUTES are long, lined sections on a steep grade, with a water cushion at the bottom to kill high velocity. WASTEWAYS are overflow weirs to carry off flood flows, or turnouts to a stream channel which act as blow-offs to empty the ditch. They are installed on many long lines.

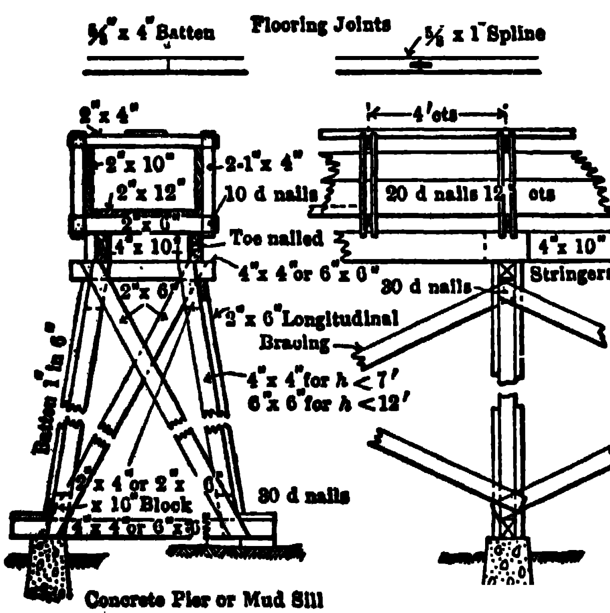

Fig 38. Details of Flume Construction

Flumes (Fig 38) are used to cross valleys, and on hillsides where the slopes are too steep or the soil is unsuited to an open ditch. The latter are called bench flumes. Breadth of flume box is generally twice the water depth (Art 16). Bench flumes are often narrower, and trestle flumes wider. Freeboard (in) may be made equal to (depth of water, ft + 12) + 2. Flume lining should be of 1.5 in, or better 2-in plank.

There are two forms of flume box: (*a*) sills are placed across the stringers, and flooring is laid parallel to direction of flow, like the sides; (*b*) flooring is transverse and nailed to stringers. The first is best and easiest to keep tight and repair. Foundations and sills are of 2 × 12 or 3 × 12-in plank, or concrete posts. Bents are spaced 12 to 18 ft centers, and stringers are designed to carry the load at a low unit stress. Semi-circular continuous wood-stave pipe has also been used for flumes; now often replaced by semi-circular steel flumes. Several patented forms, made in Denver and San Francisco, are moderate in cost, easily and quickly constructed, and watertight.

HYDRAULIC MEASUREMENTS

18. MEASUREMENT OF WATER LEVEL

Non-recording instruments. Simplest is a graduated GAGE BOARD, or piece of an old level rod, fastened to side of tank or reservoir, and read where water level cuts the rod. It can be read to

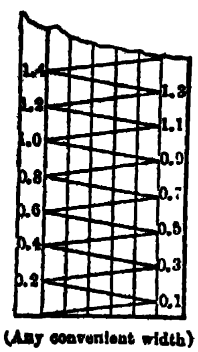

Fig 39. Gage Board

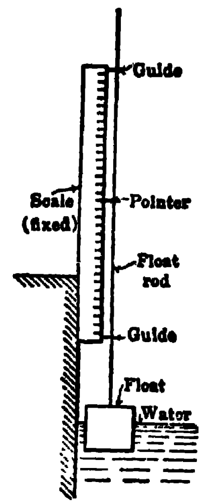

Fig 40. Float Gage

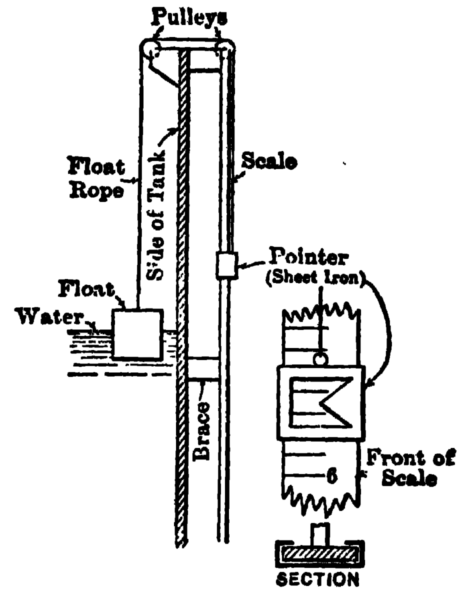

Fig 41. Float Gage for Tanks

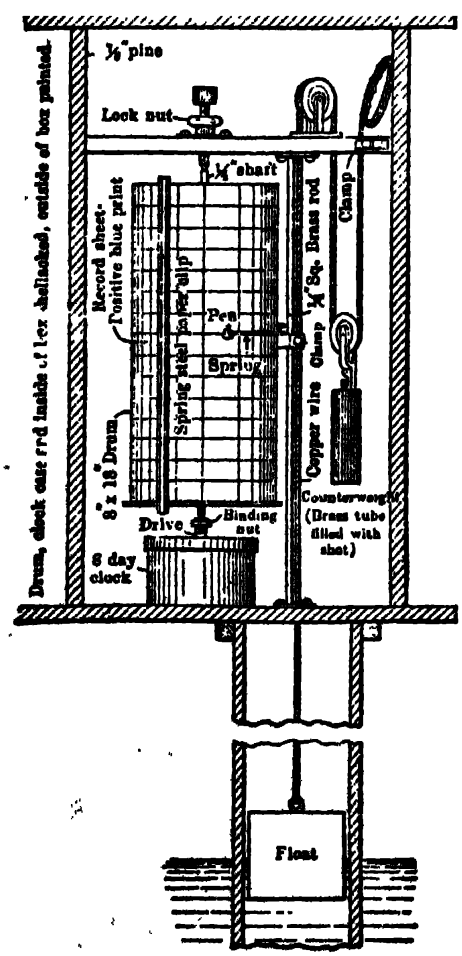

Fig 42. Recording Gage

0.005 to 0.01 ft. If the water surface is rough, a STILL WELL (a box open at the top and with a submerged opening in side) may be used and the gage placed in it. Fig 39 shows a variation from the ordinary form of gage board, the sloping lines allowing a more accurate estimate of water level. This design may be scratched with a nail on the side of a concrete tank before the concrete is fully set, or made by saw-cuts $^1/_8$ in deep on a board. Fig 40 shows a more accurate instrument, a FLOAT GAGE consisting of a fixed scale and a pointer attached to a vert rod on a float. As the reading is made on the rod, this gage is convenient where the water surface is hard to reach. If a leveling rod is used for the scale, and a target vernier attached to the float rod, readings may be made to 0.001 or 0.002 ft. Fig 41 shows a float gage for a tank. By the HOOK GAGE a skilled

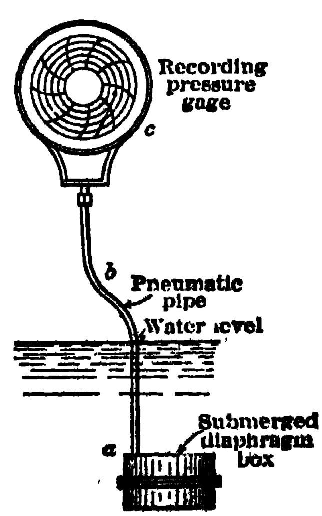

Fig 43. Bristol Recording Gage

observer can detect variations in water level of 0.0002 or 0.0003 ft. But such accuracy is seldom needed except in laboratory experimental work.

Recording gages. Fig 42 shows a simple form, which can be made by a good mechanic. The clockwork consists of an 8-day clock, with gearing to produce a revolution of the drum in any desired time. For recording weir flow, the vertical scale on the drum may be graduated to read discharge directly (Fig 15). Similar instruments, costing $75 to $150, are made by Hydro M'f'g Co, Phila, Pa; J. Fries, Baltimore, Md, and others. Fig 43 shows another recording gage. A drum *a*, containing a rubber diaphragm, is submerged in the water. Variation in water level causes variation in pressure of air in the drum, which is communicated by tube *b* to the recording gage *c*. This gage is not interfered with by floating matter in the water, nor by ice, and is said to show variations in level of 1/8 in (Bristol Co, Waterbury, Conn).

19. MEASUREMENT OF HEAD OR PRESSURE

Moderate water press in tanks or pipes is generally measured by pressure tube or PIEZOMETER; higher press, by hydraulic gage, similar to Bourdon steam gage.

For head of a few ft a WATER TUBE is convenient, consisting of a rubber tube attached to an opening in the pipe or tank, and having a glass tube at its upper end. The tube is raised or lowered until the water level shows in the glass tube, and the distance of this level above the datum (as center of pipe or bottom of tank) gives the head. The opening in the pipe should be on a straight length of pipe, at right angles to its axis, and should have a sharp inner edge. The MERCURY PIEZOMETER (Fig 44) measures heads as high as 40 to 60 ft, Hg having a sp gr of 13.6. Distance z between Hg levels in the U tube, as read on the scale, is roughly $1/13$ the actual head. True head equals ($z \times$ sp gr of Hg) $+ x$.

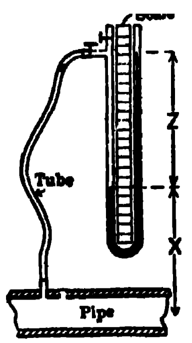

Fig 44. Mercury Piezometer

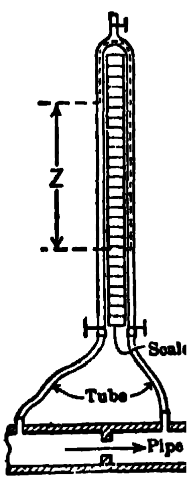

Fig 45. Oil Manometer

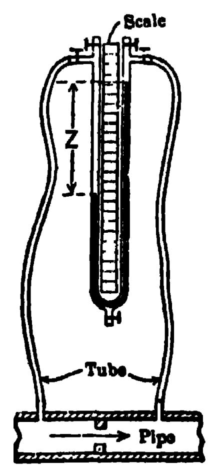

Fig 46. Mercury Manometer

Hydraulic gages measure pressures up to 1 000 lb per sq in or 2 300 ft. For measuring DIFFERENCES IN PRESSURE (if the press is very high) 2 gages are used; for very small differences, an OIL MANOMETER (Fig 45) (*Trans* A S C E, Vol 47, p 72) is used.

Kerosene oil is good. Its sp gr (which must be determined) is about 0.79. Hence the scale reading will be greater than the difference in head, which is independent of height of 0 point of the scale above datum, and equals $z \times (1 -$ sp gr of the oil$)$. There may be trouble in obtaining good readings at the junction of water and oil, due to oil adhering to sides of tube. The WATER OR AIR MANOMETER, made by tube similar to that of Fig 45, can be used for small differences in head. Air must be pumped into the tube if the press is high. The reading is the true difference in head. Two open tubes could be used if total press is small.

Mercury manometer (Fig 46) is probably the best device for work of this kind. The true difference in head $= z \times$ (sp gr of mercury $- 1$).

In all these devices the length of tubes and the quantities of liquid used must be varied to suit the difference in head to be measured.

20. MEASUREMENT OF VELOCITY AND DISCHARGE

For measuring small quantities it is best to allow the discharge for a given time to collect in a tank, where it may be measured or weighed. When this can not be done, or a permanent device is required, one of the following methods must be used. Sometimes

drop in hydraulic gradient can be measured, and discharge computed as in Art 11, but such results are liable to error due to uncertainty in value of the coeff.

Measurements in pressure pipes. There are 3 methods. For measuring water supply in 0.75 to 2-in pipes, DISK OR RING WATERMETERS are to be had in many patterns.

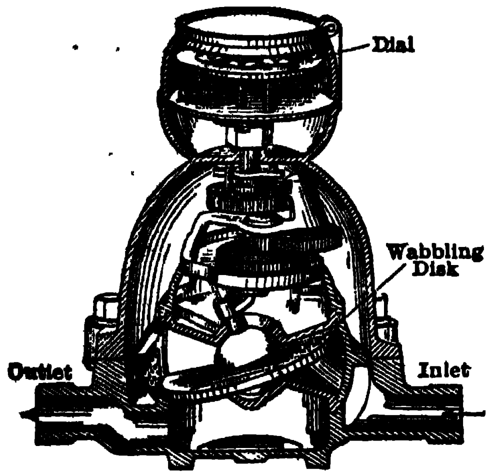

Fig 47. Disk Water Meter

The meter contains a wabbling disk or ring, so arranged that its motion is communicated to a pin which in turn works a train of clock wheels, the quantity passing being registered on a dial (Fig 47). This meter is "inferential," and must be rated to determine the discharge. Piston and other forms of meter are also used. All give reasonably accurate registration for very slow flows (within say 10% for 10 gal per hr), but their rating varies with age and condition of meter and quality of water.

Venturi meter is standard for permanent installations on pipes 3 or 4-in diam and over. They have been placed on the Catskill aqueduct for New York's water supply, pipe diam being about 14 ft. The meter consists simply of a gradual reduction in size of pipe to a throat $^1/_2$ to $^1/_3$ that of the pipe diam, and a gradual expansion back to normal size (Fig 48). There is no obstruction to the flow of the water, and no moving parts.

Formula for discharge is based on the proposition that $h_1 + v_1^2 \div 2g = h_2 + v_2^2 \div 2g$, and that $q = a_1v_1 = a_2v_2$. This gives $q = C\dfrac{a_1a_2}{\sqrt{a_1^2 - a_2^2}}\sqrt{2g(h_1 - h_2)}$, where a_1 and a_2 = areas and h_1 and h_2 = pressure heads at the pipe and throat; g = acceleration of gravity and C is a coefficient to allow for friction losses (usually taken at 0.99). A manometer is generally used to measure $(h_1 - h_2)$, and for any meter the formula reduces to $q = c\sqrt{z}$, where z is the difference in manometer readings. (This meter is made by Builders Iron Foundry, Providence, R I, who also make devices for recording total quantity and rate of flow.) For rough estimates of flow in a pipe, sawdust may be introduced at upper end and time noted for passage through pipe.

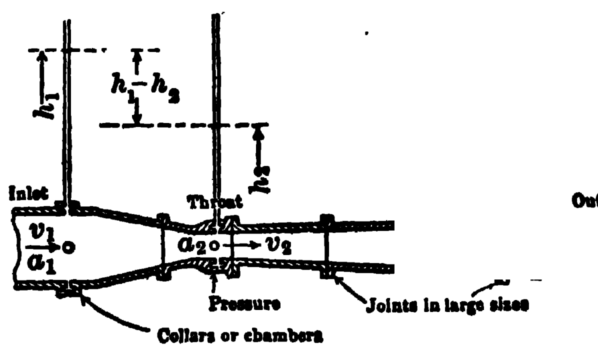

Fig 48. Venturi Meter

Pitot tube (1750) has been used in recent years. Fig 49 shows its principle. The current of water acting on the end of the curved tube causes the head in tube A to be greater than that in tube B. B measures pressure head only, and considering tube A

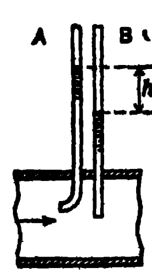

Fig 49. Pitot Tube (Diagram)

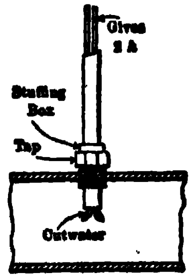

Fig 50. Pitot Tube

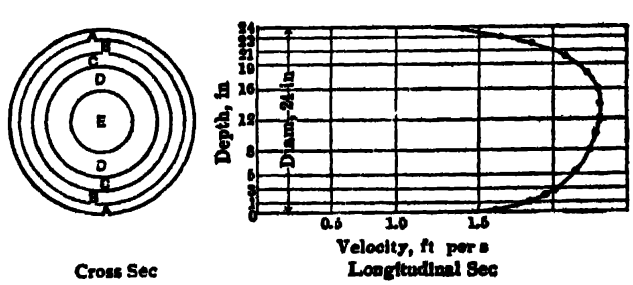

Fig 51. Diagram of Pipe Velocities

to record velocity-head only, and the difference in levels equal to h; then $v = m\sqrt{2gh}$, where m theoretically = 1. If the action of the current against the tube is considered as impact, then $m = 0.7$. It has been shown also that, when placed so as to be subject to currents of different velocities, the head is not that due to their mean, but to the mean

of their squares. For high velocities, as in nozzles, m may be taken as 1 with quite accurate results. For pipes, in which velocities are low and vary as in Fig 51, the value of m is less, and for accuracy must be determined by ratings in a pipe of same diam.

The instrument is made by the Pitometer Co, N Y, who also make a recording device. The usual form of Pitot tube (Fig 50) can be inserted in a hole tapped in a pipe, and a series of readings at different points in the diameter taken, from which the PIPE COEFF (Fig 51) is obtained. Knowing this, future measurements are made only at the center, center velocity being reduced to the mean by using the coeff. The makers advise using $m = 0.84$.

$$\text{Mean velocity} = \frac{6.202}{3.142}$$
$$= 1.97 \text{ ft per sec.}$$
$$\text{Pipe coeff} = \frac{\text{mean veloc}}{\text{center veloc}}$$
$$= \frac{1.97}{2.24} = 87.5\%.$$

Determinations of Pipe Coeff from Fig 51

Ring	Area	Aver veloc	Discharge
A	0.502	1.57	0.788
B	0.873	1.87	1.632
C	0.698	2.05	1.431
D	0.720	2.18	1.570
E	0.349	2.24	0.781
Totals	3.142		6.202

Measuring flow in open channels. The most accurate device is the weir (Art 10). Reliable data for weirs are available for a discharge up to about 200 cu ft per sec. For greater discharges, this value, which is usually higher than the limit of economy for the construction of weirs, or where weirs are not warranted or possible, floats and the current meter are used. For floats a straight, uniform section of the stream, at least 100 ft long and on an even grade, should be selected. Soundings are then taken, the stream being divided into "lanes" like those in Fig 52. If surface floats are used (small chips of wood), a large number are allowed to pass down each "lane," and the aver time noted is the surface velocity of each course.

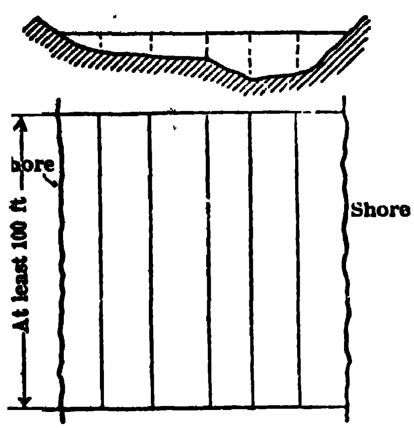

Fig 52. Soundings and "Lanes" for Measuring a Stream

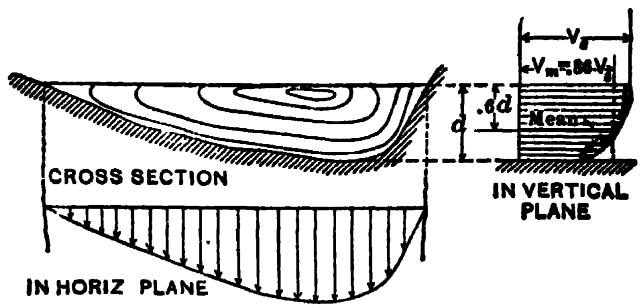

Fig 53. Velocities in Cross-section of a Stream

Fig 53 shows variation in velocity in a vertical section. To obtain the mean, the surface velocity must be multiplied by 0.79 to 0.95, varying with roughness of bed and averaging 0.86. Total discharge is found by multiplying the cross-sectional aver area of each lane by the mean veloc, and adding the results for all the lanes. Wind affects surface floats, and shallow areas of dead water on the sides must be eliminated. A rough estimate of discharge can be made, with an uncertainty usually less than 20%, by timing floats down the center of a channel, thus obtaining the max surface veloc. Mean veloc in entire cross-sec is between 0.70 and 0.85 of this; aver, 0.8.

Submerged floats (Fig 54) are used for deeper streams, and in studying tidal and other currents. By submerging the lower weighted float to a depth of about 0.6 (0.58 to 0.71) that of the vert section down which it floats, the mean veloc in the vert is obtained.

Rod floats are hollow cylinders of tin, weighted by pebbles or shot so as to stand vertically, and reaching nearly to the bottom of the channel. Francis gives $V_m = V_r(1.012 - 0.116\sqrt{d' + d})$, where V_m = mean veloc in the channel down which the rod floats with a veloc V_r, d = total depth of stream, and d' = depth below bottom of rod. d' should not exceed $0.25\,d$. In practice it is difficult to use rod floats, as they require a very uniform channel, not commonly occurring except in canals and flumes.

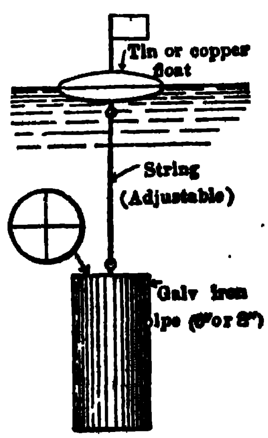

Fig 54. Submerged Float

Current meter is successfully used for measuring veloc and discharge in open channels and large pipes. It has 3 or more vanes mounted on a spindle, so arranged as to stand always normal to direction of current, the press of which causes the vanes to revolve. The number of revolutions in a given time is recorded by an electric or mechanical counter, and is approx proportional to the current veloc.

The meter is first rated by moving it through still water at known velocities and noting the revolutions. If it is then submerged, by suspending it from a rod or rope, the revolutions can be counted and the velocity obtained from the rating chart. Usually the meter is held at a depth of 0.6 that of the water, for finding mean veloc. It has been largely used by the U S Geol Surv, for obtaining curves showing the discharge of a stream at different elevations (stages) of water surface. Observers then note daily the water level, and from the curves the flow is found. Two types of meter are in common use, the Price and the Fteley: the first for deep, rapid streams, latter for shallow, slow streams (See "Use and Care of the Current Meter," *Trans* Am Soc C E, Vol 16, p 68).

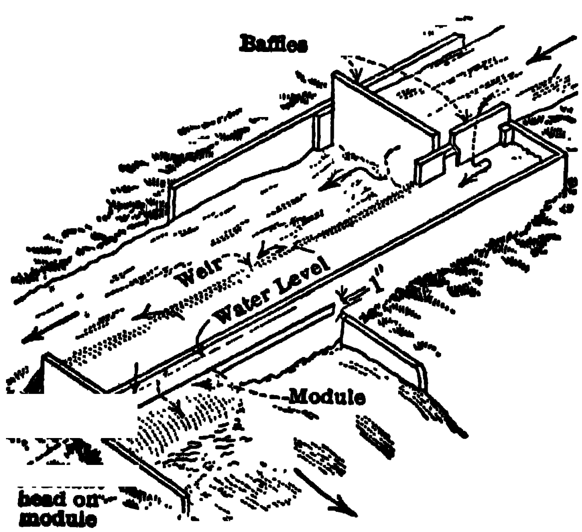

Fig 55. Foote's Weir Gage

Miner's inch, as used in western U S, is the quantity of water which will flow in 1 min from a standard vert orifice, 1 in sq, under a head at its center of 6.5 in. This would equal 1.53 cu ft, but actual value varies in different districts. In Cal and Mont, it is established by law that 40 miner's inches = 1 cu ft per sec; in Col, 38.4, and in Ariz, Idaho, Nev, and Utah, 50 is accepted by common agreement.

Fig 55 shows Foote's weir gage, one of the simpler devices for diverting a certain number of miner's inches from a canal in which flow varies. With a long weir a considerable increase in flow in canal is necessary before the head on weir is much increased. Other devices, with float and special valves, are also used to maintain constant head.

Module is an orifice used in selling water, which under constant head is to supply a certain number of miner's inches. In Fig 55, the length of opening, in, = number of miner's inches, if head is constant. As it is difficult to maintain constant head, this unit is going out of use.

WATER SUPPLY

21. ESTIMATES FOR WATER SUPPLY

Consumption is stated in gal per capita per day. While many data are available respecting requirements for small towns and cities, showing variation from 30 or 40 to 100 or more gal per capita aver daily consumption, it is only recently that the subject has received much attention in mining communities; the scanty information existing is often unsatisfactory, as such towns have been compelled to use what has been available rather than the quantity desirable. Frequently the supply for mills and power plants is the principal requirement.

Source of supply. Having estimated the quantity required, with allowance for future increase of population, a source of supply is sought and developed; either underground water or streams. The quantity available from underground water, obtained by wells or infiltration galleries, can seldom be estimated except by performance of wells driven to the same strata. To make sure that a spring or stream will give sufficient supply, measurements of its flow covering a number of years are necessary. In case of streams, which usually have large variation in flow, a reservoir may be possible, to store up the flood flows to supplement the natural flow during dry seasons (Art 22).

Main pipe lines are designed to allow for variations in consumption, unless the water goes to a small distributing reservoir, having a capac sufficient to equalize variations. The main pipe may then be designed to furnish water to the reservoir at the aver daily rate. For domestic consumption, max daily rate is about 150% of the daily aver; max hourly rate, 250% of daily aver.

Distributing pipes. The size is usually determined by fire service requirements. If the system is to be used for fire service without engines, a press of about 30 lb per sq in (70 ft head) is required at hydrants, and for an adequate stream 150–250 gal per min should be supplied. It should be possible to concentrate 2 or 3 streams at any one point without using hose over 400–600 ft long; these requirements fix the location of outlets and allowable loss of head in the pipes, and hence determine their size.

22. RAINFALL, STREAM FLOW, AND STORAGE

Water falling as rain passes off as surface flow into streams and rivers, is evaporated directly by the sun from the land surface, is taken up by plants and vegetation, or sinks into the ground forming ground storage, some of which finds its way underground to the streams and furnishes their main supply, except during and just after storms. Thus, stream flow will vary in both total amount and distribution throughout the year on two watersheds having exactly the same rainfall, but different slopes, amounts of vegetation, depth, and character of soil cover. Hence, for accurate estimates, data on flow of the stream in question are necessary; sometimes obtainable from publications of U S Geol Surv, state, city, and private reports, but often entirely lacking. It may then be possible to secure data from a similar watershed, bearing in mind what points constitute similarity, or it may be necessary to make a rough estimate from measurements of the slope and cross-sec of the stream, at its known low-water mark, applying the formulas of Art 12.

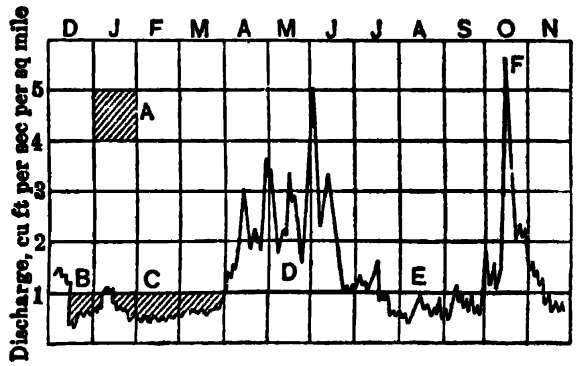

Fig 56. Hydrograph of Stream Flow

A hydrograph, like that in Fig 56, gives a complete record of stream flow, and may be used for all kinds of estimates.

For example, since a dam spillway should be designed to pass safely the flood flow shown at F, the stream records should be searched for the greatest flood, and an estimate made from high-water marks of the stream. The vert scale in Fig 56 is cu ft per sec per sq mile, which, multiplied by the area of the drainage basin gives the total flow. Area of the basin is obtained by drawing a divide line on a topographic map, enclosing the area within which all rain falling (and not lost by evaporation and seepage) would drain off to the stream in question. This area may then be taken off with a planimeter. If no storage is available, the only flow to be counted on would be the minimum shown in the hydrograph, namely, about 0.3 cu ft per sec per sq mile, which occurs in Dec. In order that the plant depending on this flow may never fail, the hydrograph used must be that for the year of lowest flow.

If storage is available, the problem is as follows. The area under the hydrograph represents total flow for the year in cu ft, or the area A of 1 square represents 2 592 000 cu ft, which, divided by 43 560 = 5.95 acre ft, or a vol of 1 cu ft per sec flowing for 1 month. For a flow of 1 cu ft per sec per sq mile, the required storage will be the shaded areas B and C, minus the small bit between them, where the hydrograph line rises above the 1-sec-ft line. This area can be taken off by planimeter and changed to cu ft, giving the required storage. This storage is filled up by the flow corresponding to D in the previous year, and will again be drawn down at E, although at E a smaller quantity is required than at B and C. If the storage is known from a contour map of the reservoir site and assumed height of dam, and it is required to find the available flow, the problem is reversed and the line corresponding to the 1-sec-ft line is found by trial so as to enclose an area equal to the given storage. The hydrograph shows that the distribution of flow throughout the year is important. Streams fed by melting snow in mountainous regions show a much steadier flow than in some southwestern rivers, which have little or no steady flow, and are subject to violent and erratic floods caused by cloudbursts. In the former case, a diversion dam may suffice, or a small storage may be needed; in the latter, a diversion dam must be built, and the flood flows diverted to a reservoir or basin having a capac sufficient to furnish the required supply for some months.

In connection with storage reservoirs note that, as evaporation losses in arid regions are large, it may be necessary to allow for 2 or 3 ft or more depth over the entire reservoir for this loss. Seepage losses also are sometimes high, especially during the first 2 or 3 years after completing a reservoir. The total losses often amount to 25% of the influent, and under best conditions are seldom less than 10%.

SECTION 39

ENGINEERING THERMODYNAMICS

BY

EDWARD D. THURSTON, Jr.

FORMERLY ASSOCIATE PROFESSOR OF MECHANICAL ENGINEERING
COLUMBIA UNIVERSITY

Note.—Numbers in parentheses in text (except numbers of equations) refer to Bibliography at end of this section.

ENGINEERING THERMODYNAMICS

Introduction. The term thermodynamics has here been extended to include not only part of the theory of the subject, but also formulas and numerical data on air compression, steam, air and internal-combustion engines, fluid flow, combustion and related reactions. This section, therefore, is one of engineering, rather than of pure thermodynamics. In it reference is frequently made to Prof C. E. Lucke's work on Engineering Thermodynamics (1). Methods of computing engine power, steam and fuel consumption, power to compress air and similar problems are given in Art 3, 4, 5, leaving to Sec 40 the subjects of mechanical construction, sizes, costs and actual test performance data of engines. Tables of physical and chemical constants frequently used in engineering computations are included in their respective articles.

1. WORK AND POWER

Work in terms of pressure and volume. Work is expressed as the product of force and distance; for the units of work see Sec 36, on Mechanics. Since pressure is force per unit area, following equations show that work is also the product of press and vol:

$$PA = F, \quad \text{hence } W = PAL; \quad \text{but } AL = V, \quad \text{whence } W = PV,$$

where P = press per unit area, A = area on which press acts, F = force acting, W = work, L = distance, ft, and V = volume swept through while pressure is acting. The result is in ft-lb, if press is in lb per sq ft abs and vol is in cu ft.

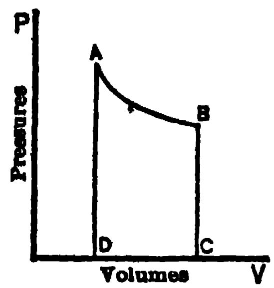

Fig 1. Graphical Representation of Work

Graphical representation of work. In Fig 1, the coordinates are press in lb per sq ft abs and vol in cu ft. Area denoting work done during any process is that under the curve, as AB, down to line of zero press; thus the work done during the volume change A to B is the area $ABCD$.

Work of expansion or compression alone. When a gas changes in volume, work is done irrespective of a change in press; without change in volume, no work is done.

$$\text{For constant press, } W = P(V_1 - V_2) \tag{1}$$

$$\text{variable press, } W = \int P dV \tag{2}$$

The general expansion law for all gases is $PV^s = K$ (constant). When integrated, equation (2) assumes 2 forms, one when value of s in the general law is unity, the other when s has a value other than unity. Results of integration are given below in several convenient forms, in which P_1 is the greatest press and P_2 the least, V_1 being the least vol and V_2 the greatest.

For special cases s has definite values for every gas. The most important case is isothermal expansion or compression, in which the temp is constant during expansion or compression, and $s = 1$ for all gases. Another important case is adiabatic compression or expansion, in which no heat is given to or removed from the gas during the process, and s equals specific heat at constant press divided by the specific heat at constant vol. Table 1 gives some adiabatic values of s, lying between 1 and 1.5.

$s = 1$	s not equal to 1	
$W = P_1V_1 \text{ Nap log} \frac{P_1}{P_2}$	$W = \frac{P_1V_1}{s-1}\left[1 - \left(\frac{P_2}{P_1}\right)^{\frac{s-1}{s}}\right]$	(3)
$= P_1V_1 \text{ Nap log} \frac{V_2}{V_1}$	$= \frac{P_1V_1}{s-1}\left[1 - \left(\frac{V_1}{V_2}\right)^{s-1}\right]$	(4)
$= P_2V_2 \text{ Nap log} \frac{P_1}{P_2}$	$= \frac{P_2V_2}{s-1}\left[\left(\frac{P_1}{P_2}\right)^{\frac{s-1}{s}} - 1\right]$	(5)
$= P_2V_2 \text{ Nap log} \frac{V_2}{V_1}$	$= \frac{P_2V_2}{s-1}\left[\left(\frac{V_2}{V_1}\right)^{s-1} - 1\right]$	(6)

Vapors may be assumed to behave as gases only when considerably superheated; when near their saturation point, s is variable, and work determination by this method is inexact. When steam expands so that it is just dry or follows the saturation law, $s = 1.0646$. For ordinary expansion of s in a cylinder the average value of s is 1, but the expansion is not isothermal.

Table 1. Adiabatic Values of "s"

Substance	s	Authority	Substance	s	Authority
Air	1.4066	Smithsonian Tables	Nitrogen	1.41	Casin
			Nitrous oxide	1.291	Wullner
Ammonia, wet	1.1	Average practice	Pintsch gas	1.24	Pintsch Co
Ammonia, superheated	1.3	Average practice	Sulph dioxide	1.26	Casin
Carbon dioxide	1.3	Röntgen	Steam, superheated	1.3	Smithsonian Tables
Carbon monoxide	1.403	Wullner

Hydrogen	1.41	Casin	Steam, wet	1+0.014 × % moist	Perry
" sulphide	1.276	Müller	Steam, wet	1.035+0.01 × % moist	Gray
Methane	1.316	Müller			

For adiabatic expansion or compression the work done is given by Eq 7, as well as by Eq 3 to 6.

$$W = JC_v(T_2 - T_1)w \tag{7}$$

where J = Joule's equivalent = 778 approx; C_v = sp heat at constant vol, T_1 and T_2 = abs temp before and after compression, and w = weight of gas. The heat added to or removed from a gas during expansion or compression is given by Eq 8.

$$Q = \frac{W}{J} \times \left(\frac{C_p}{C_v} - s\right) \div \left(\frac{C_p}{C_v} - 1\right) \tag{8}$$

where Q = heat, C_p and C_v = specific heats at constant press and constant vol, J = Joule's equivalent, W = work, and s = exponent of V in $PV^s = K$. For the isothermal case, $Q = W \div J$, heat and work being equal when expressed in same units, since $s = 1$. For the adiabatic case, $Q = 0$, since $s = C_p \div C_v$.

Example 1. 5 cu ft of air expanded to vol of 25 cu ft. If expansion occurs (a) at constant press, and (b) so that $s = 1.4$, what will be the work done, the original press being 100 lb per sq in abs?

$$(a)\quad W = 144 \times 100(25 - 5) = 288\,000 \text{ ft-lb} \qquad (b)\quad W = \frac{144 \times 100 \times 5}{1.4 - 1}\left[1 - \left(\frac{5}{25}\right)^{1.4-1}\right] = 85\,500 \text{ ft-lb}$$

Example 2. How much heat is added during the expansion of Example 1, and how much if $s = 1$ and 1.2?

For constant press, $s = 0$, since if $s = 0$, $PV^s = K$ becomes $P = K$; hence for first case from Eq 8,

$$Q = \frac{288\,000}{778} \times \frac{\dfrac{0.24}{0.17}}{\dfrac{0.24}{0.17} - 1} = 1\,270 \text{ B t u}$$

$$\text{For } s = 1.4,\quad Q = 0 \qquad \text{For } s = 1,\quad Q = \frac{144 \times 100 \times 5 \text{ Nap log } 5}{778} = 149$$

$$\text{For } s = 1.2,\quad Q = \frac{0.5\,W}{778}, \text{ and from Eq 4, } W = \frac{14\,400 \times 5}{0.2}\left[1 - \left(\frac{1}{5}\right)^{0.2}\right]$$

or

$$W = 100\,800 \quad\text{and}\quad Q = 64.3$$

Work of complete cycles. Expansion or compression of gases rarely occurs alone, but in connection with other processes, as admission of gas to a cylinder or its delivery from one. A single process, as expansion, is a phase; several phases forming a complete operation constitute a cycle, net work of a cycle being the algebraic sum of the work of each phase. The sign of the work of a particular phase is determined by whether the work is done on the gas or by it; it is immaterial which is considered positive or negative, provided the designation is consistent throughout the cycle.

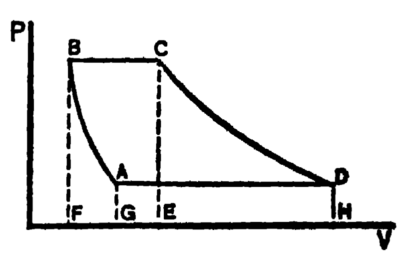

Fig 2. Complete Work Cycle, to P–V Coordinates

Thus, consider the cycle $ABCD$ (Fig 2) composed of: adiabatic compression AB, constant press vol increase BC, adiabatic expansion CD and constant press vol decrease DA. Such a cycle, considered in the order named, represents an engine case or, in reverse order, a compressor case. Net work will be $W_{bc} + W_{cd} - W_{da} - W_{ab}$, or areas $BCEF + CDHE - DHGA - ABFG$. Value for each area may be found from Eq 1 to 6, their algebraic sum giving area $ABCD$, representing net work of the cycle. Numerical value of the work is equal in either case, but the sign for the engine cycle will be opposite to that of the compressor, since the work is done by the gas in one case and on it in the other.

Example 2. Consider the pressures in Fig 2 to be 10 and 100 lb per sq in abs, and the vol at A and C to be 5 and 8 cu ft respectively. Find net work done, if $s = 1.43$.

$$W_{ab} \text{ by Eq 5} = \frac{144 \times 10 \times 5}{0.43}[10^{0.3} - 1] = 16\,800 \text{ ft-lb}$$

$$P_a V_a^{1.43} = P_b V_b^{1.43} \quad \text{or} \quad V_b = V_a \left(\frac{1}{10}\right)^{0.7} \quad \text{or} \quad V_b = 1 \text{ cu ft}$$

$$W_{bc} \text{ by Eq 1} = 144 \times 100 \times (8 - 1) = 100\,800 \text{ ft-lb}$$

$$P_c V_c^{1.43} = P_d V_d^{1.43} \quad \text{or} \quad V_d = V_c(10)^{0.7} \quad \text{or} \quad V_d = 40 \text{ cu ft}$$

$$W_{cd} \text{ by Eq 5} = \frac{144 \times 10 \times 40}{0.43}[10^{0.3} - 1] = 134\,000 \text{ ft-lb}$$

$$W_{da} \text{ by Eq 1} = 144 \times 10 \times (40 - 5) = 50\,400$$

hence,

$$\text{net work} = -16\,800 + 100\,800 + 134\,000 - 50\,400 = 167\,600 \text{ ft-lb}$$

Mean effective pressure (m e p) is that press which, if acting for one stroke, would give the same work as actually accomplished during the entire cycle irrespective of number of strokes of the cycle. If the area under curve BCD of Fig 2 be divided by the length of diagram, the result will be the mean height or press for that portion of the cycle, and the mean press for the remaining portion may be similarly obtained. The former quantity is termed the mean forward press, as it occurs during the forward stroke of the machine, the latter the mean back press. The difference between them is the mean effective press (m e p), which may be obtained algebraically in a similar manner to the work, or experimentally by the indicator.

Indicated horsepower (I H P) is the power developed in the cylinder of a machine, and is so named since it is usually obtained by the indicator. Numerically it is equal to (m e p) Lan + 33 000, where (m e p) is the mean effective press in lb per sq in, L is length

Table 2. Engine Horsepower Constants

of stroke, ft, a is the net area of piston, sq in, and n the number of cycles per min. The term nL is the PISTON SPEED, and Lan + 33 000, the ENGINE CONSTANT. Horsepower (h p) results from multiplying the constant by (m e p). Values for the constant are given in Table 2 for different size cylinders and piston speeds.

Piston speed is best obtained as the product of number of working chambers, length of stroke and rev per min, divided by number of revolutions to complete one cycle. In 2-stroke cycle machines, which include all steam and air engines, compressors, pumps and many oil engines, the no of cycles per working chamber = no of rev. In 4-stroke cycle, mainly gas and gasolene engines, no of cycles = half the revolutions.

Example 4. What is the I H P of a 9 by 12-in single-cylinder, double-acting engine, running at 300 rev per min, when the m e p is 50 lb per sq in? Diam of cylinder is always the first dimension given when expressing size of an engine. In this case there are 2 working chambers, and a cycle is completed in 1 revolution; hence piston speed is 600 and constant is 1.16, giving 58 I H P.

Example 5. What is the h p of a 6-cylinder, single-acting, 4-stroke cycle gas engine, 6 by 6 in, running at 1 000 rev per min, if the m e p is 80 lb per sq in?

Piston speed = (6 × 0.5 × 1 000) ÷ 2 = 1 500; engine constant = 1.29; I H P = 103.2.

Brake or shaft h p, so called because found by a brake, is that actually available at the shaft or belt pulley, and equals the indicated minus friction h p. Ratio of brake to indicated is the mech effic of the engine. In a combined machine, as a direct-connected air compressor or pump, the mech effic is usually taken as the ratio of I H P of the air or water end to that of the steam end. But in a pump, the output is sometimes considered as the h p equivalent of lb of water pumped × head.

Thermal efficiency is the ratio of work done in the engine cylinder to the work equivalent of the heat required to do it.

Example 6. A pump delivers 1 000 gal of water per min against a net head of 150 lb per sq in. The I H P of water end is 100 and of steam end 120, and it uses 75 lb steam per min, each lb containing 1 200 heat units. What are the mech and thermal effics? Considering the mech effic to be the ratio of work in the cylinders, there results 100 ÷ 120 = 0.833 or 83.3%. Considering the output to be the net work of the pump, which is (1 000 × 8.3 × 150 × 2.31) ÷ 33 000 = 87, there results 87 ÷ 120 = 0.725 or 72.5%. Work done per min in the steam cylinder is 33 000 × 120, and the work equivalent in the steam is 778 × 75 × 1 200; hence thermal effic is 0.056 or 5.6%.

2. FLOW OF GASES AND VAPORS

Flow through nozzles and orifices, with large pressure drop. When gases or vapors expand in nozzles the expansion occurs so rapidly that there is no time for escape or addition of heat (although actually a portion of the energy of the jet is turned back into heat by friction against the nozzle walls), hence the process is assumed to be adiabatic, and the preceding equations apply as well in this case, called free expansion, as when the expansion occurs in a cylinder, called balanced expansion. As the fluid must be brought to the nozzle and that which has expanded must be removed, the complete cycle is as in Fig 3, the area $ABFE$ representing the work done by the fluid approaching the nozzle, area $BCGF$ that of expansion, and $CDEG$ that required to remove the expanded fluid and hence negative. Algebraic sum of these areas is

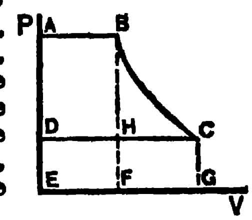

Fig 3. P–V Diagram Representing Nozzle Flow

$$W = \frac{s}{s-1} P_b V_b \left[1 - \left(\frac{P_c}{P_b} \right)^{\frac{s-1}{s}} \right] \tag{9}$$

If V_b represents the volume of 1 lb under the initial conditions, W is the work done by 1 lb, and if this work is used in accelerating the same 1 lb of fluid, then,

$$W = (u_2^2 - u_1^2) \div 2g \tag{10}$$

In nozzle work, u_1, the original velocity, is generally small as compared to u_2, the final velocity, so that u_1^2 may be neglected; in which case, from Eq 9 and 10,

$$u_2 = 8.02 \sqrt{\frac{s}{s-1} P_b V_b \left[1 - \left(\frac{P_c}{P_b} \right)^{\frac{s-1}{s}} \right]} \tag{11}$$

Weight of fluid flowing through the nozzle follows directly, since it equals the product of velocity, cross-section and wt per cu ft. Let A = area at point of max veloc, then,

$$w = uA\delta_c = 8.02\, A\delta_c \left\{ \frac{s}{s-1} P_b V_b \left[1 - \left(\frac{P_c}{P_b} \right)^{\frac{s-1}{s}} \right] \right\}^{0.5}$$

where w = lb per sec, A = area in sq ft, and δ_c = wt of 1 cu ft at the low press. It is generally more convenient to express δ_c in terms of original conditions and since

$$\delta_c = \frac{1}{V_c} = \frac{1}{V_b} \left(\frac{P_c}{P_b} \right)^{\frac{1}{s}}$$

$$w = \frac{8.02\, A}{V_b} \left(\frac{P_c}{P_b} \right)^{\frac{1}{s}} \left\{ \frac{s}{s-1} P_b V_b \left[1 - \left(\frac{P_c}{P_b} \right)^{\frac{s-1}{s}} \right] \right\}^{0.5} \tag{12}$$

w becomes a maximum when first differential $= 0$, which occurs when $\left(\frac{P_c}{P_b}\right)^{\frac{1-s}{s}} = \frac{s+1}{2}$, or for the maximum flow,

$$P_c = P_b \left(\frac{2}{s+1}\right)^{\frac{s}{s-1}} \tag{13}$$

Reducing the lower press will not increase wt, but final velocity only. Throat area of a nozzle is designed to pass the desired wt for the above press ratio, and the mouth area to permit of the complete expansion. A relation between throat and mouth area (Moyer) is

$$\left.\begin{aligned} \frac{\text{Mouth area}}{\text{Throat area}} &= 0.172\,\frac{P_b}{P_c} + 0.7, && \text{if } \frac{P_b}{P_c} < 25 \\ &= 0.175\left(\frac{P_b}{P_c}\right)^{0.94} + 0.7, && \text{if } \frac{P_b}{P_c} > 25 \end{aligned}\right\} \tag{14}$$

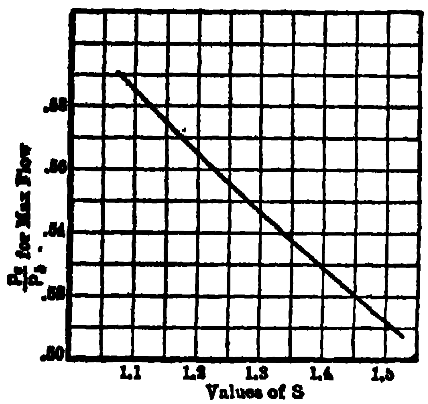

Fig 4. Pressure Ratio for Max Wt Discharged by Nozzle for any Value of "s"

The line joining mouth and throat varies greatly, but a common form is almost a straight line and a 20° angle.

The curve in Fig 4 shows the pressure ratio $P_c \div P_b$ for max flow for different values of s. For all vapors, unless considerably superheated, s varies in value throughout the expansion, and hence results for vapors by above method are not strictly accurate. For an exact method see Art 10.

The above equations are for perfect nozzles or orifices, so that the actual wt discharged, or the area to pass a given wt, may differ somewhat from that calculated, due to stream contraction. For orifices with sharp corners the effective area may be as low as 60% of the actual, while for nozzles it may be as high as 95%.

For flow occurring when the low press is below the critical value, the empiric equations in Table 3 apply.

Table 3. Formulas for Flow of Steam and Air from Orifices

Lb dry steam per hr per sq in of orifice	$60\,p^{0.97}$	Grashof
	$51.43\,p$	Napier
	$49.6\,p$	Harter
	$3.6\,p\,[16.36 - 0.96 \log p]$	Rateau
Lb superheated steam per hr per sq in of orifice	$60\,p^{0.97} + [1 + 0.00065 \times \text{degrees superheat}]$	Moyer
	$49.6\,p$ to $45\,p$ for superheat 0° to 185° at 160 lb	Harter
Lb of air per hr per sq in of orifice	$1\,900\,p_1 + \sqrt{T_1}$ for flows from 2 atmos or more to 1 atmos	Fliegener
Lb of wet steam per hr per sq in of orifice	$60\,p^{0.97} + \sqrt{\text{dryness fraction}}$	Grashof

Example 7. Calculate loss of air per hr from a tank in which the press is maintained at 90 lb per sq in gage and temp is 100° F, if there be a leak amounting to 1/8 in of effective opening. Quantity of air escaping can be no greater than if the press without the tank were 53% of that within, so this value will be used for P_c in Eq 12. For conditions given, $V_b = 2$ cu ft; hence, by Eq 12, wt per hr =

$$3\,600 \times \frac{8.02 \times 0.125}{144 \times 2} \times (0.53)^{0.71}\{3.5 \times 144 \times 105 \times 2[-(0.53)^{0.29}]\}^{0.5} = 1\,070 \text{ lb}$$

By Fliegener's empiric equation, wt per hr $= (1\,900 \times 105) + (\sqrt{560} \times 8) = 1\,030$ lb. Should the press within the tank be only 10 lb gage, the empiric formula would no longer apply, since the low press is above the critical value, and the result must be found by Eq 12. For above press, $V_b = 8.4$ cu ft, hence the wt per hr will be

$$3\,600 \times \frac{8.02 \times 0.125}{144 \times 8.4} \times (0.6)^{0.71}\{3.5 \times 144 \times 25 \times 8.4[1 - (0.6)^{0.29}]\}^{0.5} = 253 \text{ lb.}$$

Flow through orifices with small pressure drops occurs in all engine and compressor valves, and in discharge from pipes. Use is made of this drop in press for measurement purposes. For water and non-expansive fluids the velocity of flow is merely $\sqrt{2\,gh}$; but with expansive fluids the work done in expanding must also be accounted for. In Fig 3,

for a non-expansive fluid the work causing increase in velocity is represented by area *ABHD*; for expansive fluids the area *ABCD*. Naturally, for small press differences the net work of expansion *BCH* may be neglected. Hence, there are 2 sets of expressions for flow for small drops: (*a*) the exact, for expansive; (*b*) the exact, for non-expansive and approximate for expansive.

$$\left.\begin{array}{r}\text{Lb per sec per sq ft}\\ \text{of effective orifice}\end{array}\right\} = \sqrt{2g\frac{s}{s-1}\frac{P_1}{V_1}\left(\frac{P_2}{P_1}\right)^{\frac{2}{s}} - \left(\frac{P_2}{P_1}\right)^{\frac{s+1}{s}}} \quad (a)$$
$$= \sqrt{2g\frac{P_1 - P_2}{V}} \quad (b) \qquad (15)$$

where P_1 and P_2 are initial and final press, in lb per sq ft; V_1, the vol per lb at initial press; and V, the vol per lb at aver press, $(P_1 + P_2) \div 2$. The effective opening is always less than the actual; Table 4 gives values for the ratio of effective to actual.

For air Eq (16) is useful, and Table 5 gives values for C found by Durley (6). These values apply exactly for air flowing into a press of 30 in of mercury, between 40° and 100° F, when the orifice is less than 1/20th the area of the approaching pipe or chamber, has sharp edges, and a thickness of 0.057 in. For a distance, they apply fairly well beyond the above conditions, the character of the orifice edge being the variable having the most influence; values of C as high as 0.99 having been found for orifices with rounded approach.

Table 4. Values of Ratio of Effective to Actual Openings in Orifices (Weisbach)

$P_1 \div P_2$	1.05	1.09	1.43	1.65	1.89	2.15

4	0.598	0.597	0.596	0.594	0.593
4 1/2	0.598	0.596	0.596	0.593	0.592

In general, the constants for different types of orifice may be taken between the limits shown in Table 6, no rule for specific cases being possible.

If the gas being measured is other than air the wt of flow is found from Eq 17:

$$w_G = w_A \sqrt{V_A \div V_G} \qquad (17)$$

where w_G and w_A are the wt of gas and air respectively, and V_G and V_A their vol per lb.

Table 6. General Limits of Constants (Weisbach)

Type of orifice	Constant
Rounded entrance	0.97–0.99
Sharp edge thin plate	0.55–0.80
Short straight tubes	0.80–0.85
" rounded entrance tube	0.92–0.93
Converging orifice	0.90–0.99

Venturi tubes are used commercially for measuring gases and vapors, and here again 2 expressions result:

$$\left.\begin{aligned}\text{Lb per sec} &= A_2\left(\frac{P_2}{P_1}\right)^{\frac{1}{s}}\sqrt{2\,g\,\frac{s}{s-1}\,P_1\delta_1\,\frac{1-\left(\frac{P_2}{P_1}\right)^{\frac{s-1}{s}}}{1-\left(\frac{A_2}{A_1}\right)^2\left(\frac{P_2}{P_1}\right)^{\frac{2}{s}}}} \qquad (a)\\ &= \frac{A_1A_2}{\sqrt{A_1^2-A_2^2}}\sqrt{2\,g\,(P_1-P_2)\,\delta} \qquad (b)\end{aligned}\right\} \qquad (18)$$

where A = area in sq ft, P = press in lb per sq ft, δ = wt per cu ft of gas, and s = ratio of specific heats, $C_p \div C_v$, of the gas. Subscript 1 refers to upstream, and 2 to throat conditions, no subscript referring to the mean value. For steam the exact expression is simplified, since the factor

$$\frac{s}{s-1}\,\frac{P_1}{\delta_1}\left[1-\left(\frac{P_2}{P_1}\right)^{\frac{s-1}{s}}\right] = 778 \times \text{work of Rankine cycle in B t u}$$

between pressures P_2 and P_1, and may be found by the Mollier diagram, Fig 27, hence,

$$\text{Lb steam per sec} = A_2\left(\frac{P_2}{P_1}\right)^{\frac{1}{s}}\delta_1\sqrt{\frac{2\,g \times 778\ (\text{work of Rankine cycle})}{1-\left(\frac{A_2}{A_1}\right)^2\left(\frac{P_2}{P_1}\right)^{\frac{2}{s}}}} \qquad (19)$$

Pitot tube is also used for measuring gases. As it is primarily a velocity meter, 2 sets of values are possible for its results, one neglecting the work of expansion, the other accounting for it. But, to secure accurate readings the velocities must be high, so that the use of the exact expressions is more important than in the orifice or Venturi meter. As the readings are often inches of water or mercury, as well as in lb, the equations are made to apply to these units also.

$$\left.\begin{aligned}\text{Lb per sec} &= A\sqrt{Z}\sqrt{2\,g\,\delta_1\left[1-\frac{K}{2s}\,\frac{1+s}{6\,s^2}K^2\right]-\left[\frac{(1+s)(1+2\,s)}{24\,s^3}\right]K^3} \qquad (a)\\ &= A\sqrt{Z}\sqrt{2\,g\,\delta_1}\\ \text{where}\quad Z &= P_2-P_1 = 5.2(hw_2-hw_1) = 70.8\,(hm_2-hm_1) \qquad (b)\end{aligned}\right\} \qquad (20)$$

$K = \left(\frac{P_2}{P_1}-1\right)$, s = ratio of specific heats, $C_p \div C_v$, δ = lb per cu ft of fluid, $(P_2 - P_1)$ = diff in press in lb per sq ft, $(hw_2 - hw_1)$ inches of water, and $(hm_2 - hm_1)$ inches of mercury, subscript 1 referring to the tangential orifice and 2 to the impact orifice.

Flow in pipes. For flow of gases and vapors through pipes there is little more reliable information than empiric formulas, some of the commoner being given below (Gebhardt). For theory of pipe flow, see (1); for pipe sizes used in practice, see (5).

$$\text{Veloc, ft per min} = A\sqrt{\frac{(p_1-p_2)\,d}{\delta L}}, \quad \text{where } A = \begin{cases}9\,240 & \text{Geipel \& Kilgour}\\ 9\,976 & \text{Hawksley}\\ 10\,350 & \text{Martin}\\ 10\,360 & \text{Hurst}\end{cases} \qquad (21)$$

$$\text{Flow, lb per min} = B\sqrt{\frac{(p_1-p_2)\,\delta\,d^5}{L}}, \quad \text{where } B = \begin{cases}50.2 & \text{Geipel \& Kilgour}\\ 54.4 & \text{Hawksley}\\ 56.5 & \text{Martin}\\ 56.5 & \text{Hurst}\end{cases} \qquad (22)$$

$$\left.\begin{array}{l}\text{Pressure drop,}\\ \text{lb per sq in}\end{array}\right\} = \frac{C\,w^2\,L}{\delta\,d^5}, \quad \text{where } C = \begin{cases}0.000396 & \text{Geipel \& Kilgour}\\ 0.000337 & \text{Hawksley}\\ 0.000313 & \text{Martin}\\ 0.000313 & \text{Hurst}\end{cases} \qquad (23)$$

$$\text{Pipe diam, in} = D\sqrt[5]{\frac{w^2\,L}{(p_1-p_2)\,\delta}}, \quad \text{where } D = \begin{cases}0.2087 & \text{Geipel \& Kilgour}\\ 0.2010 & \text{Hawksley}\\ 0.1990 & \text{Martin}\\ 0.1990 & \text{Hurst}\end{cases} \qquad (24)$$

In above equations, d = diam, in; $(p_1 - p_2)$ = press drop, lb per sq in; w = lb flow per min; L = length of pipe, ft, and δ = lb per cu ft of fluid.

Following values by Hunt show loss in press due to 90° elbows, expressed in equivalent ft of straight pipe:

Pipe, diam	Resistance	Pipe, diam	Resistance	Pipe, diam	Resistance	Pipe, diam	Resistance
1	1.5	5	20	9	44.4	16	90.1
2	4.9	6	25.9	10	50.7	18	104
3	9.4	7	32	12	63.7	20	117
4	14.5	8	38	14	76.7	22	130
....	....	....	....	......	....	24	144

Draft due to convection flow, as found in chimneys and in some ventilating systems, depends on temp and height of stack or duct. For STATIC conditions the difference in press of draft in in of water (the common unit) is $H\left(\frac{7.64}{T_C} - \frac{7.95}{T_H}\right)$ for chimney gases, or $7.64\,H\left(\frac{1}{T_C} - \frac{1}{T_H}\right)$ for air. Due to flow conditions, wall resistances, bends, changes of cross-sec in duct work, many of which can not be evaluated, the actual draft will be less. For chimneys the same is true, besides which there are fuel-bed, boiler-tube and economizer resistances, rendering any but empiric formulas of little practical value. Stirling suggests a corrected equation for actual draft:

$$\text{Actual draft, in of water} = 7.64\,H\left(\frac{1}{T_C} - \frac{1}{T_H}\right) - \frac{fw^2 CH}{A^3} \qquad (25)$$

where H = height, ft, T_C = abs temp of air, T_H = mean abs temp of hot gases, w = wt of gases per sec, C = perimeter of stack, A = area of stack, and f = a constant varying from 0.001 to 0.002, 3 values for which are: 0.001 for steel stack (abs temp = 800), 0.0015 for steel stack (abs temp = 1 060) and 0.002 for brick stack (abs temp = 760).

Tendency of heated liquids and gases to rise is often utilized in heating or cooling systems to produce flow, the thermosyphon consisting merely of 2 pipes or flues, connected at top and bottom; through one pipe the warmer, lighter fluid rises, through the other the cooler and heavier descends.

Capacity of chimneys does not increase indefinitely with stack temp, but is maximum when the temp is approx twice the abs outside temp. Formulas are numerous and are all empiric. Chimney capacities are generally stated in boiler horsepower (B H P). Common formulas are:

$$\left.\begin{aligned} \text{B H P} &= 3.25\,A\sqrt{H} \text{ (Christie)} \\ \text{B H P} &= 3.33\,E\sqrt{H} \text{ (Kent)} \\ D &= 4.92\,(\text{B H P})^{2/5} \text{ (Stirling)} \end{aligned}\right\} \qquad (26)$$

The last formula can also be stated as B H P $= 12.6\,A^{5/4}$.

In these formulas, A = area of top of chimney, sq ft; H = ht of chimney, ft; E = effective area, after deducting 4 in from diam or width, to allow for chimney friction; D = diam of chimney, in. The first 2 formulas include a function of H, and therefore require previous determination of an H that will produce the draft required to overcome the combined resistance of the fuel-bed, boiler, and flue. It is claimed that the Stirling formula gives the stack area that costs least to construct, and that this area does not change with H, determined independently.

As the coal burned and flue gas produced per B H P are indefinite, the formulas are re-stated below, giving capacity in lb of flue gas per hr; using in first formula 4 lb coal per B H P (Christie); in second, 5 lb coal per B H P (Kent); in both formulas, 24 lb flue gas per lb coal, and in the last, the Stirling value of 120 lb flue gas per B H P.

$$\left.\begin{aligned} \text{Lb flue gas per hr} &= 312\,A\sqrt{H} \text{ (Christie)} \\ \text{" " " " "} &= 400\,E\sqrt{H} \text{ (Kent)} \\ \text{" " " " "} &= 1\,508\,A^{5/4} \text{ (Stirling)} \end{aligned}\right\} \qquad (27)$$

3. WORK AND CAPACITY OF AIR COMPRESSORS (See also Sec 15)

Isothermal compression requires the least work, but is impossible to attain in practice even with the most efficient cylinder jacketing.

Actual compressors operate with the compression line somewhere between isothermal and adiabatic. Leakage of air from the cylinder during compression causes displacement of compression curve, and gives a lower value to exponent s (Art 1). Some compressor

diagrams show apparently isothermal compression, whereas result is really due to leakage. Fig 5 shows an ideal diagram for the 2 cases in a no-clearance, single-stage machine, area $ABCD$ representing the work for isothermal compression, $ABC'D$ that for adiabatic, and CBC' the saving due to the former.

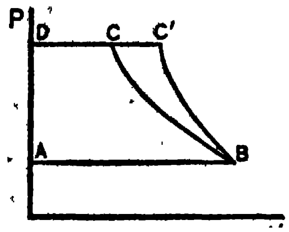

Fig 5. P–V Diagram for Ideal Single-stage Compression

Stage compression. Isothermal compression is more nearly approached if the gas be compressed in one cylinder to some intermediate press, delivered to an intercooler, and the compression completed in a second cylinder. This is termed staging, the number of stages being 2, 3, or 4, most commonly 2. Fig 6 shows the case for an ideal, no-clearance, two-stage machine. Area $ABCC'DE$ represents the process as given, area $ABCD'E$ that for single-stage adiabatic compression for same amount of air, and area $ABC'D'E$ for single-stage isothermal compression. Saving due to staging is area $CC'DD'$.

The air is generally cooled to about the original temp in an intercooler, and in the following equations this assumption is made. The press to which the air is compressed, termed the RECEIVER PRESS, affects the saving due to staging. Maximum saving occurs in 2 stages when

$$\text{receiver press} = (\text{low press} \times \text{high press})^{0.5} \tag{28}$$

and in 3 stages when

$$\left.\begin{aligned} \text{first receiver press} &= (\text{low press})^{0.67}\,(\text{high press})^{0.33} \\ \text{second receiver press} & (\text{low press})^{0.33}\,(\text{high press})^{0.67} \end{aligned}\right\} \tag{29}$$

As real compressors have a CLEARANCE vol, not all the air in cylinder can be expelled on each stroke, and the vol remaining must reëxpand to the low press before any fresh air

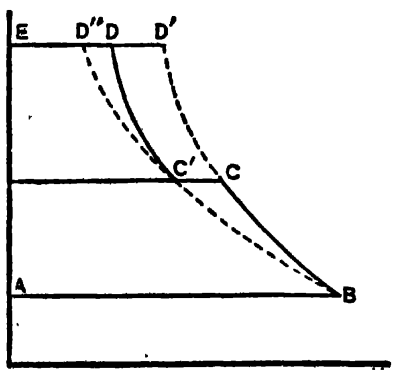

Fig 6. P–V Diagram for Ideal Two-stage Compression

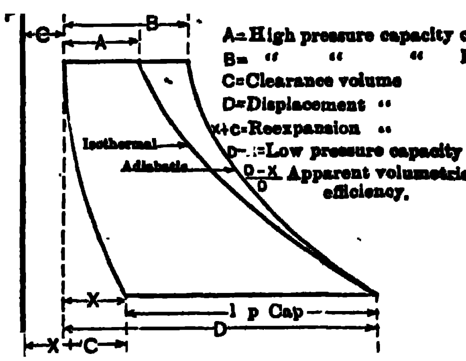

Fig 7. P–V Diagram Showing Effects of Clearance in Compressors

can be drawn in. Hence, the quantity of air compressed is always less than the piston displacement (Fig 7). The ratio of the low-press capacity to displacement is the APPARENT VOL EFFIC. Since the entering air comes in contact with the warm cylinder walls and pistons, it expands, and hence the quantity of air drawn in, when measured under external conditions of press and temp, is even less than would appear from the value of apparent vol effic. The ratio of the actual vol drawn in to the cylinder displacement is the TRUE VOL EFFIC. Eq 30 by Lucke is an attempt to formulate this quantity.

$$\text{True vol effic} = \frac{\text{apparent vol effic}}{1 + (0.3 \text{ to } 0.5)\left(\dfrac{\text{abs temp air delivered}}{\text{abs temp air supplied}} - 1\right)} \tag{30}$$

Air delivered in other than isothermal compression is at a higher temp than that supplied, and when cooled to original temp decreases in vol. Vol actually delivered is termed the high-press capacity hot; when cooled, the high-press capacity cold. These volumes for isothermal compression are equal.

Expressions for work and capacity of single and 2-stage compressors are given in Tables 7 and 8, in which following symbols are used:

lp = low press, lb per sq in absolute
hp = high press " " " "
rp = receiver press, lb per sq in absolute
c = clearance, as a fraction of displacement
cap = capacity, cu ft
d = diam of cylinder, in
l = stroke, in
n = cycles per min
D = displacement, cu ft per min
s = val of exponent of volume in equation for the compression curve $PV^s = K$, = 1.406 for adiabatic compression
T_1 = temp of entering air, abs
T_2 = temp of delivery air, abs
δ_1 = wt per cu ft of entering air
R_p = ratio of high press over low press
E_v = apparent vol effic
C_v = specific heat at constant volume
w = wt of air

Subscripts 1 and 2 refer to low and high-press cyl respectively.

Work required to compress a given quantity of air is independent of the clearance, but the size of the cylinder required varies with the clearance. A comparison of the expressions for work for the entire single-stage compressor cycle and for compression alone (Eq 5) shows that the work for the entire cycle is s times that for compression alone, that is, in Fig 8, area $ABCD$ is s times area

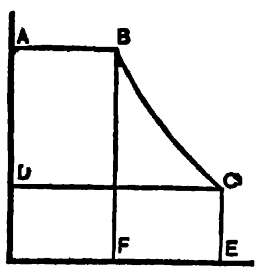

Fig 8. Ideal Compressor Card

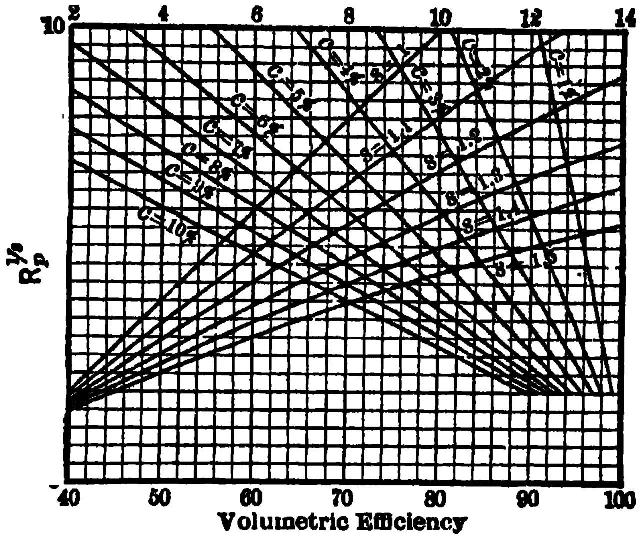

Fig 9. Chart to Find Apparent Volumetric Effic

$BCEF$. Hence, Eq 7, if multiplied by s, gives the complete work for adiabatic compression.

$$\text{Work of complete cycle for adiabatic compression} = JsC_v\,w\,(T_2 - T_1) \qquad (31)$$

Those quantities of Tables 7 and 8 most frequently required may be found graphically from Fig 9 to 11. Fig 9 is for finding the apparent vol effic for any clearance, press ratio, and s. Project from upper horiz scale to the proper curve for s, then horiz to the proper clearance curve, and then down

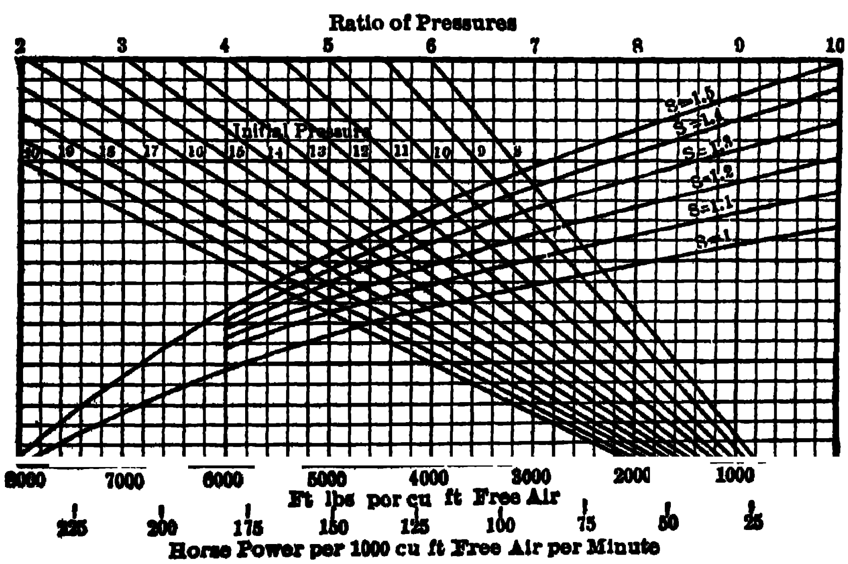

Fig 10. Horsepower for Single-stage Air Compressor

to lower horiz scale, where answer is read. By projecting from the s curve to left-hand scale the value of Rp^{1+s} is found, which gives the high-press capac hot, when the low-press capac or displacement is known, since the high-press capac hot = low-press capac + Rp^{1+s}. Fig 10 is to find the

work required to compress 1 cu ft, or the hp required to compress 1 000 cu ft of free air per min in one stage, between any pressures and for any value of s. The upper of the 2 lower scales, when multiplied by apparent vol effic, gives the m e p in lb per sq ft. To use, project downward from the value of R_p to the proper s curve, then horiz to the low-press curve, and finally downward to read the

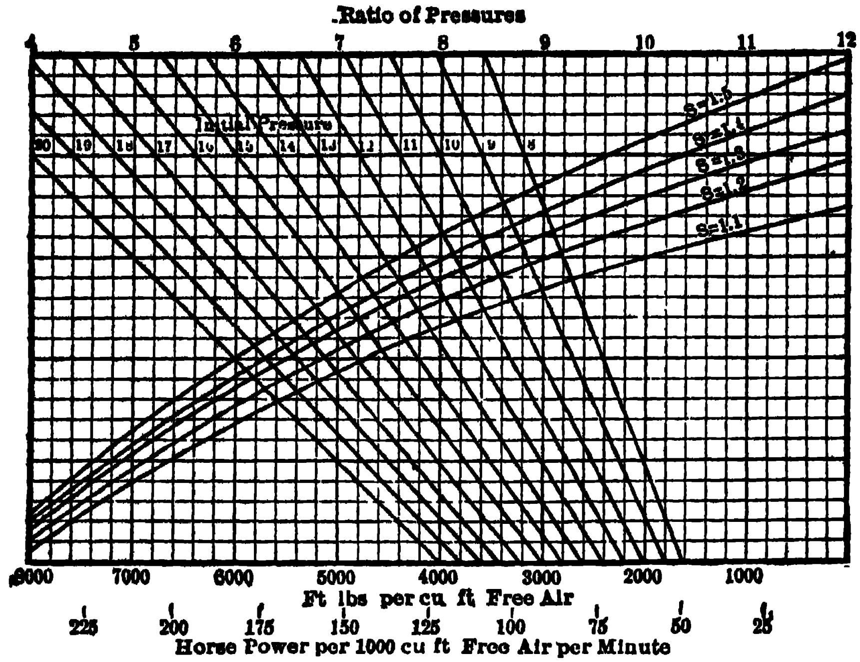

Fig 11. Horsepower for Two-stage Compression of Air, with Best Receiver Press and Perfect Intercooling

answer. Fig 11 is a diagram for 2-stage compression with best receiver press and perfect intercooling. Results obtained by the expressions of Tables 7 and 8, or from the curves, are for perfect compressors. The amount of saving by compressing in 2 stages over single-stage adiabatic is seen in Fig 12. Here the horiz scale is the ratio of high press to low, the vertical scale the ratio of the work required to compress a given amount of air in two stages to that required to compress an equal amount to the same pressure in one stage. As the value of s effects the result, curves for various values of this are given on the figure. Knowing the press ratio, project from the value to the proper s curve and then horizontally; the number so found when multiplied by the work required in single stage will give that required for 2-stage..

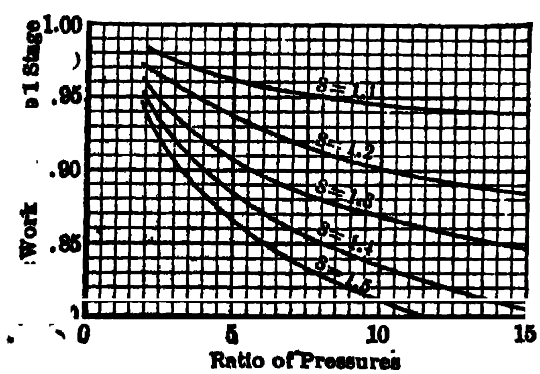

Fig 12. Diagram Showing Saving in Two-stage Air Compression

Blowers are used for compressing large volumes of air or other gas to press usually below 1 lb. As the work to compress a given quantity of gas from one press to another is independent of the type of machine, all the above work formulas apply equally to blowers. In case of fans the press to which the air is compressed is so little above that of the atmosphere that the work of compression alone becomes negligible, so that the work may be represented by the volume multiplied by the increase of press. But, increase of press must include not only that actually observed, but also that required to produce the velocity with which the air leaves the fan or blower, or,

$$W = 144(p_s + p_v)Q \tag{32}$$

where Q = cu ft of air per min, p_s = increase of press, and p_v = velocity head, both in lb per sq in. Since

$$v = \frac{Q}{60A} \qquad p_v = \frac{s}{144 \times 2g}\left(\frac{Q}{60A}\right)^2,$$

$$W = 144\,Q\left[p_s + \frac{s}{144 \times 2g}\left(\frac{Q}{60A}\right)^2\right] \tag{33}$$

in which s = wt per cu ft of gas, and A = area of discharge opening, sq ft.

The above equations and curves are for the ideal or perfect machine. Actual machines require greater hp, to allow for frictional and other losses. Relation between the ideal and actual hp, termed the DIAGRAM FACTOR, varies from 0.5 to 0.85; that is, the power

Table 7. Expression for Work and Capacity of Single-stage Compressors

required in aver practice will be 2 to 1.2 that calculated for isothermal compression. For further data on the compression of air, see Sec 15.

Example 8. What cylinder displacement per min and hp are required to compress adiabatically 1 200 cu ft of air from atmos press to 60 lb gage, in single-stage compressors, cylinder having 3% clearance? From Table 7 the apparent vol effic is $1 + 0.03 - (0.03 \times 5) = 94\%$. Assuming the inlet air to be at 60° F, the real effic (Eq 30) is

$$\frac{0.94}{1 + 0.4[1.58 - 1]} = 76\%.$$

The displacement per min will be 1 580 cu ft, and the work

$$\frac{144 \times 15 \times 3.5 \times 1\,200}{33\,000}[5^{0.29} - 1] = 162 \text{ h p.}$$

Similar results are obtainable from Fig 9, 10.

Example 9. What are the high and low-press capacities of a 2-stage compressor, 10 and 17 by 12-in cyl, speed 120 rev per min, with 3% clearance in low-press cyl, operating at best receiver press and perfect intercooling? Compression is to 9 atmos abs. What power is required and how does it compare with that for a single-stage machine?

From Eq 28, receiver press $= (15 \times 135)^{1/2} = 45$ lb; hence, low-press apparent vol effic is $1 + 0.03 - (0.03 \times 3) = 96.5\%$. Assuming an initial temp of 60° F, the real effic (Eq 30) is $0.965 \div [1 + 0.4\,(1.36 - 1)] = 85\%$. Low-press capacity will be 85% of the displacement, or 323 cu ft. High-press capacity hot (Table 8) is $323 \times (1/9)^{0.86}$, or 49 cu ft, the high-press capacity cold being $323 \div 9$, or 36 cu ft. Power required for an ideal compressor is (Table 8 or Fig 11) 53.6, and from Fig 12 is seen to be about 84% of that for compression in one stage.

4. POWER, FUEL CONSUMPTION AND THERMAL EFFICIENCY OF PISTON STEAM AND AIR ENGINES

Simple engines are those in which the fluid does work on the piston, and is then exhausted to the atmos or to a condenser. The fluid may be admitted for the entire stroke, or may be cut off at some point of the stroke and then expanded. Similarly, the exhaust may be for an entire stroke, or for only a part, followed by compression. Fig 13 shows the series of operations forming a cycle, for which 2 strokes are required. When the fluid is admitted to one end of cylinder only, engine is single-acting; if to both ends, double-acting. Referring to Fig 13: A = admission, inlet valve opens; B = cutoff, inlet valve closes; C = release exhaust valve opens; D = compression, exhaust valve closes; A–A' = admission at constant vol; A'–B = admission at constant press; B–C = expansion; C–C' = exhaust at constant vol; C'–D = exhaust at constant press.

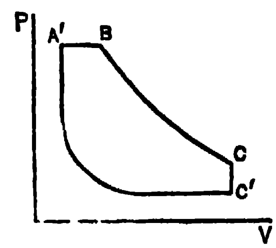

Fig 13 P-V Diagram for Simple Engine Cycle

Expansion curve BC may be of any form, but in steam practice it is a logarithmic curve, so that $PV = K$; for air, it is usually assumed to be adiabatic, so that $PV^{1.41} = K$. Two sets of expressions are given in Table 9, one for $PV = K$, the other a general one for $PV^s = K$, where s may have any value other than 1. Four degrees of expansion and compression may exist (Fig 14, 15, 16, 17). In complete expansion the fluid expands in the cyl to the exact press of the exhaust, in incomplete expansion it fails to reach exhaust press, and in over expansion it falls below it. Similarly, for complete compression the steam trapped in the cyl at the end of exhaust is compressed to the initial press.

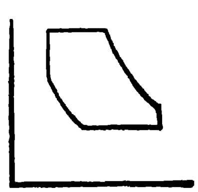

Fig 15. Incomplete Expansion and Compression

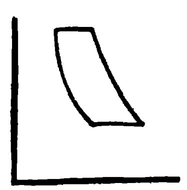

Fig 16. Complete Expansion and Compression

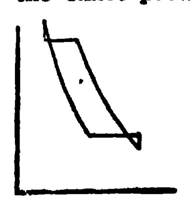

Fig 17 Over Expansion and Compression

Indicated horsepower (i h p) of an engine is given by the expression $pLan \div 33\,000$, where p is the mean effective press (m e p), lb per sq in, L the length of stroke, ft, a the net area of piston (area of piston minus area of rod, if there be one), sq in, n number of cycles per min. The quantity $Lan \div 33\,000$ is the ENGINE CONSTANT (see Table 2 and its explanation).

Consumption of engines is expressed in cu ft, or in lb of high-press fluid per hp hr, the latter value being termed the WATER RATE. In the equations, the letters have following designations: Z = cutoff = fraction of stroke completed when inlet valve closes; X = compression = fraction of stroke remaining when exhaust valve closes; c = clearance expressed as a fraction of the stroke; δ_1 = wt of a cu ft of fluid at the high press, as found from steam tables; (in pr), (bk pr), and (rel pr) = initial, exhaust, and release press, in lb per sq in abs (Fig 18).

Table 9. Expressions for M e p and Consumption of Steam or Air Engines

	For $PV = K$	For $PV^s = K$
m e p	$(\text{in pr})\left[Z + (Z + c)\text{ Nap log}\dfrac{1+c}{Z+c}\right] - (\text{bk pr})\left[\begin{array}{c}(1 - X) + (X + c)\\ \times \text{ Nap log}\dfrac{X+c}{c}\end{array}\right]$	$(\text{in pr})\left\{Z + \dfrac{Z+c}{s-1}\left[1 - \left(\dfrac{Z+c}{1+c}\right)^{s-1}\right]\right\} - (\text{bk pr}) \times \left\{(1 - X) + \dfrac{X+c}{s-1}\left[\left(\dfrac{X+c}{c}\right)^{s-1} - 1\right]\right\}$
Cu ft of fluid per hr, per i h p	$\dfrac{13\,750}{\text{m e p}}\left[(Z + c) - (X + c)\dfrac{\text{bk pr}}{\text{in pr}}\right]$	$\dfrac{13\,750}{\text{m e p}}\left[(Z + c) - (X + c)\left(\dfrac{\text{bk pr}}{\text{in pr}}\right)^{\frac{1}{s}}\right]$
Lb of fluid per hr, per i h p	$\dfrac{13\,750}{\text{m e p}}\left[(Z + c) - (X + c)\dfrac{\text{bk pr}}{\text{in pr}}\right]\delta_1$	$\dfrac{13\,750}{\text{m e p}}\left[(Z + c) - (X + c)\left(\dfrac{\text{bk pr}}{\text{in pr}}\right)^{\frac{1}{s}}\right]\delta_1$
Release press	$\left(\dfrac{Z+c}{1+c}\right)(\text{in pr})$	$\left(\dfrac{Z+c}{1+c}\right)^s(\text{in pr})$

For complete expansion and compression Z and X have special values as follows:

For $PV = K$ For $PV^s = K$

$$Z = (1 + c)\frac{\text{bk pr}}{\text{in pr}} - c \qquad Z = (1 + c)\left(\frac{\text{bk pr}}{\text{in pr}}\right)^{\frac{1}{s}} - c \tag{34}$$

$$X = c\left(\frac{\text{in pr}}{\text{bk pr}}\right) - c \qquad X = c\left(\frac{\text{in pr}}{\text{bk pr}}\right)^{\frac{1}{s}} - c \tag{35}$$

Diagram factor of an engine is the ratio of the m e p actually realized in the cyl to that calculated as above. Actual m e p is always less, due to valve interference with steam flow and other causes. Values of diagram factors for different types of engines are given under description of engines, averaging about 0.8 to 0.7. SHAFT OR BRAKE HP of an engine is always less than the i h p, due to friction losses. Ratio of brake hp to i h p is the MECHANICAL EFFICIENCY.

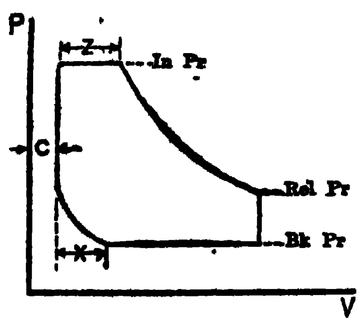

Fig 18. Diagram Representing Cutoff, Compression, and Pressures in Steam Engine Cycle

Actual consumption of engines is greater than the above values, due to leakage past valves and from one side of piston to other, and to condensation of steam in the cyl. During exhaust stroke the cyl tends to cool down, since the temp of exhaust steam is relatively low. On admission of high-press steam, some is condensed on striking the cooler cyl walls, allowing more to enter.

Missing water is the difference between actual and computed consumption. It is difficult to predict, as the condition of the engine (frequently unknown) affects it greatly. Following empiric formulas (Perry) are in common use:

$$\text{Non-condensing engines, } R = m\frac{1 + \frac{1}{Z}}{d\sqrt{N}}. \quad \text{Condensing engines, } R = 120\frac{1 + \frac{1}{Z}}{d\sqrt{np}} \tag{36 (37)}$$

in which R is missing water divided by computed consumption, Z the cutoff, d the diam of cyl, in N the rev per min, n the cycles per min, p the initial press, and m a constant varying from 5, in engines in very good condition and with jackets, to 30 or more in engines without jackets.

Multiple-expansion engines are those in which the steam, after doing work in one cyl, is exhausted to one or more cyls and does more work by further expansion. Amount of work which 1 cu ft of steam can do in expanding between initial and back press is independent of the number of cyls in which expansion takes place, but a greater range of expansion can be had in a multiple than in a single-cyl engine. This, together with a decrease in condensation and leakage losses, is the reason for employing compound and triple-expansion engines. Should expansion occur in 2 stages, the engine is termed a compound, a triple if in 3 stages, and quadruple if in 4. But, 2 cyls may be used instead of 1 large one for the lower press cyl, so that a compound is not necessarily a 2-cyl, or a triple a 3-cyl engine. Exhaust from 1 cyl may be led directly to the next, or to an intermediate receiver. Should the fluid be heated between cyls, the receiver is a reheating receiver. It is considered good practice to reheat air, but not steam. Since the size of receiver, arrangement of cranks, type of expansion curve, clearance, cutoff, and compression, in each cyl all enter into the expressions for m e p for multiple-expansion engines, these expressions become too complicated for presentation here (1). (See textbooks.)

Expressions for cu ft or lb of fluid consumed, as given for simple engines, may be used for multiple-expansion engines as follows: Z, X, c, and the pressures may be taken for either cyl and the m e p taken as referred to that cyl for which the values of Z, etc, are taken. The m e p referred to 1 cycle is a hypothetical m e p, which, if existing in a single cyl of the same size as that to which it is referred, gives the same hp as the whole engine.

$$\text{For compound engines:}\quad \begin{cases} (\text{m e p})\text{ referring to high press} = (\text{m e p})_H + (\text{m e p})_L \dfrac{D_L}{D_H} \\ (\text{m e p})\text{ referring to low press} = (\text{m e p})_H \dfrac{D_H}{D_L} + (\text{m e p})_L \end{cases} \tag{38}$$

where D_H and D_L are the displacements of the high and low-press cyls.

Thermal effic of steam engines is the ratio of output to input. Reducing both to 1 hp, this becomes thermal effic = 2 545 ÷ (water rate × H_1), in which H_1 is the heat content of 1 lb of steam above the feed-water temp, for values of which see Art 12.

Thermal effic of air engines is generally considered as the work obtained from the engine for a given quantity of air, divided by the work to compress the same quantity. Should there be preheating and reheating, the work-equivalent of the heat so supplied must be added to the work of compression. For the work of engines, see above; for work of compressors, see Sec 15. Work-equivalent of the heat of preheat or reheat will be $778\, wC_p\,(T_2 - T_1)$ where w = wt of air, C_p = specific heat at constant press = 0.24 for air, and $(T_2 - T_1)$ the number of degrees through which the air is heated.

Example 10. Find the hp which a 15 by 18-in double-acting engine, with 5% clearance, running at 200 rev per min, could probably furnish at the belt pulley for following conditions. Initial press, 125 lb gage; back press, atmosphere; cutoff, 1/2; compression, 20%. What is the probable steam consumption? Taking s as 1 (customary for steam work), from Table 9 the ideal m e p would be

$$140\left[0.05 + 0.55 \text{ Nap log} \frac{1.05}{0.55}\right] - 15\left[0.8 + 0.25 \text{ Nap log} \frac{0.25}{0.05}\right] = 102.$$

Assume a diagram factor of 80%, and a mech effic of 85%, as fair values. Then probably m e p = 0.8 × 102 = 82. The piston speed = 2 × 200 × 1.5 = 600; hence from Table 2, h p constant is 3.21. The i h p will then be 3.21 × 82 = 263 and the b h p, 0.85 × 263 = 223. From Table 9 the indicated steam per i h p per hr is $\frac{13\,750}{82}\left[0.55 - 0.25 \times \frac{15}{140}\right] \times 0.31 = 27.5$ lb. From Eq 37, $R = \frac{30 \times (1 + 2)}{15\sqrt{200}} = 0.42$. The total steam per hr will then be 27.5 × 1.42 × 263 = 10 270 lb.

Example 11. If the engine in above problem be run for best economy, complete expansion and compression must be had; hence (Eq 34, 35), $Z = 1.05 \times \frac{15}{140} - 0.05 = 0.062$ and $X = 0.05 \times \frac{140}{15} - 0.05 = 0.42$. From Table 9, the ideal m e p is 21. Probable b h p is then 46. The indicated consumption (Table 9) is $\frac{13\,750}{17}\left[0.112 - 0.47 \times \frac{15}{140}\right] \times 0.31 = 15.5$, and R (Eq 37) is 2.4. Total steam per hr is 15.5 × 3.4 × 54 = 2 846 lb.

5. POWER, FUEL CONSUMPTION AND THERMAL EFFICIENCY OF INTERNAL COMBUSTION ENGINES

In these engines the heat is developed directly in the working cyl by burning the fuel therein. Such engines may be divided into 2 classes; (a) those burning the fuel at con-

stant vol; (b) those at constant press. Fig 19 and 20 show the cycles on which they operate. Fig 19 shows the Otto cycle, where

AB = adiabatic compression	BC = heating at constant volume
CD = " expansion	DA = cooling " " "

Fig 20 shows the Diesel cycle, where

AB = adiabatic compression	BC = heating at constant pressure
CD = " expansion	DA = cooling " " volume

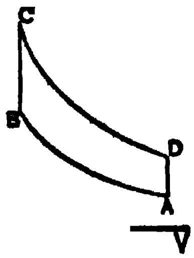

Fig 19. P–V Diagram of Otto Cycle

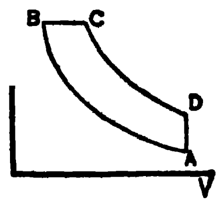

Fig 20 P–V Diagram of Diesel Cycle

As actually operated, both types draw in a new charge in each cycle, and expel the products. These transfer phases may each take 1 stroke, or occur at the dead-center periods. In first case, the engine is a 4-cycle, in second, a 2-cycle, the 4 or 2 indicating the number of strokes per cycle. Expressions for m e p, thermal effic and fuel consumption, for Otto and Diesel cycles are given in Table 10.

Table 10. M e p, Efficiency, and Fuel Consumption for Otto and Diesel Cycles

	Otto cycle	Diesel cycle
M e p...........	$\dfrac{JQ_1\left[1-\left(\frac{P_a}{P_b}\right)^{\frac{s-1}{s}}\right]}{144\,V_a\left[1-\left(\frac{P_a}{P_b}\right)^{\frac{1}{s}}\right]}$ or $5.4\dfrac{H_1}{a+1}\left[1-\left(\frac{P_a}{P_b}\right)^{\frac{s-1}{s}}\right]$	$\dfrac{J\left\{Q_1-C_vT_a\left[\left(1+\frac{Q_1}{C_pT_b}\right)^s-1\right]\right\}}{144\,V_a\left[1-\left(\frac{P_a}{P_b}\right)^{\frac{1}{s}}\right]}$
Thermal efficiency	$1-\left(\frac{P_a}{P_b}\right)^{\frac{s-1}{s}}$ or $1-\left(\frac{V_b}{V_a}\right)^{s-1}$ or $1-\frac{T_a}{T_b}$	$1-\dfrac{c_vT_a\left[\left(1+\frac{Q_1}{C_pT_b}\right)^s-1\right]}{Q_1}$
Fuel consumption per hr per i h p	$\dfrac{2\,545}{EH}$	$\dfrac{2\,545}{EH}$

J = Joule's equiv = 778; Q_1 = heat added per lb of working gases in cyl; P_a = press at beginning of compression; P_b = press at end; V_a = vol per lb of air-gas mixture at beginning and V_b at end of compression; C_p and C_v = specific heats of gases at constant press and constant vol; H_1 = B t u per cu ft of gas or vapor; H = B t u per cu ft of gas or per lb of oil; E = thermal effic, a = the air required to burn 1 cu ft gas or vapor; T_a = abs temp at beginning of compression; T_b = abs temp at end of compression.

Efficiency of Otto cycle depends only upon the degree of compression and is independent of amount of heat added. It may be expressed in terms of temp, vol or press, before and after compression, the latter being commonest. Table 11 gives values for efficiency for different compression ratios for the usual value of $s = 1.4$. Efficiency of Diesel cycle varies with the degree of compression, and with amount of heat added. In practice, efficiency is further decreased at heavy loads due to incomplete combustion when large amounts of fuel are added. The m e p in each case is work divided by change in volume. In above expressions, work is the product JQ_1E, and vol change is expressed as a function of original vol. Heat liberated per cycle Q_1, divided by vol of mixture admitted, or vol change, is the heat content per cu ft of mixture; hence, the m e p expression for Otto cycle may have the simpler form given in Table 10. Table 12 gives the quantity $\frac{H_1}{a+1}$ or B t u per cu ft of air-fuel mixture for the common fuels, at 32° F and 14.7 lb. For other conditions of press and temp, the values vary directly as the abs press and inversely as abs temp. Hence, solutions of problems on the Otto cycle are chiefly a matter of finding tabular quantities. For solution of m e p by the other expressions, the heat liberated per lb of stuff in cyl must be known. Considering V_a to be the vol of 1 lb of mixture external to the cyl,

$$V_a\left[1-\left(\frac{P_a}{P_b}\right)^{\frac{1}{s}}\right]\frac{H_1}{a+1}=Q_1.$$

Table 11. Values of Otto Cycle Efficiency

$\frac{P_b}{P_a}$	$1-\left(\frac{P_a}{P_b}\right)^{\frac{1}{s}}$	$1-\left(\frac{P_a}{P_b}\right)^{\frac{s-1}{s}}=E$	$\frac{P_b}{P_a}$	$1-\left(\frac{P_a}{P_b}\right)^{\frac{1}{s}}$	$1-\left(\frac{P_a}{P_b}\right)^{\frac{s-1}{s}}=E$
3	0.544	0.269	5.8	0.715	0.395

Table 12. Values of B t u per Cu Ft of Best Air and Gas Mixture

Fuel	$\frac{H_1}{a+1}$ at 32° F and 14.7 lb	Fuel	$\frac{H_1}{a+1}$ at 32° F and 14.7 lb
Carbon monoxide...............	100	Average coal gas.............	90
Hydrogen.....................	88	" oil gas..............	97
Methane......................	91	" coke-oven gas........	90
Benzene......................	103	" blast-furnace gas.....	60
Alcohol......................	101	" water gas............	88
Gasolene.....................	107	" anthracite producer gas	67
Crude oil....................	110	" lignite producer gas...	69
Kerosene.....................	107	....	....

Note.—Values at any other press and temp = values at 32° and 14.7 lb × $33.45\frac{p}{T}$, where p is press in lb per sq in and T is abs temp in deg F. (Constant 33.45 is 492 + 14.7.)

Table 11 gives values for $1-(P_a \div P_b)^{\frac{1}{s}}$ and as the air-fuel mixture is largely air the vol per lb may be considered the same as air, values for which are given in Table 20. As the fuel mixture external to engine is generally at atmos press and temp, an aver value of 13 is not greatly in error.

For liquid fuels the value for $\frac{H_1}{a+1}$ averages about 105, for city and natural gases 90, and producer gases 70. Values given for m e p and effic are all for perfect engines. The diagram factor varies far more than for steam engines, but a rough value is 45 to 55%. Values for different types of engines are given in Sec 40.

Example 12. Find full-load hp, fuel consumption, and thermal effic of a single-acting Otto 4-cycle 3-cyl 10 by 12-in engine, running at 500 rev per min, with a compression press of 90 lb gage; fuel, alcohol. Compression ratio = (90 + 15) ÷ 15 = 7. Effic (Table 10) = $1-\left(\frac{1}{7}\right)^{\frac{s-1}{s}}=$ 0.427, as also shown in Table 11. Assuming the diagram factor = 0.5, real effic = 0.21. Fuel per hp hr (Table 10), and value of 12 100 B t u per lb alcohol (Table 26) = 2 545 ÷ (0.21 × 12 100) = 1. This value is the probable consumption, since the probable effic of 0.21 was used. Same result could be found by using the hypothetical value 0.427, and dividing by diagram factor 0.5. B t u per cu ft mixture, at say 60° F and atmos press (Table 12) = 95.5; hence m e p = 5.4 × 95.5 × 0.427 = 220 lb. Applying same diagram factor, real m e p = 110. Piston speed = (3 × 500) ÷ 2 = 750. Hp constant from Table 2 = 1.785; hence, hp = 196.

Example 13. Find the m e p, fuel consumption, and thermal effic, of a single-cyl, 2-cycle Diesel engine, operating on crude oil at full load. Compression ratio, 40. At theoretical full load in a Diesel there would be heat liberated due to best mixture, but actually there is always excess air. Assuming best mixture, Q_1 = 13 × 104 × 0.93 = 1 250, for temp of 60° F external to cyl. From the expressions following Eq 42, the temp ratio equals the press ratio raised to $(s-1) \div s$ power, hence T_b = 2.87 × T_a = 1 500 abs;

$$\text{hence } E = 1 - \frac{0.17 \times 520\left(1+\frac{1\,250}{0.24 \times 1\,500}\right)^{1.4}-1}{1\,250} = 0.515$$

Assuming diagram factor of 0.5, real thermal effic becomes 26%. Fuel consumption, assuming 19 000 B t u per lb oil, is 2 545 ÷ (0.26 × 19 000) = 0.51 lb.

$$\text{M e p} = (778 \times 1\,250 \times 0.515) \div (144 \times 0.13 \times 0.93) = 290 \text{ lb.}$$

Applying same diagram factor, real m e p = 145 lb.

6. HEAT AND TEMPERATURE UNITS

Thermometer scales in common use are Cent and Fahr, usually the latter in American engineering practice. The fixed points on each are the freezing and boiling points of water, at standard press of 760 mm of mercury. Freezing point is denoted by 0° and 32°, boiling point, by 100° and 212°, on the Cent and Fahr scales respectively. 1° F = $^5/_9$° C, or 1° C = $^9/_5$° F. Temp F = $^9/_5$ temp C + 32, or temp C = $^5/_9$ (temp F − 32). (See also Sec 37.)

Absolute temperature. Scales given above are purely arbitrary, and can not be used in thermodynamic calculations for which abs temps are required. The more permanent gases, as air, hydrogen, oxygen, etc, or those much above their condensation temp, when cooled at constant press, lose a definite amount in vol per degree of cooling. If cooled at constant vol, there is a definite decrease in press of $^1/_{273}$ per deg C, which is the same as the decrease in vol for constant-press cooling. Considering a unit press or vol at 0° C, cooled through 273°, there would be zero press if the cooling were at constant vol, or zero vol if cooling were at constant press. Temp of −273° C is therefore called the abs zero Cent, and 0° on the same scale becomes 273° C abs. Similarly, 0° on Fahr scale is 460° abs. The above values are in the nearest round numbers. More exact values are:

0° C scale = 272.85° abs (Regnault), and 0° F scale = 459.64° abs (Marks & Davis).

Units of heat. There are 2 units of heat, one corresponding to each of the above thermometer scales. That corresponding to the Cent scale, or metric unit, is the calorie, or heat required to raise the temp of 1 kg of water from 15° C to 16° C. This unit is sometimes called the large calorie, to distinguish it from the small calorie, which is the heat required to raise the temp of 1 gm water an equal amount. The unit used in English-speaking countries is the British Thermal Unit (B t u), and is the heat required to raise the temp of 1 lb water from 62° F to 63° F (Peabody) or $^1/_{180}$ of the heat required to raise 1 lb of water from 32° F to 212° F (2). These values would be identical were the specific heat of water constant. The variation is slight, and for practical purposes the error arising from considering it constant and equal to unity may be neglected. For detailed discussion of different values of specific heat of water, see (17, 21). 1 B t u = 0.252 calorie; 1 calorie = 3.968 B t u.

Mechanical equivalent of heat varies in different latitudes; a common value in engineering work is 1 B t u = 778 ft lb (Table 13).

Table 13. Power Conversion Factors

Ft lb	B t u	Calorie	Hp sec	Hp min	Hp hr
1	1.26×10^{-3}	0.324×10^{-3}	1.818×10^{-3}	0.303×10^{-4}	$5\ 05 \times 10^{-7}$
778	1	0.252	1.414	$2\ 356 \times 10^{-2}$	$3\ 93 \times 10^{-4}$
3 086	3.968	1	5.61	$9\ 35 \times 10^{-2}$	1.56×10^{-3}
550	0.707	0 178	1	1.67×10^{-2}	2.78×10^{-4}
3.3×10^4	43.44	10 70	60	1	$1\ 67 \times 10^{-2}$
1.98×10^6	2 545	641	3 600	60	1

7. SPECIFIC HEATS

When substances are so heated that no change of state occurs, as from solid to liquid or liquid to vapor, and no heat is conducted away, the temp rises. Quantity of heat required to cause temp of equal weights of different substances to rise the same number of degrees varies. The standard is the heat required to raise 1 lb water 1° F. Ratio of the heat required to raise 1 lb of a substance 1° F to that required to raise 1 lb water 1° F is its SPECIFIC HEAT.

Heat may be applied to a substance at constant press or at constant volume. In first case the vol changes, and hence work is done; in second case no work results. As work is done at the expense of heat, more is required to cause a given temp rise in the case of constant-press heating. Hence, there are 2 specific heat values, C_p for constant press, and C_v for constant vol conditions. But, in case of solids and liquids, the change in volume is so small as to be negligible in engineering work, hence for these substances only one

value is reported. Specific heats of substances are not constant over the entire range of temps, but have the form of equation, $C = a + bt + ct^2$, where a, b, and c are constants. As the values of b and c are not definitely determined, and expressions involving specific heats become very complicated when the variable values are used, it is customary to use the constant values and apply correction factors where necessary at end of the calculation. See Tables 14, 15, 16.

1. Wiedeman. 2. Regnault. 3. Holborn-Austin. All values for C_v from (1).

For a mixture of substances the specific heat may be found by Eq 39:

$$\text{Specific heat of mixture} = \frac{c_1w_1 + c_2w_2 + c_3w_3}{w_1 + w_2 + w_3} \tag{39}$$

where c_1, c_2, etc, are the specific heats and w_1, w_2, etc, the weights of the components.

Equation 40 (Dulong and Petit) is useful where no experimental values are available:

$$\text{Specific heat of solids} = 6.4 \div \text{atomic weight} \tag{40}$$

Quantity of heat absorbed by or removed from a body on heating or cooling is given by $H = Cw(t_2 - t_1)$, where H = heat, w = wt, C = specific heat, and t_2 and t_1 temp.

8. COEFFICIENTS OF EXPANSION

Substances may be heated at constant vol or at constant press, but the change in vol of liquids and solids when heated at constant press is very small and is usually expressed in the form of a coefficient or change per deg. Solids may undergo both linear and volumetric change, the latter being substantially 3 times the former. Liquids are subject to volumetric expansion only. All gases have substantially the same coef over a wide range, which is $^1/_{460}$ of their vol at 32° F and atmos press. A gas following this law exactly is termed a perfect gas. Most of the common gases follow the law closely enough for practical purposes, but vapors, being gases only when at temperatures considerably above their condensation points, follow it less closely, so that for them results are only approx. Tables 17 and 18 give the coef of expansion for common substances.

Table 17. Coefficient of Linear Expansion of Solids

9. PRESSURE, VOLUME, AND TEMPERATURE RELATIONS FOR GASES

$$\text{For a perfect gas, } PV = wRT \tag{41}$$

where P = abs press, lb per sq ft; V = vol, cu ft; w = wt, lb; R = the gas constant = $778\,(C_p - C_v)$; T = abs temp, deg F.

$$\text{When a gas expands, } P_1V_1^s = P_2V_2^s \tag{42}$$

and a comparison with Eq 41 shows the following relations:

$$\frac{P_1}{P_2} = \left(\frac{V_2}{V_1}\right)^s = \left(\frac{T_1}{T_2}\right)^{\frac{s}{s-1}} \qquad \frac{V_1}{V_2} = \left(\frac{P_2}{P_1}\right)^{\frac{1}{s}} = \left(\frac{T_2}{T_1}\right)^{\frac{1}{s-1}} \qquad \frac{T_1}{T_2} = \left(\frac{P_1}{P_2}\right)^{\frac{s-1}{s}} = \left(\frac{V_2}{V_1}\right)^{s-1}$$

These relations are shown graphically in Fig 21, the vertical scales representing press ratios, horiz scale at top vol ratios, and horiz scale at bottom, temp ratios. The curves denote values of s. Left-hand group of curves give relations between press and vol, right-hand, between press and temp Thus, for air expanding from 7 atmos to 1 atmos, when expansion is such that s = 1.4, the press ratio = 7, final vol will be 4 times original, and final abs temp 1 ÷ 1.74 times original abs temp.

Volume per lb of a gas may be experimentally determined for a given press and temp; Table 19 gives values for common gases. Specific vol may be found from the molecular wt of the gases by Avogadro's law, that "equal volumes of gases at the same press and temp contain the same number of molecules"; hence $\delta_1 \div \delta_2 = m_1 \div m_2$, where δ = density of the gas, lb per cu ft, and m = molecular wt. Density of hydrogen is 0.00559 lb per cu ft, at 32° F and atmos press; its molecular wt is 2. Considering this as the most reliable gas on which to base the others, the wt of any gas in lb per cu ft = 0.00279 × molecular wt, and its vol in cu ft per lb = 358 ÷ molecular wt. These equations

Table 19. Specific Volumes and Densities at 32° F and 14.7 Lb per Sq In and Gas Constants of Common Gases

Gas	Lb per cu ft	Cu ft per lb	Gas constant	Authority
Air	0.0807	12.39	53.33	Rayleigh
Ammonia	0.0476	21.02	90.47	Leduc
Carbon dioxide	0.1227	8.15	35.08	Rayleigh
" monoxide	0.0781	12.81	55.14	Leduc
Ethylene	0.0795	12.58	54.15	Saussure
Hydrogen	0.0056	177.91	765.89	Rayleigh
Methane	0.0447	22.35	96.20	Thomson
Nitrogen	0.0783	12.77	55.98	Rayleigh
Oxygen	0.0892	11.21	48.24	

give the values at 32° F and atmos press of 14.7 lb per sq in. To convert this value into that for any other press and temp use the following relation:

$$\text{Vol at any temp and press} = \text{vol at } 32° \text{ F and } 14.7 \text{ lb} \times \frac{T}{492} \times \frac{14.7}{p} \tag{43}$$

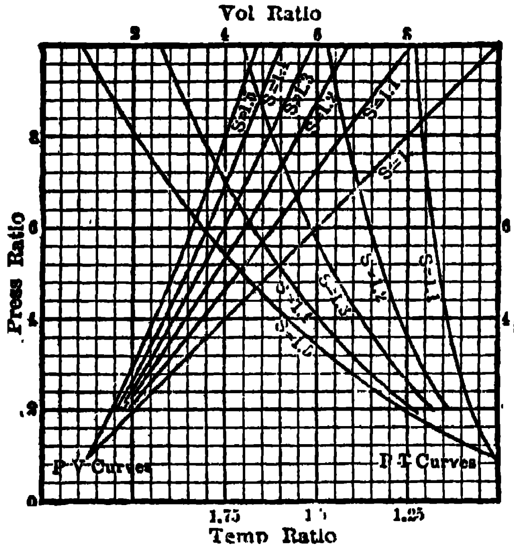

Fig 21. P–V–T Change Relations for Gases

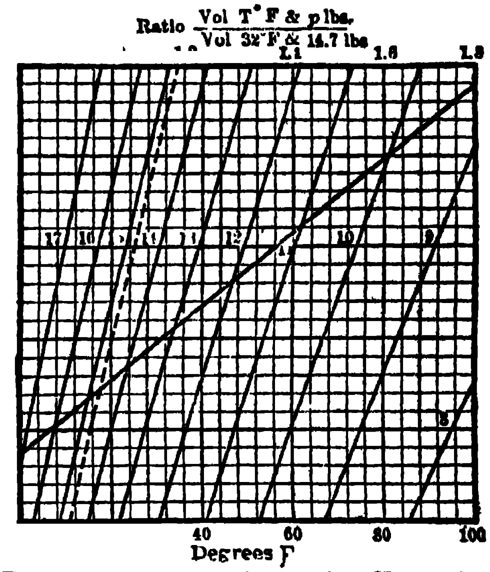

Fig 22. Diagram to Determine Change in Specific Vol, with Press and Temp

where T is abs temp F, and p abs press, lb per sq in. Fig 22 gives the ratio of the vol under the desired conditions to that under standard conditions. Lower scale is in deg F; the upper is the ratio, and the diagonal lines are different pressures. Should the vol of a certain gas be desired at 100° F and 10 lb press, when the vol at standard conditions is known, simply multiply the standard vol by the factor found by projecting upward from 100 on lower scale to the heavy diagonal, then horiz to the 10-lb line, and then again up to the top scale, where 1.67 is read; hence actual vol = 1.67 times that under standard conditions. Density, or lb per cu ft under the actual conditions, is of course the reciprocal of the vol per lb. The vol per lb dry air at different press and temp being often required is given in Table 20. Table 21, with the following simple equations, takes the place of tables giving the wt of dry air and of water vapor contained per cu ft of moist air, and lb of moisture per lb of air for all conditions of saturation, temp and barom press, which would be too bulky for insertion here.

t = temp, deg F; P_B = barom press, in of Hg; P_V = partial press of vapor (Art 10) at $t°$, lb per sq in abs; P'_V = partial press of vapor at $t°$, in of Hg; P_A = partial press of saturated air, lb per sq in abs; P'_A = partial press of saturated air, in of Hg; Z = cu ft per lb dry air; T = abs temp = $460 + t°$; δ = density of vapor = wt per cu ft; $P_A = P_B - P_V$; $Z = 0.37\dfrac{T}{P_A} = 0.7534\dfrac{T}{P'_A}$; Lb vapor per lb air = $Z\delta$. Total wt per cu ft of mixture = $(1 + Z) + \delta$

For non-saturated conditions, results sufficiently accurate for most purposes can be obtained by finding dew point from tables or curves (Sec 23, Fig 1), computed for standard atmos conditions.

Example 14. Find wt of 1 cu ft of air, saturated with moisture at 100° F; wt of the air alone for the same conditions; and wt of water per lb of air, for barom reading of 27 in of Hg. For 100° the vapor press is 0.946 lb per sq in, the total press at 27 in of Hg is 13.25 lb per sq in; hence, the partial press of air is 13.25 − 0.95 = 12.30. Wt of vapor per cu ft (Table 21) is 0.0028 lb. Wt of air per cu ft is $1 \div Z$, or $1 \div \left(0.37 \times \dfrac{510}{12.3}\right) = 0.0653$, and total wt = 0.0653 + 0.0028 = 0.0681 lb. Water per lb air = 0.0028 × 15.3 = 0.0429 lb.

Example 15. Considering Example 14 as for air 54% saturated. The dew point (Sec 23, Art 1) is 80° F. Vapor press is then 0.505 lb per sq in; hence, partial press of the air is 13.25 − 0.505 = 12.75 lb; wt of vapor = 0.0016, wt of air = 0.0676, total wt = 0.0016 + 0.0676 = 0.0692 lb. Water per lb of air = 0.0016 × 14.8 = 0.0215 lb, by same method as in Ex 14.

10. VAPORS

A vapor is a gas near its condensation temp, or the gaseous form of a substance normally a liquid or solid. Any liquid will evaporate or give off vapor at any temp, but only while the press exerted by the vapor is less than a certain value, different for each temp and each substance. On reaching this press evaporation ceases, but if the temp be increased evaporation again takes place until a new pressure value is attained. Thus, for a liquid and vapor together, fixing the temp fixes the vapor press, and the curve showing this relation to $P - T$ coordinates is called the vapor press-temp curve, or the vapor-tension curve, of the substance. Relation between press and temp may be expressed by an equation.

The press referred to in above paragraph is press of the vapor alone, and is independent of the presence of other gases. Thus, if water be placed in a vessel in which there is an absolute vacuum, and the temp maintained at 170° F, the press will rise to 6 lb per sq in. If, instead of having a vacuum

in the vessel, it had been filled with dry air at 170° F and 15 lb, and the water then added, the press would have risen to 21 lb = 15 + 6, the air pressure not influencing the water. Here, the values 6 and 15 are termed the partial pressures of the water vapor and air. Vapor in presence of its liquid can not have a temp other than that fixed by the press; under these conditions it is SATURATED, but if removed from the liquid it may be heated to a temp greater than the saturated value. Vapor under these conditions is SUPERHEATED, and the amount of superheat is expressed in deg above saturation temp.

Dalton's Law. When a space is filled with 2 or more gases, the press exerted equals the sum of all the partial pressures, and the mixture behaves as a single gas. Ratio of any partial press or vol to that of the whole may be expressed as a function of the weights and gas constants as follows:

$$\frac{P_1}{P_m} = \frac{w_1 R_1}{w_m R_m} \text{ and } \frac{V_1}{V_m} = \frac{w_1 R_1}{w_m R_m} \tag{44}$$

where P = press, V = vol, w = wt, and R = gas constant, the subscript 1 referring to a single constituent and m to the mixture. If one constituent is a vapor, its partial press is limited by the temp, and, when the press is that corresponding to the temp, the gas is said to be saturated, since the maximum amount of vapor is present. Actually, it is the space that is saturated, as the presence of the gas does not affect the vapor, but it is customary though quite incorrect to say that the gas is saturated. For this case, the following relation holds true:

$$W_v + W_g = P_v M_v + P_g M_g \tag{45}$$

where W = wt, P = press, M = molecular wt, subscript v = vapor and g = gas. If the gas contains less wt of vapor than corresponds to the saturated state, the ratio of actual wt to saturation is termed the relative humidity (Sec 23, Art 1). If a gas-vapor mixture, for which relative humidity is less than 100%, is cooled at constant press, the temp at which moisture begins to condense (that is, when saturation occurs), is called the dew point.

Two humidity problems are important in dealing with moisture in the atmos, and with preparation of liquid fuels for internal-combustion engines. The humidity of the air is found by the psychrometer (Sec 23, Art 1) (4). The problem of humidifying air with liquid fuels can not be treated briefly enough to be inserted here (10, 15). See "Conditioning of Air," Art 17; also Sec 14.

Sublimation is the process by which solids pass directly to the vapor state without the intervening state of liquid.

11. FUSION AND EVAPORATION

In Art 7 it was stated that if substances were heated without change of state the heat was manifested by a change in temp. But, under continued heating, solids and liquids

Table 22. Temperature and Latent Heat of Fusion (From Smithsonian Tables)

finally reach temp at which fusion, or change from solid to liquid, and evaporation, or change from liquid to vapor, will occur. During either process, the temp is constant if the press be fixed, and the heat added is directly proportional to the wt of substance changed. Quantity of heat required to fuse or evaporate 1 lb of a substance is the latent heat of fusion or vaporization, and is exactly equal to the quantity which must be removed to cause the condensation or solidification of 1 lb of the substance. LATENT HEAT OF VAPORIZATION varies considerably with change of press, but the heat of fusion is practically constant. Any change in the latter is of little importance in engineering, as fusion or solidification in most cases takes place at atmos press. For equations expressing the heats of fusion and vaporization in terms of other quantities and their derivation, see Bib (8). The temp and latent heats of fusion, and temp and latent heats of evaporation, at atmos press, for common substances are given in Tables 22 and 23.

12. PROPERTIES OF STEAM

Properties of dry saturated and superheated steam are given in Tables 24 and 25. For discussion of sources of data, see the original tables (8, 9).

Dry saturated steam is steam having the temp due to its press, but containing no moisture; it is rarely found in practice, as commercially "dry" steam usually contains from 1 to 4% of water, or is superheated. Quality of steam is designated by the amount of dry steam present in 1 lb of actual steam stuff, or by the degrees of superheat; for example, 95% dry steam means steam-stuff containing 95% of steam and 5% of water, and 100° superheat means steam having a temp 100° above that due to the press. As the values in the saturated table are for 100% dry steam, made from water at 32° F, corrections must generally be applied, first for quality and second for the original temp. Two methods are available, first to follow the procedure actually occurring in the boiler, and second, to correct the table values for the heat not added to the steam.

Example 16. Find the heat required to make 1 lb of steam at 100 lb abs press, 95% dry, from feed water at 100° F. By first method there must first be added enough heat to raise water from 100° F to the boiling point at 100 lb. From the tables the heat of the liquid at 100° F is 68, and at 100 lb is 298, or, a difference of 230. If the specific heat of water were unity throughout the entire range, this should be the same as the difference between the temp at 100 lb and 100° F, or 228. But, the resulting error is negligible for practical work, and hence the heat to raise the water to the boiling point from feed-water temp may be considered as equal to the temp difference. When water has been raised to boiling point, 95% is evaporated; therefore, to the heat necessary to heat water is added 0.95 of latent heat of evaporation, or in this case 0.95 × 888, hence total heat = 230 + 0.95 × 888 = 1 074. By the second method the total heat from tables is, for dry steam, 1 186. But, there was

Table 24. Properties of Saturated Steam

(Condensed from Marks and Davis's Steam Tables and Diagrams (4), 1909, by permission of the publishers, Longmans, Green & Co). See also Goodenough's Tables (19)

already in feed water the heat necessary to raise it to 100° F from 32° F, or 68 units, also, 5% of latent heat was not utilised, because only 95% of water was evaporated; hence, actual total heat = 1 1[illegible] − 68 − (0.05 × 888) = 1 074, as before. For the superheated condition, the correction for h[illegible] the feed water only is required.

Table 25. Properties of Superheated Steam

v = spec vol in cu ft per lb, h = total heat, from water at 32° F, in B t u per lb, n = entropy, from water at 32°. (Condensed from Marks and Davis's Steam Tables and Diagrams) (4)

13. COMBUSTION AND ITS EFFECTS

The process of combustion is exothermic or heat liberating, and consists in the rapid oxidation of practically only 2 chemical elements, C and H, either free or in combination with each other. Few natural fuels consist of these elements in the free state; they are

generally combined in a complex manner. The formation of the compound took place with the liberation or absorption of heat, so that when the fuel is burned there is liberated, not the quantity of heat which would result from the burning of an equivalent quantity of free C and H, but a greater or less quantity depending upon whether the breaking up of the compound develops or absorbs heat. The HEAT OF COMBUSTION is then the heat of formation of the products less the heat of formation of the compound. In engineering calculations, it is generally sufficiently exact to consider heat of combustion as equal to the heat of formation of products, inasmuch as in exact or test work the heat of combustion of a fuel should be determined by calorimeter.

When H burns, the product is H_2O in the gaseous state, equal to 9 times the wt of H originally present. Usually the products pass off at a temp greater than 212° F, but at lower temp the vapor will condense to liquid, giving up 970 B t u per lb, or 9 × 970 B t u per lb of H. Hence, fuels containing H may have 2 heating values, the HIGH VALUE, when the products cool to less than 212°, and the LOW VALUE, when they do not No definite rule exists as to which should be used, nor is it material, provided there be a clear understanding between the parties interested. Generally, the high values are used for boiler and other open fires, and the low values for explosive combustion. The values found by calorimeter are high values.

Table 26 gives heating values per lb and per cu ft at 32° F and 14.7 lb, for some simple substances, and for common liquid and gaseous fuels. The latter are merely averages, but give a general idea of what may be expected from each class.

Table 26. Heats of Combustion. (Selected from Lucke's Engineering Thermodynamics)

Heating value of a fuel. To compute it, the chemical analysis must be known. The fractional quantity of each constituent is then multiplied by its heating value, and the sum of these products is the heating value of the fuel. Analyses of solid and liquid fuels are reported in percentages by wt, gaseous fuels, by volume. Coals are reported in 2 ways: proximate and ultimate analysis, the former ascertaining moisture, volatile matter, fixed carbon and ash, the latter the chemical constituents, C, H, S, O, and ash. As the character of the volatile matter can not be determined, attempts to compute the calorific value of coals from proximate analysis are not very successful, the ultimate values being generally used. Following formula, by Lucke, applies with fair accuracy over a rather wide range of coals:

$$Q = 14\,544\,C + 27\,000\,V\left[1 - \frac{1}{\frac{C}{V} + 0.5}\right] \qquad (46)$$

in which Q = B t u per lb, C = fractional wt of fixed carbon, V = fractional wt of volatile matter. When ultimate analysis shows both O and H, it is assumed that the O,

and as much of the H as can chemically combine with it, exist as water, and hence only the remaining H is available as a heat producer. Following formula, proposed by Am Soc Mech Engs, is based on this assumption:

$$Q = 14\,600\,C + 62\,000\left(H - \frac{O}{8}\right) + 4\,000\,S \tag{47}$$

in which Q = B t u per lb, and C, H, O, and S are the fractional weights of carbon, hydrogen, oxygen, and sulphur per lb of coal.

Example 17. The calorific value of a coal was 13 900 by calorimeter. Proximate analysis: moisture, 1.25; vol matter, 39.03; fixed C, 53.72; ash, 6.00. Ultimate analysis: H_2, 2.47; C, 87.57; N_2, 1.09; O_2, 2.87; S, 0; ash, 6.00. Calculated values would be:

(a) by Eq 46, $14\,544 \times 0.537 + 27\,000 \times 0.39\left[1 - \dfrac{1}{1.38 + 0.5}\right] = 12\,750$ B t u

(b) by Eq 47, $14\,600 \times 0.876 + 62\,000\left(0.0247 - \dfrac{0.0287}{8}\right) = 14\,085$ "

(c) by calculation from ultimate analysis,

$$14\,544 \times 0.876 + 60\,626\left(0.0247 - \frac{0.0287}{8}\right) = 14\,003 \text{ ''}$$

Sherman and Kropff found that the heating value of oils is a function of density, and deduced following expression, which is within 2 to 3% of the calorimetric values:

$$Q = 18\,650 + 40\,(B\acute{e} - 10) \tag{48}$$

$B\acute{e}$ = deg on Beaumé hydrometric scale, the usual mode of reporting oils. Stanton and Strong revised the constant in Eq 48 for gasolene, and Allen and Strong for kerosene:

$$\left.\begin{aligned} Q &= 18\,320 + 40\,(B\acute{e} - 10), \text{ for gasolene} \\ Q &= 18\,440 + 40\,(B\acute{e} - 10), \text{ for kerosene} \end{aligned}\right\} \tag{49}$$

with an error of less than 1% in all tests.

Example 18. Find heating value of the following gas high and low values:

CO	H_2	CH_4	C_2H_4	N_2	O_2	CO_2
7	38	40	3	8	2	4

Multiply quantity of each combustible constituent by its heating value (see table).

Results found are for 32° and 14.7 lb, since the heating values for the constituents are for this press and temp. For any other press and temp the value will be the above $\times$ 33.5 $p \div T$, where p = press, lb per sq in abs, and T = abs temp F. At 70° F, the values are 576 and 527.

High value	Low value
7 × 338 = 24	7 × 338 = 24
38 × 341 = 122	38 × 292 = 111
40 × 1 060 = 424	40 × 960 = 384
3 × 1 700 = 51	3 × 1 595 = 48
621	567

Air needed for combustion is most readily computed from the chemical equations representing the reactions. The quantity required to satisfy the equations is that which is chemically necessary. But, in burning fuels, with the possible exception in the case of internal-combustion engines, considerably more air must be supplied completely to burn the fuel than is apparently required. The difference between these amounts is termed the excess air.

Chemical symbols indicate the amounts as well as the substances entering into a reaction. Thus the equation, $CH_4 + 2\,O_2 = CO_2 + 2\,H_2O$ may be stated in words in 3 ways: (a) CH_4 (methane) combining with O forms CO_2 and water vapor; (b) 16 lb CH_4 combined with 64 lb O forms 44 lb CO_2 and 36 lb water vapor; (c) 1 cu ft CH_4, combined with 2 cu ft O forms 1 cu ft CO_2 and 2 cu ft water vapor. Thus, not only does the symbol name the substance, but also gives the wt and vol reacting, as each symbol represents 1 unit vol, or the molecular wt of the substance in any units. In engineering practice the wt is taken in lb and the vol in cu ft. The molecular wt of any substance is the sum of the atomic wt of the elements forming it, taken as many times as they occur; CH_4, for example, being composed of 1 C (atomic wt, 12) and 4 H atoms (atomic wt, 1), has a molecular wt of $12 + (4 \times 1) = 16$, and the symbol CH_4 indicates 16 lb of methane. It should be noted that the molecule of simple gas is composed of 2 atoms, hence 1 cu ft of H, O, or N is represented by H_2, O_2, or N_2, and not by H, O, or N. For atomic weights of the elements, see Sec 37.

As air is approx 21% O by vol, or 23% by wt, the air required to burn a substance is found by dividing the vol of O required by 0.21, or the wt by 0.23. Table 27 gives the air required per lb or cu ft of different substances.

To find the air required by a mixture of substances, it is merely necessary to find the sum of the quantities of air needed for each constituent. In general it is simpler to find the wt of air required for solids and liquids, and convert to cu ft if needed, and to find the cu ft needed for gases and convert to lb.

Table 27. Air Chemically Required for Complete Combustion

Symbol	Substance	1 lb requires		1 cu ft requires	
		cu ft	lb	cu ft	lb
C_2H_2	Acetylene	165.1	13.3	11.95	0.96

Example 19. Find the air required to combine chemically with 1 lb coal, the ultimate analysis of which is given under Example 17:

(a) By chemical equations:

$$H_2 + O = H_2O \qquad C + O_2 = CO_2$$
$$2 + 16 = 18 \qquad 12 + 32 = 44$$

hence 1 lb H_2 requires 8 lb O_2, and 1 lb C requires 32 ÷ 12 lb O_2; therefore, the O required by coal per lb is

$$\left(0.0247 - \frac{0.0287}{8}\right) \times 8 + 0.8757 \times (32 \div 12) = 2.51 \text{ lb}$$

and the air required is 2.51 ÷ 0.23 = 10.9 lb. Should the vol be required, the wt is multiplied by the cu ft per lb at the press and temp desired.

(b) By Table 27,

$$\left(0.0247 - \frac{0.0287}{8}\right) \times 34.6 + (0.8757 \times 11.6) = 10.9 \text{ lb}$$

Example 20. Find the air required for chemical combination with a gas, the analysis of which is given under Example 18:

(a) By chemical equations:

$$CO + O = CO_2 \quad H_2 + O = H_2O \quad CH_4 + 2\,O_2 = CO_2 + 2\,H_2O \quad C_2H_4 + 3\,O_2 = 2\,CO_2 + 2\,H_2O$$
$$1 + 0.5 = 1 \qquad 1 + 0.5 = 1 \qquad 1 + 2 = 1 + 2 \qquad 1 + 3 = 2 + 2$$

hence 1 cu ft H_2 or CO requires 0.5 cu ft O_2, 1 cu ft CH_4 requires 2 cu ft O_2, and 1 cu ft C_2H_4 requires 3 cu ft O_2; therefore, the gas requires

$$(0.07 \times 0.5) + (0.38 \times 0.5) + (0.4 \times 2) + (0.03 \times 3) - (0.02 \times 1) = 1.095 \text{ cu ft } O_2,$$

and the air needed = 1.095 ÷ 0.21 = 5.22 cu ft. To convert to lb, multiply by the density at the existing press and temp.

(b) By Table 27,

$$\text{Air} = (0.07 \times 2.39) + (0.38 \times 2.39) + (0.4 \times 9.59) + (0.03 \times 14.34) - (0.02 \div 4.8) = 5.22 \text{ cu ft.}$$

$$\text{Wt air per lb fuel} = 11.5\,C + 34.6\,H \text{ (approx)} \tag{50}$$

The above expressions and methods are useful in finding the air chemically required. The actual quantity of air for combustion is found by analysis of the flue gas. Then, the air required per lb of C is determined by Eq 51, for fuels containing but little H; when there is much H, the relations are too complex to be of much use.

$$\text{Lb of air per lb } C = (3\,N_2 \div 0.165\,O_2) \div (CO + CO_2), \tag{51}$$

where N_2, O_2, CO, and CO_2 are percentages by vol by flue-gas analysis.

Products formed by combustion are chiefly CO_2, water vapor, and the N from the air. When excess air is used this is also found in the products. When insufficient air is sup-

plied, it is generally impossible to predict the analysis of the products, because the quantity of the available air received by each combustible can not be foretold.

Example 21. Compute the products of combustion for the fuels of Example 19 for the case of the necessary and of twice the necessary air. From the equations, 1 lb C makes 44 ÷ 12 lb CO_2, and 1 lb H_2 makes 9 lb H_2O; hence, 9 × 0.0247 = 0.222 lb H_2O + (44 ÷ 12) × 0.8757 = 3.21 lb CO_2 + 0.0109 lb N_2 from fuel, and 0.77 × 10.9 = 8.4 lb N_2 from air. With 100% excess air, the water vapor and N from the coal will be the same, and the N from the air twice as great, and there will be 10.9 × 0.23 lb of O from the excess air.

Loss due to incomplete combustion of C to CO instead of CO_2 is found from flue gas analysis by Eq 52:

$$\text{Loss (B t u) due to unburned CO per lb C} = 10\,193\left(\frac{CO}{CO + CO_2}\right) \qquad (52)$$

Producer reactions. Gas producers produce a combustible gas from solid fuel, as coke, anthracite coal, and to a less extent from bituminous coal, lignite, etc. The nearer pure carbon the fuel, the better the result. If the producer blast be air alone, the reactions are: $C + O = CO$, $C + O_2 = CO_2$, and $CO_2 + C = 2\,CO$; if with steam alone, not a continuous process, the reaction is $C + H_2O = CO + H_2$; or steam and air may be used together, in which case the composition of the gas formed is too complex to discuss here (1).

Final temp and press due to combustion. Combustion may take place at either constant press or constant vol, explosively or nonexplosively, a rise in press being characteristic of explosive combustion, but not necessarily defining it. For explosive combustion a mixture of fuel and O, with or without neutral gases, as N, must be present and intimately mixed, so that a flame once started proceeds rapidly throughout the mass.

A rise in temp always occurs, but which can only be estimated, because of uncertainty of specific heats and other phenomena. Mode of procedure is to apply correction factors found by experience to the hypothetical results computed. Temp rise due to combustion is

$$\left.\begin{aligned} t_2 - t_1 &= C\frac{Q}{0.17w}, \text{ for constant vol} \qquad (a)\\ t_2 - t_1 &= C\frac{Q}{0.24w}, \text{ for constant press} \qquad (b)\end{aligned}\right\} \qquad (53)$$

where t_1 and t_2 are the initial and final temp, Q the heat liberated, w the wt of products formed, and C a constant. Value of C lies between 0.45 and 0.55 for both furnace combustion and gas-engine work, when there is about the chemically correct amount of air, but it has higher values for excess air. The vol and press changes due to combustion are

$$V_2 - V_1 = \frac{V_1}{T_1}\left(\frac{CQ}{0.24w}\right) \text{ and } P_2 - P_1 = \frac{P_1}{T_1}\left(\frac{CQ}{0.17w}\right), \qquad (54)$$

where V_1, P_1, T_1 are the original vol in cu ft, press in lb per sq ft, and temp in deg abs; V_2, P_2, T_2 the final values, Q the heat liberated, C the constant as above, and w the wt of products. The press rise is more conveniently expressed by

$$\begin{matrix}\text{Press rise,}\\ \text{lb per sq in}\end{matrix} = 72.3\,C\left(\frac{\text{initial press, lb per sq in abs}}{\text{initial temp, °F abs}}\right) \times \left(\frac{\text{B t u per cu ft of mixture}}{\text{at 32° F \& 14.7 lb abs}}\right) \qquad (55)$$

Temp of ignition is the temp to which a substance must be heated before combustion takes place. Experiments by Falk and others indicate that this temp is not constant.

Falk proved that for gaseous mixtures, it varies with the proportion of gas to air. He gives following values, as true over a 100% range of proportions:

Ignition temp of gasolene mixtures with air .... 986° F
" " " alcohol " " " .... 1 292° F

Beyond certain limits of the air-gas ratio, mixtures will not ignite. Table 28 gives this limit for several gases, expressed in terms of the percentage of detonating mixture which must be present for ignition to occur. By DETONATING MIXTURE is meant the combustible portion of fuel plus the O chemically required for combustion.

Table 28. Percentage of Detonating Mixture in Total Air-gas Mixture at Explosive Limits of Proportion (Bunte)

Gas	For excess air	For excess gas	Gas	For excess air	For excess gas
Carbon monoxide	24.8	15.8	Ethylene	16.4	23.9
Hydrogen	14.2	21.2	Alcohol	15.0	24.2
Water gas	18.2	21.0	Methane	18.3	27.5
Acetylene	11.7	14.0	Benzene	19.9	22.3
Coal gas	17.4	31.2			

Rate of combustion of coal is controlled by the draft. Following relation (1) holds for small-sized anthracite and bituminous coal:

$$\text{Lb coal per sq ft grate surface per hr} = C\sqrt{\text{draft, in of } H_2O} \qquad (56)$$

where C has the following values: anthracite rice, 17.3; anthracite No 1 buckwheat, 24.5; anthracite pea, 31.5; semi-bituminous, 50.2; bituminous, run-of-mine, 81.6; bituminous, slack, 59.3.

Efficiency of combustion in furnaces is the ratio of heat developed to that contained in the coal; sometimes termed furnace effic, and ranges from 80 to 95%. In producers, the effic is a matter of gasification, and is the ratio of the heat in the gas from 1 lb of coal to the heat originally in the coal (Sec 37, Table 12).

14. HEAT TRANSFER

Except in the burning of explosive mixtures, heat is practically never developed in the substance heated. In all other cases, heat must be conducted or transmitted to the desired point, generally through separating walls. Flow of heat may be grouped in 3 classes, internal conduction, radiation, and convection.

Table 29. B t u Transmitted per Hr per Sq Ft per Deg F Difference in Temp per In Thickness

Substance	K	Substance	K

Leather (cowhide)	1.22		
Lime	0.84		

Internal conduction is the passage of heat along a bar of any substance, from a hot to a cooler zone. In this case, the characteristics of different materials are fairly well known.

Values for common substances are given in Table 29, in which K is the B t u transmitted per hr through a plate 1 ft square and 1 in thick per deg difference in temp. K is not constant, but varies with the temp in a linear relation; that is, $K_t = K_{32}[1 + a(t - 32)]$. Where value of a is known, it is given in Table 29; when not given, the single value found must be used regardless of temp. For great temp range, the mean value of the coeff must be used, the mean value of K between 2 points being

$$K_{32}\left(1 + \frac{a}{2}[(t_2 - 32) + (t_1 - 32)]\right),$$

hence the heat flow through a body by internal conduction is

$$Q = \frac{A}{l} K_{32} \left(1 + \frac{a}{2}[(t_2 - 32) + (t_1 - 32)]\right)(t_2 - t_1), \tag{57}$$

where Q = B t u per hr, A = cross-sec of path in sq ft, l = length of path, in, K_{32} = coeff at 32° F, t_2 = high temp, t_1 = low temp. Temp t_2 and t_1 must be taken in the body itself; not in the fluid surrounding it.

Radiation of heat by a body is the transfer of heat from a hotter to a cooler body, without warming the intermediate space. Most common example is the sun's heat, which warms the earth, but not the intervening medium. The permeability of different materials to heat waves varies as with light waves, but a substance easily passed by one is not necessarily passed by the other. The most accepted law for heat radiation is that of Stefan and Bolzman; the heat radiated from an incandescent body, black when cold, varies as the difference of the fourth powers of the temp, thus:

$$\text{B t u radiated per hr per sq ft} = 16 \times 10^{-10}\,(T_2^4 - T_1^4), \tag{58}$$

where T_2 = abs temp F of the radiating, and T_1 = that of the receiving body.

Practically the only black body (that is, one which is 100% efficient in absorbing heat rays and reflecting or transmitting none) is carbon, the crystalline form excepted. All other bodies reflect some heat and fail to radiate to the same extent. As radiation increases with roughness and darkness, surfaces from which radiation is not desired are frequently polished. Table 30 gives relative radiating and reflecting power of different substances, compared to carbon as unity for radiation and zero for reflecting power. Of course heat rays striking at an angle are partly reflected, and for small angles nearly all the heat may be reflected.

Table 30. Radiation and Reflection Coefficients (Kent)

Substance	Radiating or absorbing power	Reflecting power	Substance	Radiating or absorbing power	Reflecting power
Brass cast	0.11	0.89	Ivory, Jet, Marble	0.93–0.98	0.07–0.02
Brass polished	0.07	0.93			
Carbon, porous	1.00	0.00			
Carbonate of lead	1.00	0.00	Mercury	0.23	0.77
Cast iron	0.25	0.75	Platinum, polished	0.24	0.76
Copper, hammered	0.07	0.93	" sheet	0.17	0.83
" varnished	0.14	0.86	Silver polished	0.03	0.97
Glass	0.90	0.10	Steel "	0.17	0.83
Gold, plated	0.05	0.95	Tin	0.15	0.85
Ice	0.85	0.15	Wrought iron	0.23	0.77
			Zinc	0.19	0.81

Convection is the actual conveyance of heat by the movement of particles of a subtance. The most important example is the heating of water in vessels, where the heat applied to the bottom is carried up through the liquid by the particles of water, which, on becoming warmer, grow less dense and tend to float or rise through the mass being heated. Convection can occur only in liquids or gases, substances in which the particles are free to move, and as radiation and conduction generally take place at the same time it is difficult to isolate the convection effect.

Heat transfer between separated fluids. When heat flow passes from one body to another, a high resistance to flow is encountered, even a carefully-made joint being equivalent to several inches of the bar itself. Hence, boiler seams are not allowed in contact with the fire, because the high resistance of the joint would prevent the carrying away of heat fast enough to prevent the fire side from overheating. Between a plate and a fluid a film adheres to the plate, causing high resistance; by reducing this, agitation of the fluid or high velocity increases the rate of heat transfer.

Generally, in heat transfer apparatus, there is high resistance to flow on one side or the other of the separating wall, and but little improvement is realized by agitation or similar effort on the low-resistance side. In boilers, for example, the high resistance lies between the gases and tubes, and effort spent on the water side avails little. The total resistance to heat transfer is therefore made up of the resistance of the materials through which the heat must pass, plus the joint resistances, plus the film resistances, of which the values of very few can be determined. Considering a boiler tube, the path is made up of a layer of soot and ash of unknown thickness and conductivity, a film resistance between the gases and this, a joint resistance between the soot or ash and tube, the tube itself and a film resistance between tube and water. The practical solution of such a problem employs a coeff of heat transmission experimentally determined for various frequently-occurring conditions, and including all the separate resistances and radiation and convection effects. Such coeff, generally

designated by U, expresses the B t u transmitted per hr per sq ft of surface per deg difference in temp, measured in the separated fluids, one of which is receiving heat from the other. Values of U in aver practice are in Table 31. The heat transmitted per hr is

$$Q = AUt_m, \tag{59}$$

where Q = B t u per hr, A = area in sq ft, U = coeff, t_m = mean temp difference between the fluids.

Table 31. Coefficients of Heat Transfer U. Averages Used in Practice

Giving heat	Receiving heat		
	Liquid warming	Liquid boiling	Gas warming
Liquid cooling	50–75	{25–50, 100*}	2–6
Gas cooling	2–5	2–5	2–5
Vapor condensing	{150–350, 1 000*}	400–600	2–4

* High liquid velocity or agitation.

Mean temp difference is merely the difference between the hot and cold fluids, if throughout each the temp be constant. But, in most cases the temp of one or both is changing in accordance with which one of the 4 possible cases shown below is being considered:

	Substance losing heat may be	Substance receiving heat may be
(a)	at constant temp	at constant temp
(b)	" " "	rising in temp
(c)	falling in temp	
(d)	" " "	at constant temp

Case (c) may occur for either parallel or counter-current flow; in the former, both fluids enter at same end of the system, the final temps approaching the same value; in the latter, the fluids enter at opposite ends, final temp of one approaching initial of other. For cases where either or both fluids are changing in temp,

$$\text{Mean temp difference} = \frac{\text{Initial temp difference} - \text{final temp difference}}{\text{Nap log}\left(\dfrac{\text{Initial temp difference}}{\text{Final temp difference}}\right)} \tag{60}$$

Example 22. A solution the specific heat of which is 1.2 is to be heated to 170° from 60° by exhaust steam at atmos press and 90% dry. Find the surface required to heat 50 000 lb per hr, also the steam needed, neglecting any heating by condensed steam.

By Eq 60, $t_m = \dfrac{(212 - 60) - (212 - 170)}{\text{Nap log}\left(\dfrac{212 - 60}{212 - 170}\right)} = 86.$ $Q = 50\,000 \times 1.2 \times 110 = 6\,600\,000$ B t u

$$\text{Heat per lb steam} = 970 \times 0.9 = 873, \text{ and lb steam} = \frac{6\,600\,000}{873} = 7\,550$$

$$\text{From Table 31, } U = 150 \text{ to } 350, \text{ say } 300, \text{ and from Eq 59, } A = \frac{6\,600\,000}{300 \times 86} = 256 \text{ sq ft}$$

Example 23. The same quantity of the same liquid as in Example 22 is to be used as it cools to heat boiler-feed water, by passing the liquids in a counter-current direction through concentric pipes. 10 000 lb of water per hr are to be heated from 50° to 150°. Find required heating surface; also the required surface should it be desired to raise the final temperature of the feed water to 160°. The heat required to be transmitted will be 10 000 × 100 = 1 000 000 B t u, hence fall in temp of solution will be 1 000 000 ÷ (50 000 × 1.2) = 16.7°, and final temp will be 153.3°.

$$\text{By Eq 60, } t_m = \frac{(153.3 - 50) - (170 - 150)}{\text{Nap log}\left(\dfrac{153.3 - 50}{170 - 150}\right)} = 50.5$$

From Table 31, assume U = 60, whence from Eq 59, A = 1 000 000 ÷ (60 × 50.5) = 332 sq ft. For second case, Q = 1 100 000; final temp of sol = 151.6; t_m = 39.3; A = 464; showing the large increase in area needed for increased final temp of the cold liquid as it approaches the initial temp of the hot liquid.

Capacity of boilers and other heat-transfer apparatus is usually expressed in BOILER HORSE POWER (b h p). A b h p was originally assumed to be such that a boiler of a certain hp would supply enough steam to run an engine of the same hp. The term became too

indefinite, since engines differed widely in consumption of steam for 1 hp, and the following definitions were adopted by the Am Soc of Mech Engs:

1 b h p = 34.5 lb steam made at standard atmos press, or temp of 212° F per hr from feed water at 212° F, or 33 305 B t u absorbed per hr.

Originally these terms were equivalent, but later investigations show that if the first definition is true the second should be 33 479 B t u. The first is generally used. For ordinary feed-water temp and steam press, 34.5 lb from and at 212°, as it is termed, do not differ greatly from 30 lb under common conditions, and this being an even number is generally used as the h p unit for rating boilers, feed-water heaters, condensers, etc. That is, a feed-water heater of 100 b h p capacity will heat 30 × 100 = 3 000 lb water per hr. Boilers require from 10 to 12 sq ft of heating surface per hp, depending on type, and are frequently rated by dividing the sq ft of heating surface by these numbers.

Efficiency of a boiler is the ratio of the heat absorbed by the water or steam to that in the coal and may be separated into 2 parts:

$$\left.\begin{array}{lll}(a) \text{ Furnace effic} & = \text{heat liberated} \div \text{heat in coal} \\ (b) \text{ Surface effic} & = \text{heat absorbed} \div \text{heat liberated} \\ (c) \text{ Total boiler effic} & = a \times b = \text{heat absorbed} \div \text{heat in coal}\end{array}\right\} \quad (61)$$

Boiler effic defined above is sometimes designated as boiler and furnace effic. Among the losses tending to reduce furnace effic are coal lost to ash pit, carbon burning to CO instead of CO_2, H, and hydrocarbons passing out of stack unburned; that tending to reduce surface effic is the sensible heat of the stack gases above the room temp. For description of a complete heat balance, defining each loss and a manner of determination, see (18).

15. ENTROPY AND ENTROPY DIAGRAMS

Definitions. Just as work may be expressed as the product of press and vol change, when these quantities are expressed in proper units, so may heat be expressed as the product of temp and the change in a quantity termed entropy. One of the best definitions of entropy is that it is "heat per degree of temperature." In engineering calculations it is the CHANGE IN ENTROPY during a process, rather than the ABSOLUTE ENTROPY at any one time, that is important; hence any arbitrary zero of entropy may be chosen.

For steam work the zero generally taken is that of 1 lb of water at 32° F, and in steam tables (Art 12) the values given are above that value as a base. For ordinary work on gases the point in the process having the least entropy is selected as the zero. Entropy is usually designated by the Greek letter ϕ, and a diagram drawn to temperature-entropy coordinates is the $T\phi$ or heat diagram, precisely as one drawn to P-V coordinates is the P-V or work diagram. The area representing the amount of heat change during a process is the area under the curve down to line of zero temp, this quantity being expressed to the absolute scale. Thus, in Fig 23, the heat change from A to B is represented by area $ABCD$.

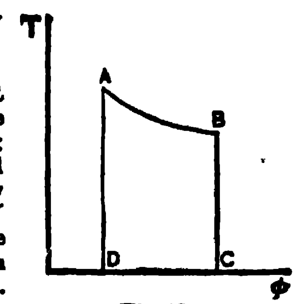

Fig 23.

Change in entropy, being the change in heat divided by the temp at which it occurs, is simply expressed if the change takes place at constant temp. If the temp is also changing, a differential form is required, for which a relation between heat and temp is necessary. This is found in the quantity known as specific heat, and the change in entropy is found by integrating. The results are given in Eq 62 for constant specific heats, the expressions resulting from varying specific heats being too complex for general use:

$$\left.\begin{array}{l}\phi_2 - \phi_1 = w\,Q \div T, \text{ for constant temp} \\ \phi_2 - \phi_1 = w \text{ Nap log } (T_2 \div T_1), \text{ for water (sp ht} = 1) \\ \phi_2 - \phi_1 = wC_v \text{ Nap log } (T_2 \div T_1), \text{ for gases at constant vol} \\ \phi_2 - \phi_1 = wC_p \text{ Nap log } (T_2 \div T_1) \text{ '' '' '' '' press}\end{array}\right\} \quad (62)$$

For superheated vapors the values for gases may be used with fair accuracy, especially for high degrees of superheat. The four commonest processes, isothermal and adiabatic expansion constant press-vol change, and constant vol-press change for gases, are shown in Fig 24 to P–V and T–ϕ coordinates.

Temperature-entropy diagram. For vapors 2 entropy diagrams are used, the temp-entropy and the B t u-entropy or Mollier diagram. Fig 25 shows on a small scale the temp-entropy diagram for steam.

The liquid line ABB''' represents the heating of water from 32° F, the area below it denoting the heat required, or the heat of the liquid at any point above 32° F. Lines BC, $B'C'$, etc, represent

steam-making at constant temp, the area under any horiz line denoting the latent heat at that temp. The third group CD, $C'D'$, etc, represents superheating at constant press. Lines of constant vol, constant quality or constant heat may also be added (omitted from this diagram for clearness). Adiabatic expansion or compression is represented by a vertical line; one of the chief uses of the diagram is to determine the quality after an adiabatic change. The length of any of the horizontals BC is equal to the latent heat divided by the temp. Should the steam be wet, all of the latent heat will not be used; hence the line will be shorter and C will move to the left to some indefinite position X.

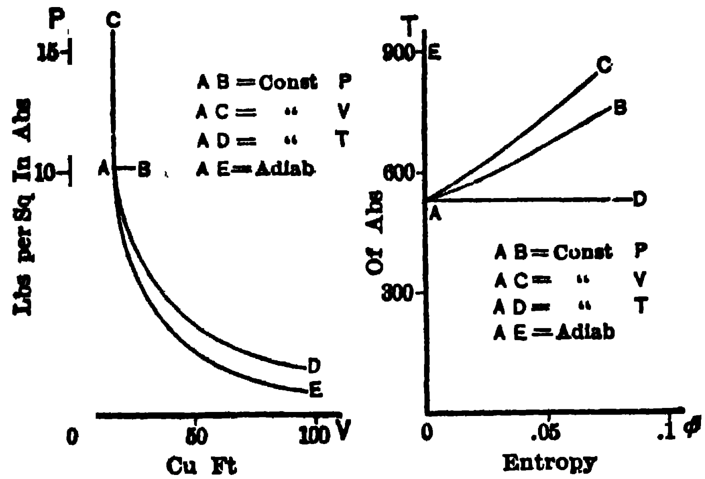

Fig 24. Constant Press, Vol, Temp, and Adiabatic Lines, for Air to P–V and T–ϕ Coordinates

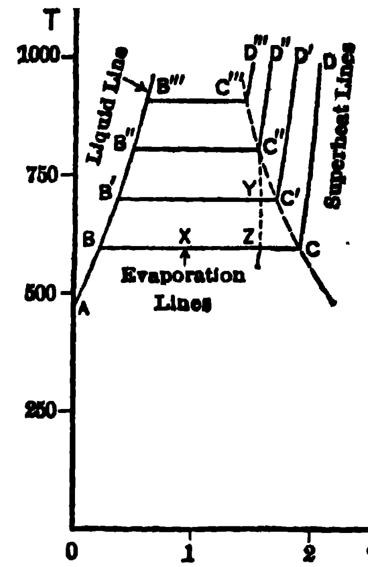

Fig 25. T–ϕ Diagram for Steam

Then as BX is proportional to the quantity of latent heat used, and BC to all the latent heat for the same press, $BX \div BC$ is the percentage of steam present, or the dryness fraction, and $XC \div BC$ the percentage of moisture present. The quality after any adiabatic change can be quickly determined by projecting from the original point up or down on the diagram. For example, if adiabatic expansion occurs from point C'' (representing dry steam at some press), when the press drops to Y the quality will be $B'Y \div B'C'$, and when pressure Z is reached, the quality will be $BZ \div BC$. The diagram shows that adiabatic expansion of dry steam causes wetness, expansion of superheated steam causes loss of superheat, and expansion of very wet steam causes drying. Compression under the above conditions causes the reverse action. For more complete description see (1).

Mollier diagram for steam, drawn to as large a scale as possible, is shown in Fig 26. This, named from its originator, Prof Mollier, is of much wider use than the temp-entropy diagram. On it, horizontals are lines of total heat; verticals, lines of constant entropy; lines nearly horiz but sloping toward the lower right-hand corner represent constant quality, and lines making an angle of more than 90° with them are lines of constant press. By projecting to the side from the intersection of a quality and press line the total heat may be read directly, or the entropy by projecting downward. Adiabatic expansion or compression is represented by a vertical line, constant total heat by a horiz.

The greatest use of the diagram is in solving Rankine-cycle problems (Art 16) for effic and for velocity of steam jets. To find the work done in a Rankine cycle it is merely necessary to read the total heat corresponding to any given press and quality, project from the original point downward to the line representing final press, read the total heat at this point and subtract the two. The final quality needed for determining m e p is found from the nearest quality line intersecting the final press line.

As explained in Art 2, the velocity of a jet is substantially equal to $\sqrt{2\,g \times \text{work}}$ and as the work is readily found by the Mollier diagram it is customary to add an extra scale giving velocity directly for any total heat difference.

Example 24. Find the quantities required in Example 26 by means of the Mollier diagram.

Heat originally in steam, per lb	= 1 248
" finally " " " "	= 1 045
Work per lb................	203 B t u
Final quality................	90%
Jet velocity................	3 190 ft per sec

Remaining quantities are found as in Ex 26. For discussion of the Rankine cycle and method of solution without the Mollier diagram, see Art 16.

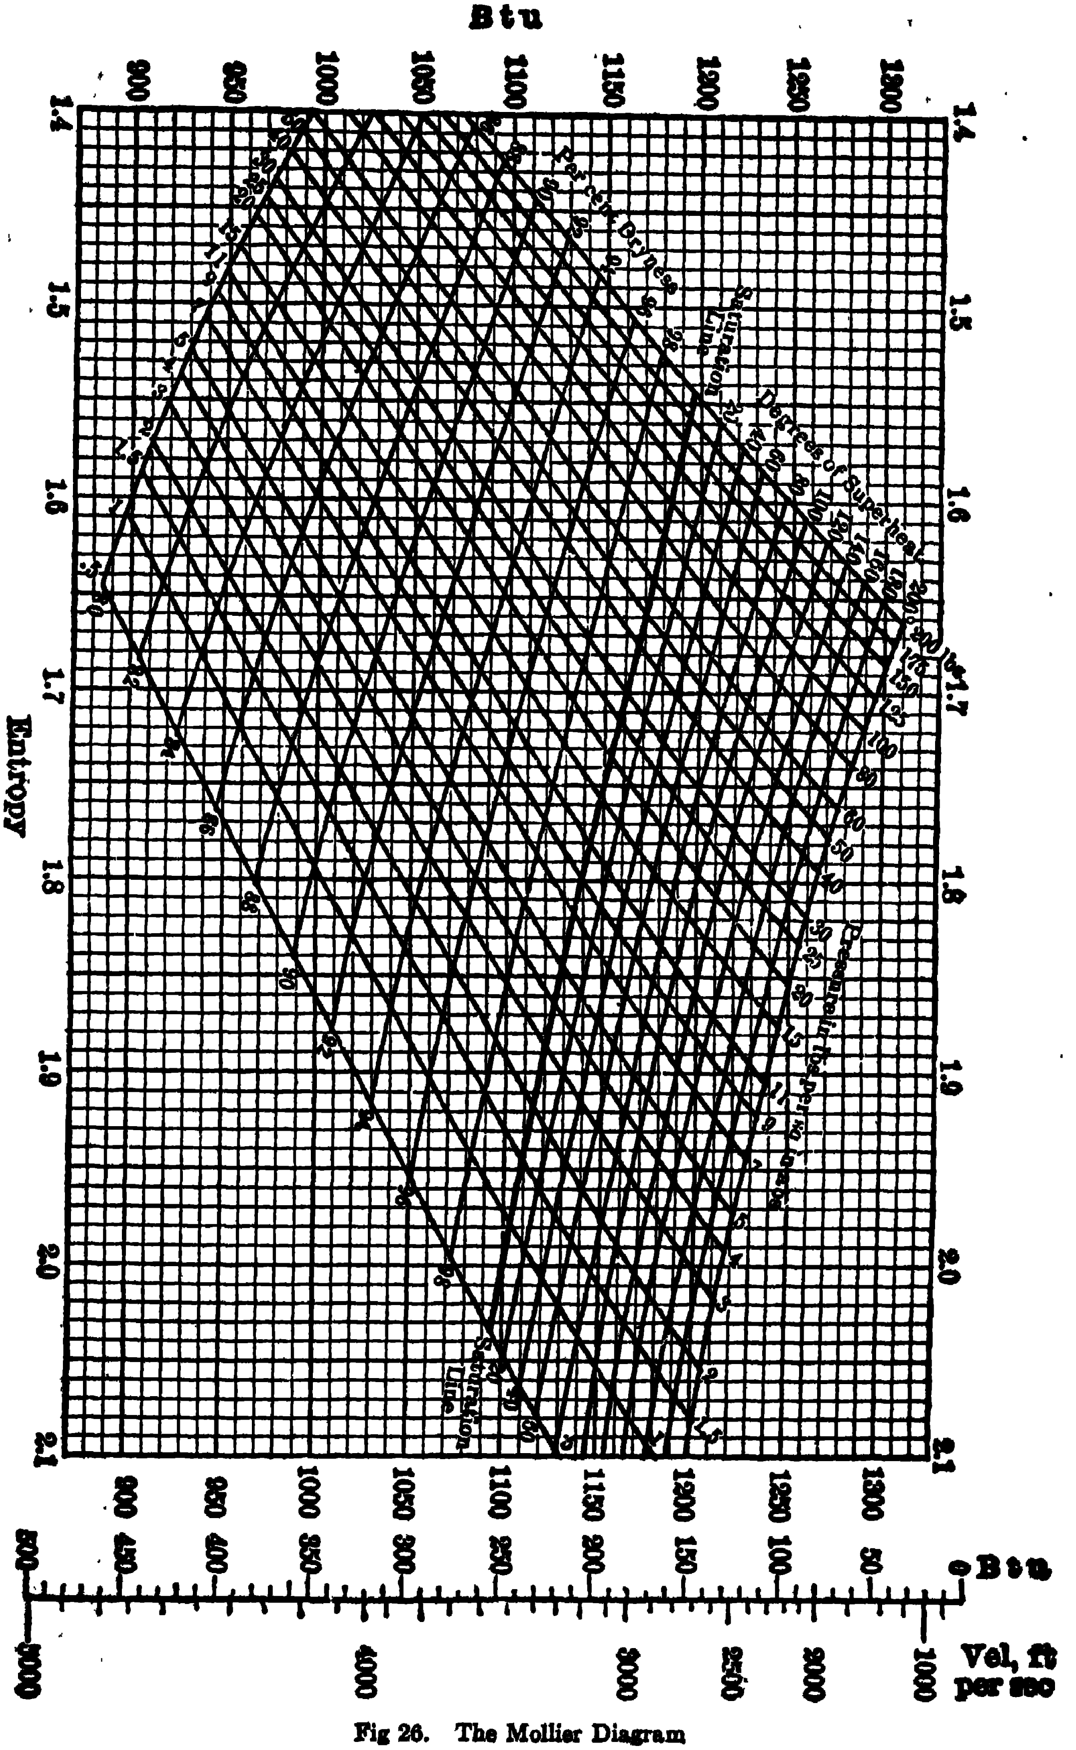

Fig 26. The Mollier Diagram

The Mollier diagram is useful also for finding the quality of steam by the throttling calorimeter. The temp and press of steam are read on the low-press (generally atmosphere) side of an orifice through which the steam has expanded, and subsequently brought to rest, being the equivalent of constant total-heat expansion. Knowing the temp and press of the steam at the low press, the amount of superheat for this condition is readily found; if there be no superheat at this point this method of obtaining the steam quality is not applicable. When the degree of superheat and low press are known, a point may be found on the diagram and, projecting horizontally (at constant total heat) to the high press, the quality line passing through the intersection of the horiz and high-press line gives the quality at the high press.

Example 25. In a throttling-calorimeter chamber, attached to a steam line in which the press was 110 lb gage; temp after expansion was 222° F, and the pressure, atmospheric; situation, sea level. Determine the quality in the line. Press at sea level, 14.7 lb abs, and saturation temp = 212° F, hence 10° superheat. Projecting from 14.7 and 10° on Mollier diagram horizontally to intersect with (110 + 14.7 lb) shows quality to be 96%.

16. HEAT CYCLES

Definitions. Work is always done at the expense of heat. During the process some heat may or may not be added; if none is added, the work must be at the expense of the heat already contained in the substance, and hence the decrease in this heat content is exactly equal to the work done. The energy stored up or contained in a body is internal or intrinsic energy, and may be reckoned above any arbitrarily-chosen zero. As with entropy, however, it is the change in intrinsic energy during a process, rather than the absolute quantity at any one time, which is of interest. If, while work is being done, heat is added, the difference between the added heat and work done is the change in intrinsic energy, and this relation is one way of expressing the first law of thermodynamics. It applies, of course, only to reversible processes.

For a complete cycle the intrinsic energy is the same at the end of the process as at the beginning, or the change is zero; hence, all the work must have come from the heat added during the different phases. As heat may have been abstracted as such at some part of the cycle, or work added as such, the term added heat must be the net heat added, or the algebraic sum of the heats added; similarly for the work done; hence,

$$\text{Work done in any complete cycle} = \text{Heat added} - \text{heat abstracted,} \qquad (63)$$

and as the effic of any thermal cycle is the ratio of work done to heat supplied,

$$\text{Effic of any complete cycle} = 1 - (\text{Heat abstracted} \div \text{heat added}) \qquad (64)$$

Steam-engine cycles. In Art 3, the action of steam in a cylinder was described on the basis of press-volume analysis. It can also be dealt with on the basis of heat-cycle analysis, and expressions for effic and m e p derived in this way. For the phases of constant press, admission and exhaust of the P–V diagram are substituted for the equivalent constant press-vol change processes of steam making, with possible superheating and condensation, on the heat diagram.

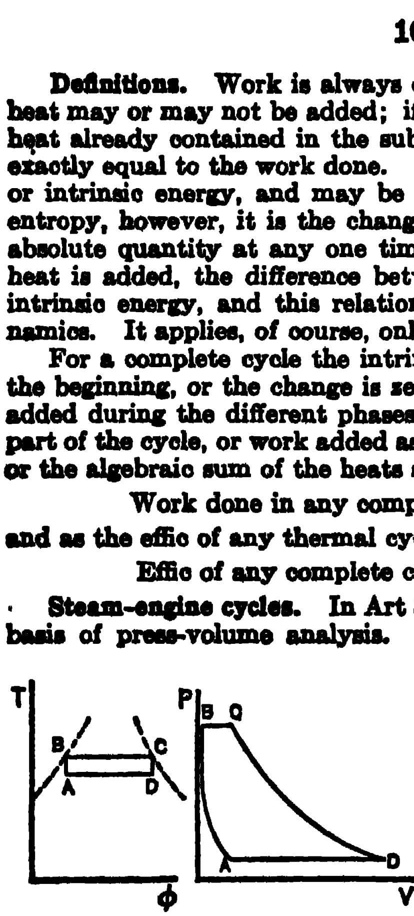

Fig 27. The Carnot Cycle

Two standard cycles represent the ideal steam engine process, the Carnot and the Rankine. Both are shown to *P–V* and *T–φ* coordinates; the former for dry steam only in Fig 27, the latter for wet and dry steam, and steam with different degrees of superheat, in Fig 28, as follows:

ABCD, initially wet, finally more wet; *ABC'D'*, initially dry, finally wet; *ABC''D''*, initially superheated, finally wet; *ABC'''D'''*, initially superheated, finally dry; *ADC*^{IV}*D*^{IV}, initially superheated, finally superheated.

Carnot cycle, which assumes complete adiabatic expansion and compression, was formerly universally accepted as standard, chiefly because it was the most efficient cycle between any 2 temperatures, and hence for steam pressure limits. Its effic depends only on the temp, or,

$$\text{Carnot-cycle effic} = (T_2 - T_1) \div T_2 \qquad (65)$$

where T_2 and T_1 are the high and low abs temp, respectively.

Rankine cycle assumes complete adiabatic expansion, but no compression, and is now widely used as a standard of comparison, chiefly because it represents an effic more nearly attainable, is equally applicable to superheated and to dry steam, and serves as well for a

basis for turbine work as for engine work, features not possessed by the Carnot. Engines are spoken of as attaining a certain fraction of the Rankine cycle possibility.

In Fig 28 the constant-vol, press-rise line of the P–V diagram is represented on the T–ϕ diagram by a liquid heating line, which is substantially a constant-vol process. Heat is added from A to B and then from B to C, C', etc, as the case may be, adiabatic expansion follows to D, D', etc, and finally heat is removed from D, D', etc, to A. Considering one case only, that of initially dry steam, for example (as the rest are similar), the heat added is $H_{C'} - H_A$, that removed $H_{D'} - H_A$, and the work done is $(H_{C'} - H_A) - (H_{D'} - H_A)$ or $H_{C'} - H_{D'}$. Thus, the work of the Rankine cycle is merely the difference in the total heats at beginning and end of expansion. That at beginning is readily found from the steam tables (Art 12), when the initial press and quality are known, or from the Mollier Diagram (Fig 26). The final quality is not known, but can be computed or more readily obtained directly from Fig 28. For methods of computation, see Example 26. Effic will be $(H_{C'} - H_{D'}) \div (H_{C'} - H_A)$, H_A being the heat in the liquid at beginning of the cycle, or at the temp corresponding to the back press, and may be found from the steam tables. The m e p is the work done divided by the vol change, and since originally there is only liquid present, the vol of which may be neglected as it is very small compared to the final vol, the vol change may be taken as equal to the final vol. This quantity is the tabular value (from steam table) times the quality, if wet, and times the actual temp divided by the saturation temp, both absolute, if superheated. Rankine cycle applies equally to turbines, and all of the above except the expression for m e p applies equally to both piston engines and turbines. But, there is one more quantity applicable to turbines only, viz, the velocity of the jet. Considering 1 lb of steam and a zero initial velocity, the final velocity will be $\sqrt{2\,gW}$ or $8.02\sqrt{H_{C'} - H_{D'}}$. These expressions are grouped in Table 32.

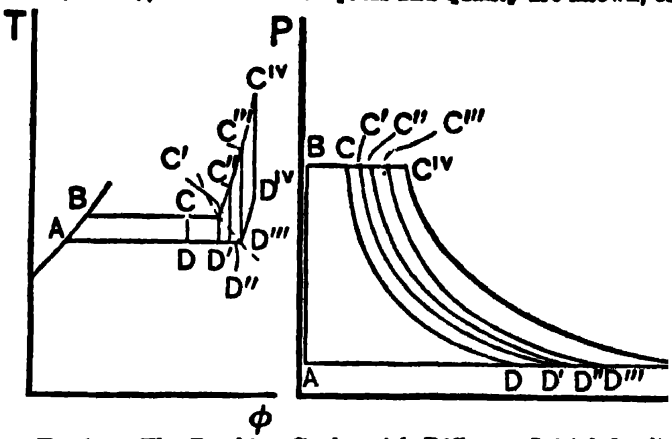

Fig 28. The Rankine Cycle, with Different Initial Qualities

Table 32. Rankine Cycle

Work	$H_2 - H_3$
Efficiency	$(H_2 - H_3) \div (H_2 - H_1)$
M e p (lb per sq in)	$778\,(H_2 - H_3) \div 144\,V_3$
Heat consumption per hr per h p	$2\,545\,(H_2 - H_1) \div (H_2 - H_3)$
Steam consumption per hr per h p	$2\,545 \div (H_2 - H_3)$
Jet velocity	$\sqrt{(H_2 - H_3) \times 778 \times 64.4}$

H_1 is the heat in the liquid at the low press; H_2, the heat in the steam prior to expansion; H_3, the heat in the steam after expansion.

The thermal effects of change of initial press, back press, superheating, jacketing, and reheating, in a steam engine are best seen from examination of a T-ϕ diagram of a Rankine cycle. In Fig 29 (*a*), *ABCD* represents a cycle between the pressures of 100 lb and 20 lb, the area being proportional to the work of 1 lb of initially dry steam. *AB'C'D* shows the case for an initial press of 160 lb, all other conditions being the same, the gain in work being *BB'C'C*. *A'BCD'* is the case of the original initial press, but with back press lowered to 1 lb, the gain in work being *A'ADD'*. Thus, the gain in the latter case is considerably greater than in the former, although the change in press is less. Efficiencies in the 3 cases are: *ABCD* ÷ *EABCF*, *AB'C'D* ÷ *EAB'C'F*, and *A'BCD'* ÷ *E'A'BCF*. Increase of initial or decrease of exhaust pressure both tend to increase the efficiency. Complete expansion is assumed in all cases of the Rankine cycle, which is not possible to realise in real engines with high ratios of expansion, that is, with either very high initial or very low-back press, so that the gains in cyclic performance may not be fully attained in practice or may possibly be losses in the case of piston engines. Expansion always being complete in turbines, any cyclic gains offered by changes in press or superheat may be realised to a great extent in this type of machine. Hence, higher initial press and degree of superheat are now in more common use than formerly believed possible. For the same reason, exhaust pressures have been lowered to within a fraction of a pound of abs vacuum.

In Fig 29 (*b*), *ABCD* represents the work of a cycle for saturated steam between certain press limits, and *ABCC'D'* for steam with 300° of superheat and the same press limits, the area *DCC'D'* denoting the gain in work. Efficiencies for the 2 cases are *ABCD* ÷ *EABCF* and *ABCC'D'* ÷ *EABCC'F'*. It is obvious that superheat causes a gain in work, but thermally with but little increase in efficiency. In practice, however, the smaller leakage and heat transmission losses generally produce a greater improvement than would be expected from the cyclic effect.

In Fig 29 (c), cycle *ABCD* is for saturated steam with adiabatic expansion, and *ABCD''* represents a case with jackets imparting heat enough to the steam to cause it to remain saturated during expansion. Other cases, in which insufficient or more than sufficient heat is added during expansion to produce continued saturation, are possible, but ideally all show a loss in thermal efficiency and in practice either a loss or such a small gain as generally to render the use of jackets inadvisable. Cycle *ABCxyzD'* represents the case of reheating after partial expansion, a process, if used at all, occurring between the cylinders of a multiple-expansion engine, or between an engine and a low-press turbine. Point *X*, to which expansion is allowed to proceed, is arbitrary, as is also the reheating temp. A common practice is to make the receiver pressure *X* such that equal work is done in each expansion. Reheating can not well be carried above the original temp. As with jackets, the gain due to reheating is either negative or too small to warrant its use on engines. Efficiencies for the 3 cycles in Fig 29 (c) are *ABCD* ÷ *EABCDF* for the original, *ABCD''* ÷ *EABCD''F''* for jackets, and *ABCxyzD'* ÷ *EABCxyzF'* for reheating.

Example 26. Find the cyclic effic, water, and steam consumption of an engine operating on initial press of 140 lb abs, with 100° superheat and back press of 10 lb abs. Also find the jet velocity for same press drop, and the m e p.

From the steam tables (Art 12) the heat at beginning of expansion is 1 248 B t u and that originally in the liquid at 10 lb abs (= 193° F) is 161 B t u. The quality after expansion is found as follows.

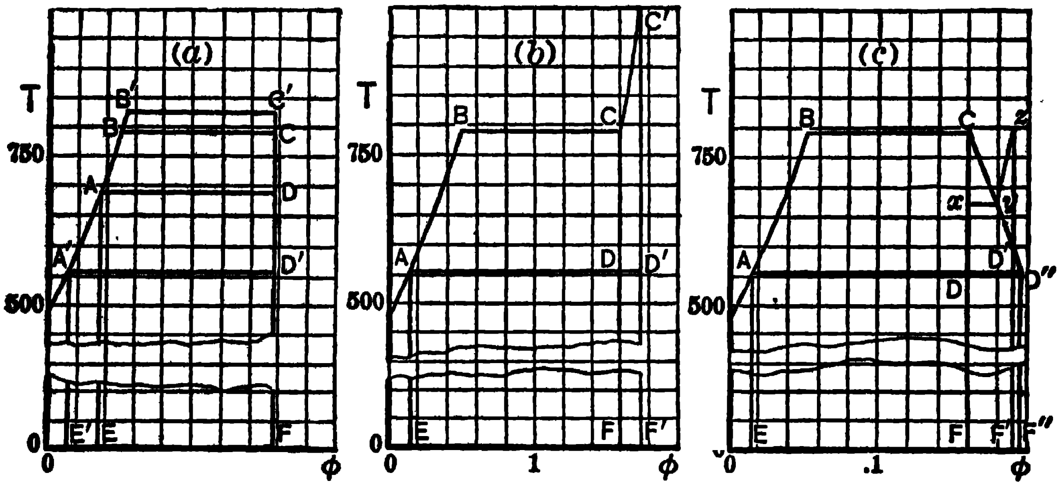

Fig 29. Rankine Cycles Showing Effect of Initial and Back-Press Changes, Superheat, Reheat, and Jacketing

The entropy originally (Table 25) is 1.6395, and since expansion is adiabatic the final entropy must have same value. The total entropy of steam is made up of 2 parts if wet, or 3 if superheated, precisely as is the total heat. If for any press the entropy is less than the dry saturated value for that press, the steam is wet and the missing entropy must be part of that of evaporation; the percentage of moisture is the amount of missing entropy divided by the entropy of evaporation for the given press. Entropy for dry steam at 10 lb is 1.7874, hence the amount missing is 1.7874 − 1.6395 = 0.1479. As the entropy of evaporation for this press is 1.5042, the percentage of moisture is 9.8, or dryness is approx 90; hence, the total heat is 1 045 B t u. The final quality could be read directly from a temp-entropy or a Mollier diagram (Art 15).

By Table 32 the effic will be (1 418 − 1 045) ÷ (1 240 − 161) = 18.7%. Steam consumption will be 2 545 ÷ (1 248 − 1 045) = 12.5 lb, and jet velocity

$$= \sqrt{(1\,248 - 1\,045) \times 778 \times 64.4} = 3\,190.$$

Final quality being 90%, the final vol will be 90% of the tabular, or 0.9 × 38.4 = 34.6 cu ft; hence, m e p = 778 (1 248 − 1 045) ÷ 144 × 34.6 = 37 lb. Same results could be obtained with practically no calculation by the Mollier diagram, and this example is worked by that method in Art 15.

17. CONDITIONING OF AIR

Working conditions in deep mines, where temp is high, may be improved by the cooling action of the air supplied (Sec 14). The heat that can be absorbed by air is a function of change in its temp and moisture content; that is, its relative humidity (Sec 23, Art 1). In computing these changes, the customary unit is a mixture containing 1 lb of dry air. Heat and moisture content for relative humidity at any temp may be computed from humidity tables (19); or, for temp above 32° F, from steam tables (Art 12). Fig 30 shows a graphical solution. For saturated conditions, the moisture content is given in the tables; for incomplete saturation, it is the amount for saturated air at the temp for which the vapor pressure, divided by vapor pressure at given temp, gives a value equal to the relative humidity. That is, moisture content for air 50% saturated at

64° F is the same as for saturated air at 45° F; since 0.3 in of mercury, the vapor pressure at 45° F, is 50% of 0.6 in mercury, the vapor pressure at 64° F.

The heat content of mixed air and moisture is considered to be the heat necessary to warm the air from some base point, usually taken as 0° F, plus heat required to evaporate the moisture present, evaporation being assumed to occur at saturation temp. The heat to warm the water and superheat the vapor are generally neglected, since it is very small compared with the other quantities. Heat and moisture absorbed or given up, when air changes from one temp and relative humidity to another, are merely the differences between these values at original and final conditions.

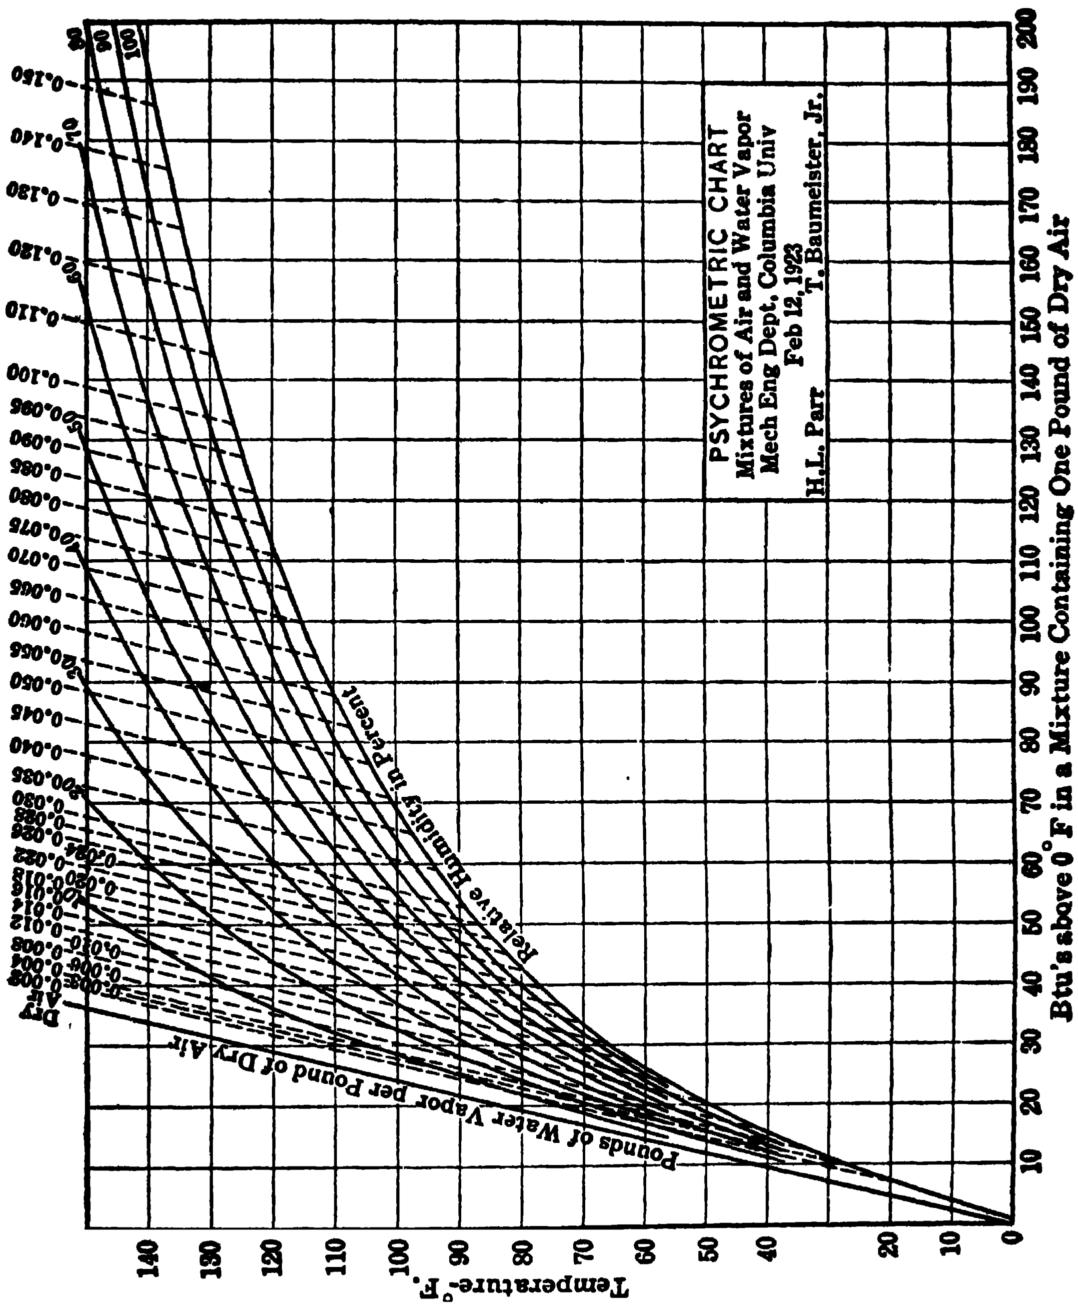

Fig 30. Psychrometric Chart

Example 27. How much heat and moisture must be removed from saturated air at 90° F, to bring it to 40° with a relative humidity of 30%?

Moisture and heat content for original condition are read directly in the tables (19), as 0.0311 lb and 54 B t u, respectively, for a mixture containing 1 lb dry air. Vapor press at 40° F is 0.25 in mercury; hence press at saturation is 0.25 × 0.3 = 0.075 in mercury, and the corresponding temp, 13.5° F. At this temp the moisture content is 0.0015 lb. Heat content of final air is 0.24 × 40 + 0.0015 × 1 260 = 11.5 B t u. Hence, 0.0311 − 0.0015 = 0.0296 lb of moisture, and 54 − 11.5 = 42.5 B t u, which must be removed per lb dry air.

Example 28. How much heat and moisture could be absorbed if the air warms to 70° F, with 60% humidity? Vapor press at 70° F is 0.74 in mercury; hence, saturation press is 0.6 × 0.74 = 0.444 in mercury, for which the temp is 55.5° F. Moisture content for final condition is thus 0.0093 lb, and heat content 0.24 × 70 + 0.0093 × 1 075 = 26.8. Hence, there will be absorbed 0.0093 − 0.0015 = 0.0078 lb moisture, and 26.8 − 11.5 = 15.3 B t u per lb dry air.

Values for moisture and heat content in above examples may all be read directly from Fig 30, in which the vert scale is temp and the horiz, B t u. Solid curves represent % relative humidity; dotted curves, lb moisture in a mixture containing 1 lb dry air. By projecting over from any temp on the vert scale to a given relative humidity curve, the heat content may be read on the horiz scale and the moisture content on the dotted line passing through point of intersection. For the final condition in Ex 28 (70° F and 60%), the heat content is 27 B t u; moisture content, 0.0095 lb (approx) as computed. The method of computing heat and moisture content from data in ordinary steam tables is too complicated to be given here.

POWER AND POWER MACHINERY

BY

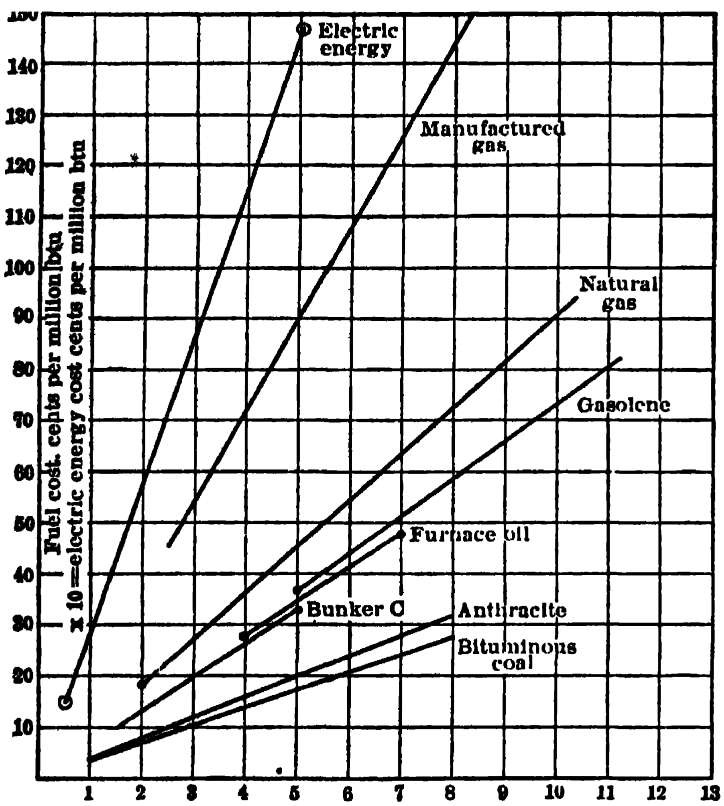
THEODORE BAUMEISTER, JR

PROFESSOR AND EXECUTIVE OFFICER,
DEPARTMENT OF MECHANICAL ENGINEERING,
COLUMBIA UNIVERSITY; CONSULTING ENGINEER

POWER AND POWER MACHINERY

1. POWER SYSTEMS

Extent of requirements of the mining industry for adequate and economic sources of power is indicated in Table 1. Power service can be: (1) purchased from a central station; or (2) generated in a self-contained plant. Basic sources of energy are: (*a*) an elevated water supply; or (*b*) heat-energy of fuel. Plants include: (1) water power; (2) steam, utilizing any type of fuel; (3) internal-combustion engines, requiring oil or gaseous fuels; (4) waste heat. Stationary plants are chiefly represented by steam and hydro; portable plants are mostly internal combustion (Table 2a).



Fuel prices. Dollars per short ton for all coals
Cents per gal, gasolene, furnace oil, bunker C
Cents x 10 per MCF, natural and illuminating gas
Cents per kw-hr, elec energy

Fig 1. Fuel Costs

Fuel-burning systems are of major importance. Continuity and reliability of fuel or water supply and fuel cost control selection. Condensing steam plants typically require 500 to 1 000 lb circulating water per lb coal burned. Steam plant site and cycle selection are dictated by circulating water adequacy. Internal-combustion plants do not have this limitation. With any fuel-burning installation, fuel cost is the largest single operating item. Comparisons between fuels are best made on basis of cost in cents per million btu. Fig 1 aids conversion to this basis. Typical competitive fuel prices are shown in Table 3, with bunkerage data. Prices given are for heat in fuel, and must be modified by various efficiencies to determine their worth at point of utilization.

Thermal performance of fuel-burning plants. By the laws of thermodynamics, heat can be converted into work only by sacrifice of availability. Mechanism inefficiency, coupled with cyclic limitations, result in low overall thermal effic (Table 4). Heat rate is more directly usable than thermal effic, and is defined as:

$$\text{Heat rate, btu per kw-hr} \quad \frac{\text{Heat input in fuel, btu}}{\text{Energy output, kw-hr}} = \frac{3\,412.75}{\text{Thermal effic}} \times 100$$

Minimum heat rates in steam plants are obtained only with the largest equipment sizes and max press and temperature. Internal-combustion engines give good heat rates, even in smallest sizes. Fuel price, cents per million btu, can be multiplied directly by heat rate, to give fuel cost per kw-hr generated.

Loads and load curves. Power plants can not be properly designed or operated without considering the load and its hourly, daily, seasonal, and annual variations. Fig 2, 2*a*, 2*b* give typical daily load curves for a coal mining plant; ANNUAL LOAD DURATION CURVE for same data is in Fig 3, the latter curve showing: (1) demand of 50 kw exists for 8 760 hr; (2) peak is 920 kw; (3) annual energy generation is the area under the curve, 2 650 000 kw-hr; (4) area divided by the product of peak and the 8 760 hr of the period is the annual load factor, 33%. LOAD FACTOR is defined by the relation: Load factor = average load ÷ peak load, and covers a definite operating period, as a day or year. Both loads are net delivered outputs. Peaks are not instantaneous, but generally taken over a 30-min interval. CAPAC FACTOR is defined by the relation: Capac factor = gross generation ÷ plant capac × hr in period, and is usually expressed as an annual amount. It shows the extent to which installed capac is used, bearing no relationship to load factor. Equipment reliability is measured by the

Table 4. Typical Thermal Performance of Fuel-burning Power Plants

Type of plant	Heat rate, btu per kw-hr	Thermal effic, %
Public utility aver, steam, 1935	19 000	18

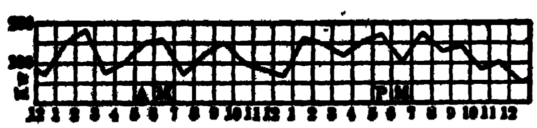

Fig 2*b*. Typical Load Curve, Coal Mine, Saturdays, Sundays and Holidays

AVAILABILITY FACTOR, defined by the expression: Availability factor = Annual hr operated or operable ÷ 8 760. It is best applicable to specific equipment within a plant. For modern power machinery it exceeds 85%, with good maintenance and operating technique. Equipment reliability reflects the need for spare capac to provide continuity of service. While reserve factors may be of some worth, it is more rational to install spare capac at least equal to

largest unit in the plant. For large plants this often offsets the merits of lower unit first cost and operating economy. Cold, hot, and spinning reserve are all affected.

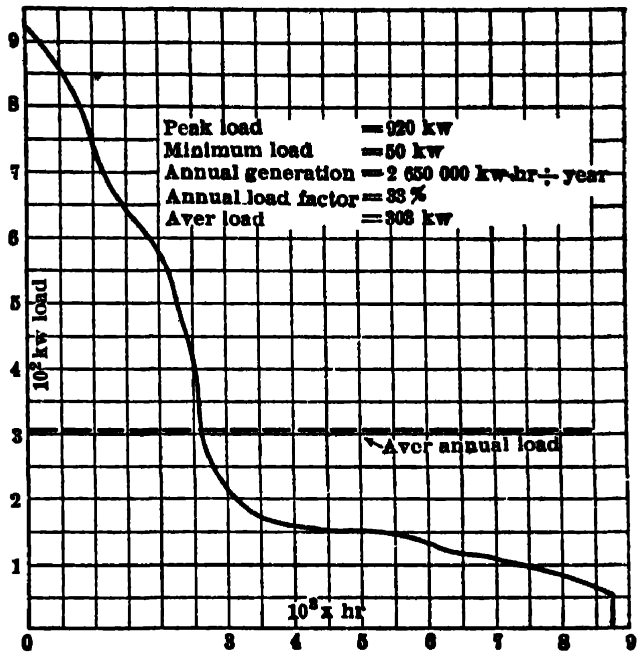

Fig 3. Typical Annual Load Duration Curve, Coal Mine

2. COST OF POWER

Total cost is the sum of: (1) fixed charges; (2) operating charges or production expense. FIXED CHARGES include: (1) cost of money; (2) insurance and taxes; (3) depreciation; and are usually computed as an annual percentage of the investment. COST OF MONEY includes interest, discounts, and financing charges, and is not under control of the designer. It ranges from 5 to 10% per annum. INSURANCE varies with the nature of the risk and embraces fire, boiler explosion, machinery breakdown, public liability, and workmen's compensation. TAXES cover real estate, franchise, incorporation, receipts, income, and social security. Annual charges for insurance and taxes are from 1 to 3%. DEPREC charges reflect loss in value of equipment due to use and passage of time, and result from physical deterioration, obsolescence, change in use, and inadequacy of equipment. While physical deterioration can be largely offset by proper maintenance, functional deprec is beyond control. Replacement of equipment will ultimately be required. Deprec reserves should therefore be accumulated on some convenient basis, as straight line, sinking fund, or observed deprec. Table 5, 6, 7 give depreciable life data; annual charges are 1–10%. The usual aggregate annual allowance for all FIXED CHARGES on power plant equipment is 10–20%; commonly 12.5% for steam plants. In case of short-lived enterprises, industrial undertakings, or possible depletion of ore reserves in mining, fixed costs are often computed on other bases.

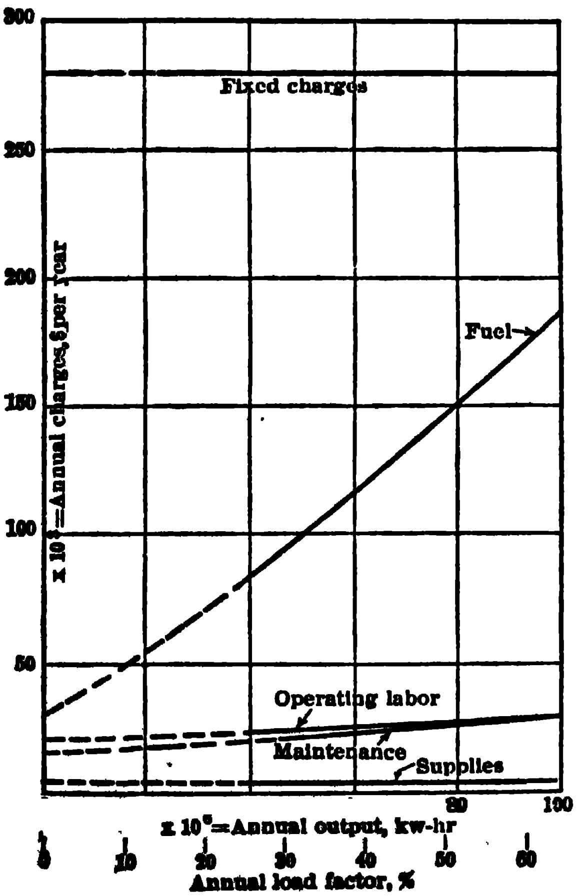

Fig 4. Annual Cost of Generation; Small Steam Plant

Operating charges or production expense (see also Sec 21) vary with output and load factor and are classified as: (1) fuel; (2) labor and supervision; (3) maintenance, materials and labor; (4) misc supplies and expense. FUEL COST is the largest item, and varies with heat rate, fuel price, load factor, and operating practice. There is one best effic point for any plant, which is generally approximated in design to occur at "average" load (Fig 4). OPERATING LABOR is largely constant, irrespective of plant load. A straight line, with an intercept equal to 50–100% of the full load cost, is representative. MAINTENANCE follows a characteristic similar to labor, but varies so widely in

different plants as to preclude statistical comparison. For preliminary estimates, annual maintenance can be taken as 1–3% of investment cost. MISC SUPPLIES can be treated as a constant charge of 5–15% of the maintenance or labor cost.

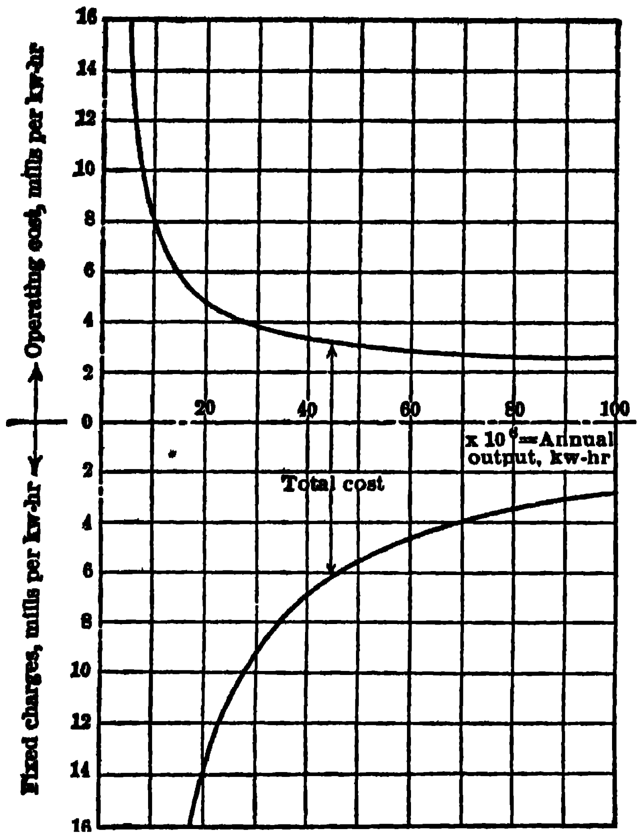

Fig 5. Unit Cost of Generation, Small Steam Plant

Total cost of power. The annual costs of generation are plotted for a small steam plant in Fig 4, and the results transferred to a two-quadrant plot for unit costs in Fig 5. Total cost of generation (Fig 6) reflects a constant portion or intercept, regardless of output. The cost of service can be approximated by the relation: Annual cost of service = $K_1 + K_2$ (kw-hr output per kw capac) $= K_1 + K_2$ (8 760) (capac factor). More accurate equations in 3 or 4 parts, can be written to reflect: (1) capac charge; (2) peak load; (3) hrs of service; (4) energy charges. Such relations show the small significance of direct comparison of unit costs for power. Table 8 gives production costs for several power plants; their values are illustrative, and should be used cautiously for comparison with data from other sources.

Cost of power at point of use. Distinction must be made between cost of generation at the power plant and cost of service at point of use. Fuel transport, elec transmission lines, comp air or water lines, all add to cost of energy. All forms of power plant are not equally suitable from this viewpoint. Waterpower plants must be located at the hydro site; steam plants, if condensing, must have adequate circulating water; internal-combustion engines require little water and may be portable.

Purchased *vs* generated power. Purchased power from a central station is usually the best basis for measuring the worth of any proposed plant. Reliability of service and rate schedules should be studied to assure continuity and economy of service. Purchased power generally minimises capital investment on the part of the industrial plant and results in a short term commitment. Rate schedules are usually based on cost equations, as given above, to reflect a demand plus an energy charge. Discounts are often made for prompt payment of bills; high power-factor loads; off peak power; and secondary service. Special contracts and rates can also be obtained under favorable conditions.

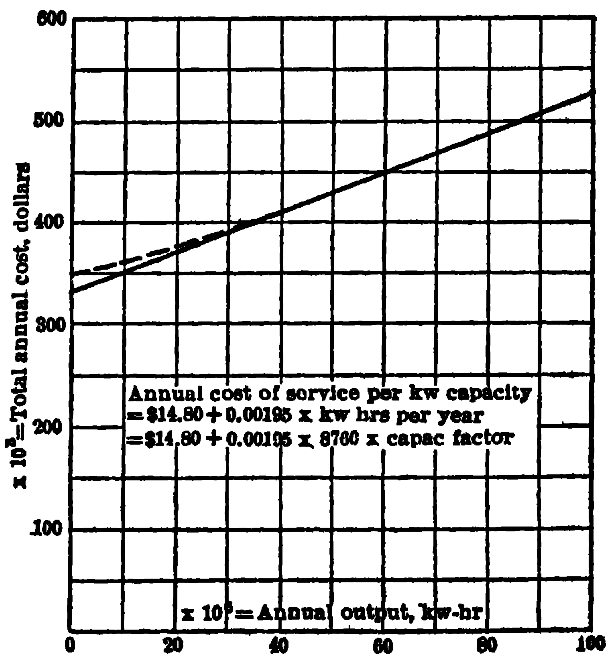

Fig 6. Total Cost of Generation, Small Steam Plant

3. STEAM POWER CYCLES

Heat balance diagrams (Fig 7) give data on fuel, steam, water, and energy for each item of equipment. Preparation of such diagrams involves the operating performance, characteristics, costs, and limitations of all the machinery. Fig 7 and Table 9 give data

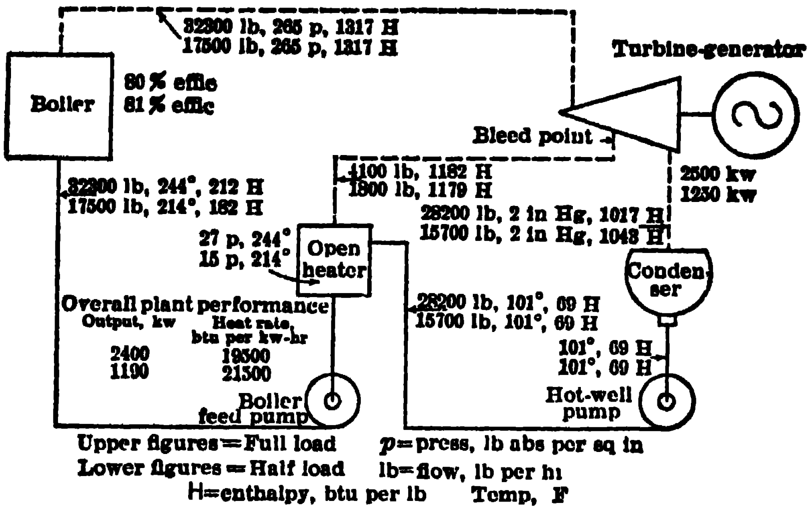

Fig 7. Heat Balance Diagram, 2 500-kw Unit

for an elementary plant containing one 2 500-kw turbine-generator, using steam at 265 lb and 600° F, exhausting at 2 in abs, and with extraction feed heating. Calculations depend on the turbine state lines of Fig 8, using 75% Rankine effic ratio, and plotted on a

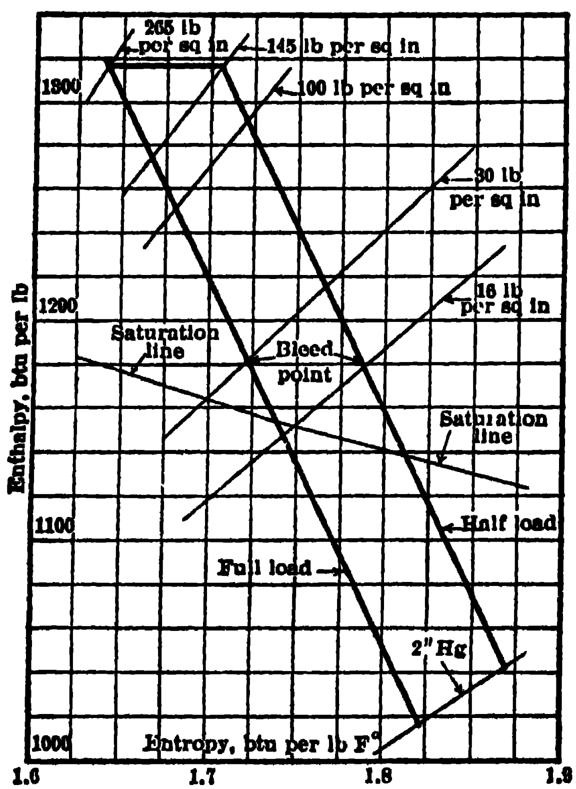

Fig 8. Turbine State Lines, 2 500-kw Unit

Mollier chart (Sec 39, Fig 26). Overall thermal performance includes allowances for generator effic = 95%; boiler effic = 80%; elec-driven auxiliaries = 4%; plant realization ratio = 96%. While elec drive gives favorable cost and operating economy for auxiliaries

spare equipment, as steam-driven feed pumps, should be provided. The diagram in Fig 7 may be extended to include other items, as stage heating, air ejectors, gland condensers and generator air coolers.

4. BOILERS AND THEIR APPURTENANCES

Boiler room must be carefully designed, to reduce power cost. No other part of the plant can accumulate losses so rapidly from poor effic or maintenance. This concerns both the combustion chamber (furnace) and the boiler proper, which are constructed under rigorous laws and codes, such as that of Am Soc of Mech Engrs, regulations of boiler insurance companies, and local laws.

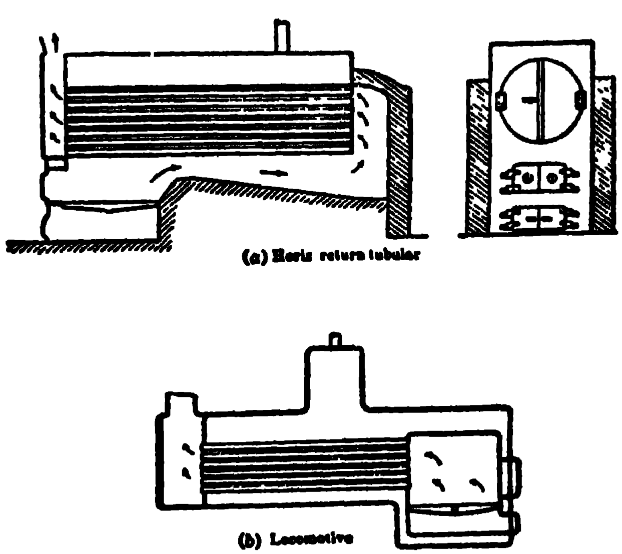

Fig 9. Fire-tube Boilers

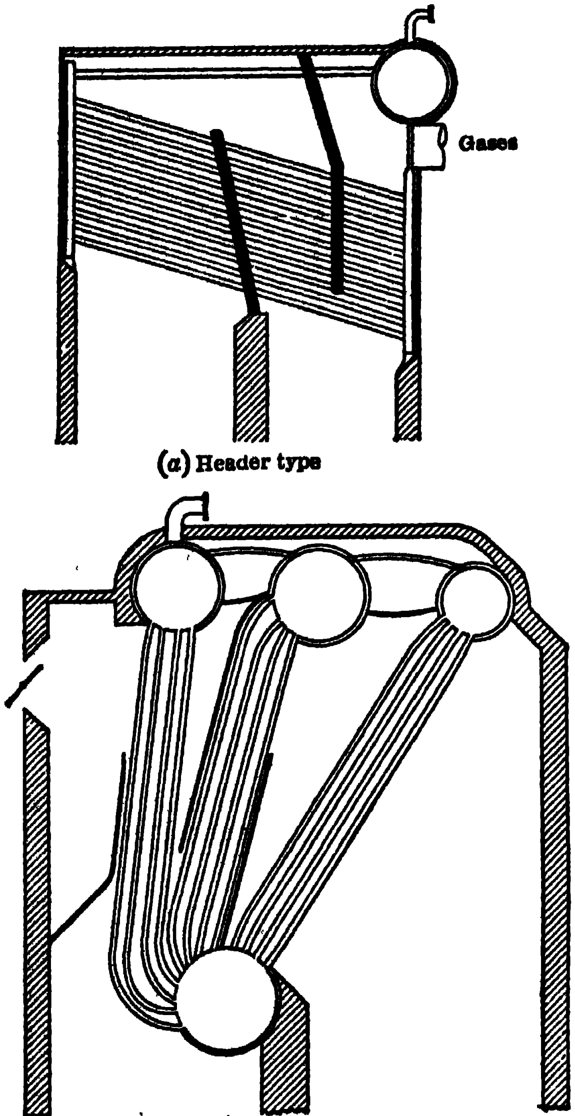
Chief objectives: high steaming capac per sq ft, low first cost, and high effic; but high capac and high effic are directly opposed, because the former requires high mean temp differences; the latter, low mean temp differences. Max steaming capac and effic can not therefore be expected in the same boiler; in heat transfer there is a complicated thermal path through gas film, soot, metal, scale, and water film. As the relative thermal resistances of metal, water and gas are as 1 : 100 : 1000, the controlling resistance, with clean surfaces, is on the furnace gas side. Vigorous circulation, scrubbing, mixing, and high mean hydraulic depth are needed on the gas side to promote heat transmission. On the water side, the metal surface must be kept wet, to prevent a shift in the controlling resistance and consequent overheating

of the metal (steel loses its structural strength rapidly with increase in temp above 800° F). Thermal action due to the difference in density of water and steam provides necessary circulation. Surfaces must be kept clean of scale further to prevent overheating, and clean of soot to maintain effic.

Boilers are either fire-tube, in which the gases pass through the tubes, or water tube, in which the water flows through the tubes. FIRE-TUBE BOILERS comprise a nest of straight 3–4 in tubes, between the heads of the shell; they are externally fired as in Fig 9*a* (horiz return tubular), or internally fired as in Fig 9*b* (locomotive); the former require brick setting, the latter are self contained and portable; both are limited to low press and low capac services (less than 250 lb per sq in and 250 boiler hp); are low in first cost, but can not be operated at high ratings with sustained effic. WATER-TUBE BOILERS (Fig 10) are header or drum types. The headers, into which the tubes are rolled, may be of box or sectional design; the former are suitable for press below 400 lb per sq in and require stays for bracing; the latter have only one vert row of tubes, which, when made sinuous, allow close spacing and good gas mixing. Hand holes give access to tubes for cleaning. Tubes are limited to 20–24 ft length. Larger capac is obtained by increasing the number of vert sections. Drums are horiz or slightly inclined. Cross drums (Fig 10*a*) permit of high capac with one drum; for the longit arrangement, 2 or 3 drums are needed. Drum size is determined by disengaging surface requirements. Hot gases circulate over the tubes in a 1, 2, or 3-pass construction (Fig 10*a*), but longit baffling may be used instead of cross baffling. DRUM BOILERS, having no headers, cost less and the curved tubes permit a variety of designs. Tubes are spaced farther apart than in header boilers, to allow tube replacement. There are no hand-hole covers. Some water-tube boilers produce steam at rate of 1 000 000 lb per hr in a single unit and at press of 1 400 lb.



(*a*) Header type

(*b*) Drum type

Fig 10. Water-tube Boilers

Superheaters may be of the convection type in the gas pass, or the radiant type in the furnace wall. With the superheater at top of the first pass (Fig 10*a*) the final superheat temp increases with boiler output; in the radiant position, steam temp decreases with increase in load. Internal boiler dampers, interdeck positions, and convection-radiant series arrangements allow of superheat control. Steel is suitable for steam temp below 750° F, but alloy steels are needed for sections exposed to higher temp (950° F max).

Fuels are mixtures of C and/ or H, either as elements or in combination. A fuel burner and its furnace must bring the necessary O molecules from the air supply into contact with the combustible elements. Table 10 gives analyses of power-plant fuels, their heats of combustion and chemically required air. The air is estimated for coals and fuel oils by the relation:

$$\text{Lb air chemically required per lb of fuel} = \frac{\text{High heating value, btu per lb}}{1\,300}$$

No furnace can give perfect combustion; excess air for fuels containing negligible amounts of nitrogen is calculated from analysis of the combustion products by the equation: Excess air,

$$\% = \frac{3.78\left(O_2 - \frac{CO}{2}\right)}{N_2 - 3.78\left(O_2 - \frac{CO}{2}\right)} \times 100,$$

where O_2, CO, and N_2 are vol percentages in the dry flue gas. Fig 11 shows relationship between CO_2 and excess air for several fuels. The wt of products is determined by adding to the wt of fuel actually converted into the gaseous state, the wt of chemically-correct air and excess air. Table 11 gives excess air performance figures, together with firing rates, for different furnaces. For chemistry of combustion, see Sec 39.

Gaseous fuels and furnaces. Gas is the ideal fuel. Flame length is controlled by the proportions of primary and secondary air. Ash

problems are absent, unless the gas is impure. Refractory furnace-wall construction is relatively simple.

Oil fuels and furnaces. Fuel oil is generally a refinery residue, as Bunker C or No 6, which has 100–300 seconds Saybolt Furol viscosity, 10°–16° API density; and contains impurities of sand, S, and water. External strainers, and heaters to raise the temp above 150° F, condition the fuel for spraying into the furnace. Steam, comp air, or mechanical atomizing nozzles are used; fine sprays reduce flame length, but some coarseness is desirable for penetration. Air enters in the secondary form, through louvres surrounding the burner tip. Checkerbrick and "bouncing walls" are sometimes used to increase furnace turbulence. The combustion chamber must effectively mix the fuel and air. Straight refractory walls prevail, due to absence of ash and slag. Firing rates are controllable by burner multiplicity, together with regulation of individual burners.

Table 11. Typical Average Furnace Firing Rates

Fuel	Heat liberation rate, btu per hr per cu ft	Excess air, %
Natural gas	20 000–40 000	10– 30
Fuel oil	20 000–40 000	15– 30
Pulverized coal	20 000–40 000	15– 30
Stokers, large	20 000–40 000	20– 40
Stokers, small	15 000–25 000	30– 60
Hand fired, industrial	5 000–10 000	50–150
Hand fired, domestic	less than 5 000	more than 100

Coal and coal-burning furnaces. While coal is the commonest fuel, ash and volatiles cause difficult firing problems. Volatile is driven off rapidly, and must be intimately mixed with enough air while at high temp. Chilling by contact with cool surfaces lowers combustion, and forms smoke and soot. Ash composition and improper ash fusion temp may destroy furnace linings by fluxing with the refractory. Water-cooled or steam-cooled walls, with varying amounts of firebrick facing, may be required. With stationary grates for HAND FIRING the ash must be pulled out through the firing door; it is difficult to keep air spaces clear of ash and clinker. Rocking grates are dumped, or worked by levers at the front of boiler.

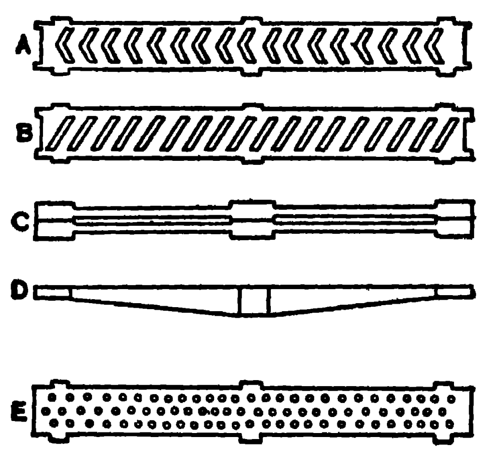

Fig 12. Grate Bars

Grates are divided into 2 or more sections, so that coal may be piled on one part while cleaning another. Fig 12 shows ordinary grate bars: A, herringbone; B, Tupper; C, D, common straight bar; E, pinhole. The bars are about 3 ft long, and arranged in sections to form a rocking grate. Air openings must be suited to size and kind of coal. Table 12 shows sizing standards; uniformity of sizing aids materially in firing. Hand-fired grates are limited in length to the 10–12 ft that a fireman can toss coal, as with anthracite; and 6–7 ft in slicing, as with bituminous. Hand-firing is limited to furnaces burning less than 0.5 ton per hr, and where high effic is not sought. Savings by experienced firemen repay the extra labor cost. Bituminous coal should be spread evenly, in beds 8–10 in thick, and the fire kept without holes, and not be allowed to become dirty, as evidenced by a dark ash pit. If a heavy layer is added, the volatile is driven off without burning; smoke and inefficiency result. Instead of uniform spreading, fresh coal may be piled on a dead plate in the front, where the volatile is distilled, and the resulting coke then pushed over the fire. The coking method is preferable for low fires. The smokeless burning of anthracite is simpler, because of low volatile. Steam sizes (Table 12) form a dense bed, not over 3–4 in thick, to reduce draft losses. Care is needed to maintain uniformity on thin beds, prevent formation of holes, and attain effic firing.

Table 12. Round-hole Openings in Testing Screens for Anthracite (A S T M)

Size	Passing through	Retained on
Broken	4 3/8″	3 1/4
Egg	3 1/4	2 7/16
Stove	2 7/16	1 5/8
Chestnut	1 5/8	13/16
Pea	13/16	9/16
No 1 Buckwheat	9/16	5/16
No 2 Buckwheat (Rice)	5/16	3/16
No 3 Buckwheat (Barley)	3/16	3/32

Tolerances of ±3% on aver openings and 10% in max openings are permissible.

Mechanical stokers give high capacities at sustained effic. Feed is continuous, at controllable rates, with minimum labor, and air is supplied in controlled proportions to

each bed section, so as best to distill, gasify, reduce, or oxidise the fuel. The fire is kept even with reasonable excess air, the furnace being maintained at a high even temp. Ash is automatically removed on completion of combustion. The best stokers accomplish all these purposes; cheaper ones are available, which only partly fulfill the requirements.

While stokers may be designed to give good performance, constant, intelligent supervision in the fireroom is essential. From a hopper in front of the furnace, OVERFEED STOKERS feed raw coal above, UNDERFEED STOKERS, below the incandescent bed. In some small overfeed types the coal is mechanically or pneumatically distributed over horiz or inclined grates; in others, it is deposited in a coking zone or on a dead plate at the hopper end. The coked fuel is then controllably moved down the stepped and inclined grate by oscillation of the grate bars, or is conveyed by a chain or traveling grate toward rear of furnace. In underfeed, coal is fed from the hopper by rams or screws, operating in troughs or retorts, beneath the air admission zone. The rams gradually feed from the cold, through the volatile distillation zone, to the incandescent zone on top. Air enters through tuyeres on the top edges of the retorts, which are horiz or inclined; in the former, there is a single retort with ash removal laterally; in the latter, a multiplicity of retorts, and ash is discharged to the rear. The agitating action of the rams makes the underfeed stoker suitable for caking coals of high ash fusion temp; traveling grates are best for non-caking, non-clinkering bituminous and anthracite. Underfeed stokers carry thick (2-ft) beds with combustion rates controlled by ram speed and draft. Chain grates carry thinner fires (6 in), with control effected by depth of bed, grate speed, and draft. Best results are by forced draft, with combustion rates of 30–40 lb per hr per sq ft of grate area.

Pulverized coal firing requires a grinding plant to reduce the coal to proper size. Standard sieve sizes are given in Table 13; it is usual to specify 60–75% through 200 mesh; uniformity of particle size is as important as fineness.

Pulverizers may be of the hammer, impact, ball, tube, or attrition type. Mill size, power requirements, and maintenance are dependent on coal grindability, moisture content, and desired fineness. Energy requirements for mill operation are usually 10–20 kw-hr per ton. Mills formerly were arranged in a bin-and-feeder system, but have been largely displaced by the unit or direct system, in which the fuel is burned as soon as it is ground, dryers controlling the moisture content. The classified coal dust is handled by fans and fed through burners in which say 15% of the air is primary and 85% secondary. Burner and furnace arrangements mix the fuel and air, contribute turbulence, shorten the flame, and increase volumetric heat-release rates. Ash problems are often severe, and fusion, slagging and fluxing require proper furnace-wall construction, first-row tube spacing, and ash removal system. Low-fusion ash (2 000° F) can be removed in a molten state from a tap or drip type furnace; high-fusion ash (2 500° F+) is usually dealt with in a powder form from a hopper. Correct ash fusion temp must be specified, and the furnace designed to handle ash over the entire operating load range. Pulverized coal and stokers are in close competition in the steam making range of 50 000–150 000 lb per hr, with stokers prevailing below the lower limit and powdered coal above the upper.

Furnace walls. Refractory walls are suitable for gas and oil firing, but with coal, especially under high firing rates, the furnace may grow too hot and lead to ash and slag problems. WATER-COOLED screens and arches prevent washing away of furnace refractories. Heat transfer rates of 100 000 btu per hr per sq ft are attained on these surfaces, and strong water circulation is essential to prevent overheating. The walls may be bare tubes, or faced with blocks, fins, studs and varying thickness of refractory to control furnace temp. AIR-COOLED walls are no longer used. Radiant superheaters may be employed for part of the walls.

Economizers are placed in the boiler exit gas stream to preheat feed water and lower the stack temp. C-I tubes were formerly used, but steel tubes, plain or protected, prevail with use of oxygen-free feed water. AIR-HEATERS preheat the air for combustion to

improve boiler effic by lowering the stack temp and shortening the flame length. Degree of preheat is fixed by furnace conditions and firing methods; 500° F is the usual max. Preheaters are either recuperative (plate or tubular) or regenerative. Heat transfer rates of air heaters and economizers are low (2–6 btu per hr per sq ft per deg); hence they require large surfaces. Boilers may use economizers or preheaters, or combinations of both; or they may be omitted entirely. Stack temp should never be below the dew point, because of flue gas corrosion; 250° F is the usual minimum.

Draft systems provide the necessary air, and remove products of combustion. The combustion chamber should be maintained at a press just below the atmos (−0.1 in water) to minimize air leakage into the furnace; the press should not be positive or flame will pass through cracks in the setting. FORCED DRAFT provides air at positive press to the grates or burners; INDUCED DRAFT removes the stack gases by maintaining negative press at the flue. Balanced draft results when forced and induced draft maintain a press of −0.1 in water. Chimneys, fans, blowers, or steam jets are used. Chimneys provide only induced draft; the other devices are for both forced and induced draft. Draft varies with type, design and condition of equipment and the load carried. CHIMNEYS provide natural draft by difference in density between the vert column of hot gas inside and the similar column of cold air outside the stack. Theoretic draft (Sec 39) is a function of the gas temp, chimney height, and physical properties of the gases. Effective draft is obtained by deducting friction and veloc head losses from the theoretic draft. Gas velocities of 30–40 ft per sec at full load are common. Stack temp is 400–700° F with natural draft.

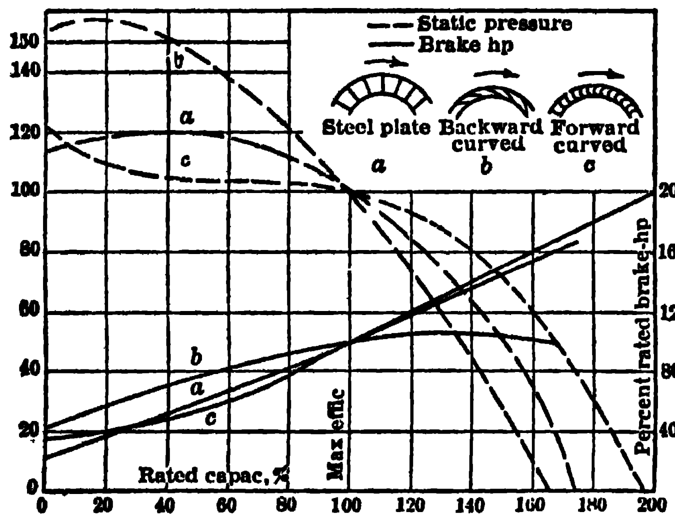

Fig 13. Fan Performance Characteristics, Percentage Basis

Chimneys are of brick, concrete, or steel, lined or unlined. Their effic is only 0.1–0.2% thermodynamically. For high rates of firing they are not practical, and must be supplemented by mechanical draft (fans and jet blowers). FANS are generally centrifugal; direct, geared, or belt-connected to elec motors, steam turbines, or engines. High-speed drives reduce space and wt of the units. Design details fix fan performance (Fig 13). The curves are definitive, because a fan must operate on its characteristic. If the resistance demands do not coincide with the fan characteristic, the supply must be throttled, or the speed varied. Flat or steep head characteristics, self-limiting hp, inherent high speed, or inherent high capac can be built into a fan. Forced-draft fans handle only air and hence are smaller and run faster than induced-draft fans, which must handle hot, dust-laden flue gas. Propeller or disk fans, set in the ash pit wall and direct-connected to turbines or motors, are favored for smaller plants. STEAM JET-BLOWERS, entraining gas by a steam jet in the throat of a Venturi tube, may be installed in the ash pit wall or at base of the stack; they are uneconomical and may consume 5–20% of the steam generated, but are low in first cost, foolproof, suitable for small plants, or where natural draft must be supplemented to carry peak loads.

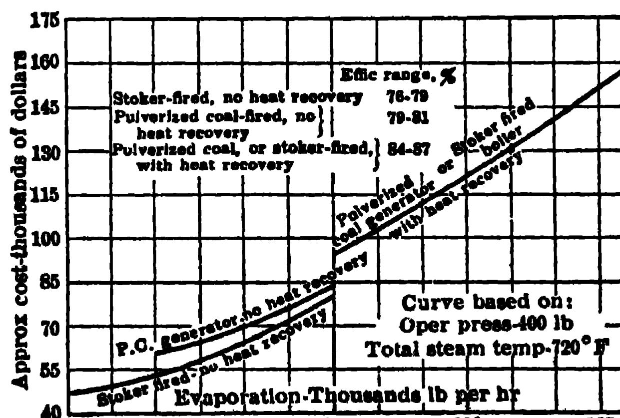

Fig 14. Variation of Steam Generating Unit First Cost, with Size and Type

Boiler settings and casings. Boilers which are not self-contained require supporting steel, and a casing of brick or brick and sheet steel, with doors for inspection and repairs. Settings must be gas tight, resist strain due to heating and cooling, and minimize radiation losses.

Accessories. BOTTOM BLOW-OFF VALVES remove accumulated solids in the boiler; SURFACE BLOW-OFF VALVES remove floating matter or scum. GAGE GLASSES indicate water level in the drum and are supplemented by TRY COCKS for operation when the gage glass is out of service. PRESSURE GAGES are also needed. SAFETY VALVES, required by law, are of the spring-loaded pop type, with adjustments for relieving press and the degree of blowdown. With superheated steam, the first safety valve to relieve should be on the superheated outlet, to prevent burning of the elements. FEED-WATER REGULATORS may be manual or automatic. Draft and damper regulators, draft gages, and CO_2 recorders, aid good operation. The entire steam producing function can be made automatic by COMBUSTION-CONTROL EQUIPMENT. It is expensive, but assures high sustained effic. SOOT BLOWERS, served by steam or comp air, keep gas side surfaces clean.

Boiler performance. Capac was formerly measured in boiler hp. A developed boiler hp was defined as the heat added, in steam, to evaporate 34.5 lb of water per hr, from and at 212° F; or 33 479 btu per hr. Makers rated hp was defined as the heating surface ÷ 10; the % rating is the ratio of developed to rated hp. In current practice, as a boiler is seldom on the line below 100% rating, the concept of hp has been abandoned in favor of lb of steam per hr, or heat added per hr. BOILER EFFIC is the ratio of heat absorbed by the steam to heat supplied in fuel. Heat-balance calculations are made according to methods specified in the Boiler Test Codes, to allocate inefficient items. The largest loss in boiler operation is generally represented in the sensible heat of stack gases. Standby, banking losses, and variable loads always make the actual effic lower than test figures; 80% is readily obtained by well designed and operated modern plants; poor design, maintenance, or operation may give effic below 50%. Actual evaporation, in lb steam per lb of fuel, is a convenient means of measuring effic. The evaporation factor is the ratio of actual heat added per lb of steam to the latent heat at 212° F (970.4 btu per lb). Equivalent evaporation is actual evaporation × evaporation factor, or lb of steam made from and at 212° F, per lb of fuel.

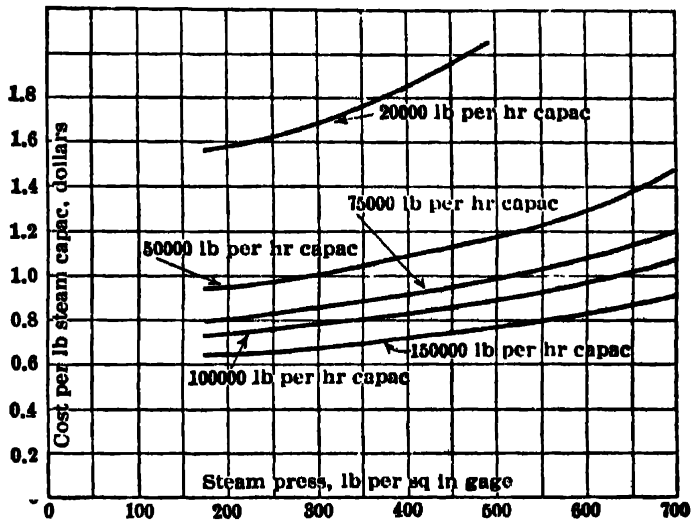

Fig 15. Variation of Steam Generating Unit First Cost, with Size and Pressure (Kolflat, Powerfax, Winter, 1938)

Costs of steam generating units, as influenced by size, type and press, are shown in Fig 14, 15.

5. STEAM TURBINES

Steam power prime movers are turbines or reciprocating engines. Turbines operate by steady flow, with free expansion of steam to utilize the energy in its kinetic form; in engines, with intermittent flow and balanced expansion, the press acts on a piston.

Turbines comprise a group of nozzles, in which steam expands and is accelerated in accordance with the relation, $(H_1 - H_2)\ 778$, where u = veloc, ft per sec; H = enthalpy, btu per lb; subscripts 1 and 2 denote initial and final conditions. If initial veloc u is zero, the veloc of the issuing steam jet is $u_2 = \sqrt{2g(H_1 - H_2)\ 778} = 223.5\sqrt{\text{enthalpy drop}}$. Enthalpy drop is most conveniently determined by a Mollier chart (Sec 39). The nozzles of IMPULSE TURBINES are fixed in the casing, the issuing jet impinging on a row of curved vanes on the wheel periphery. By Newton's second law of motion, the momentum of the fluid is altered by change in direction and magnitude by friction and impact, to give the turning effort. In REACTION TURBINES the nozzles are on the moving wheel. Accel of the steam turns the wheel by the reactive force opposite to direction of the issuing jet, and in accordance with Newton's third law. Commercial turbines employ both principles. Reaction turbines are distinguished by a press drop across the moving buckets. Vectorally, it can be demonstrated that for best effic the tip speed should be 40–45% of jet speed on impulse turbines, and 85–90% on reaction turbines. Expansion from supply to exhaust press must be in stages, to keep the bucket speed within practical limits (600 ft per sec). Impulse turbines may be of the RE-ENTRY

TYPE, with staging on a single wheel. Steam passes several times through the single row of moving blades by means of fixed reversing buckets. These turbines are suited to small sizes (100 kw); are inexpensive, and seldom exceed 50% Rankine effic ratio (50% of isentropic enthalpy drop). With multiple-wheel construction, the staging may be veloc (Curtis) or press (Rateau). With VELOCITY STAGING, all expansion occurs in the row of fixed nozzles, and steam flows axially through alternate rows of moving and reversing buckets. Curtis staging is practically limited to 2 or 3 stages, due to friction losses. In PRESSURE STAGING, the construction is cellular, with a single row of moving buckets in each cell and nozzles in the separating diaphragms. With the reaction principle, multiple rows of fixed and moving nozzles give the Parsons design.

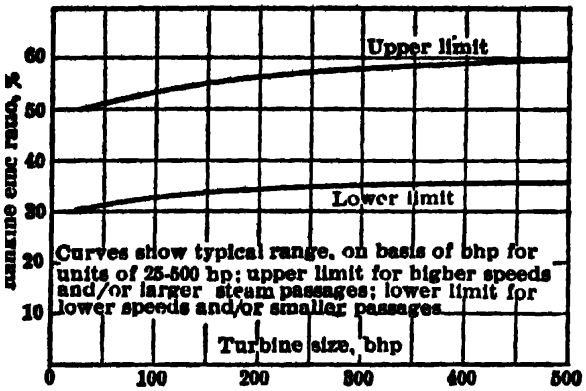

Fig 16. Rankine Effic Ratios of Small Steam Turbines

Commercial turbines are combinations of these types, with drive either direct or geared.

Turbine sizes as small as 5 kw, and as large as 60 000 kw at 3 600 rpm available; when less than 250 kw they have advantages of high speed, low first cost, and small floor space, but are less effic than reciprocating engines. Blade heights are limited to 0.5 in minimum, due to friction losses, and 40 in max, because of structural problems. Blade speeds of 500 ft per sec are common, but special designs may run at 1 200 ft. Turbines can utilize the highest vacua. Steam temp is fixed by the allowable moisture in the exhaust (not more than 10–12%); more moisture causes excessive vane erosion and increased water rate; reduction of 1% moisture in any stage causes approx 1% improvement in effic in that stage. Proper selection of material, as stainless steels and irons, reduces erosion. Labyrinth packings and glands decrease interstage leakage. Fig 16, 17 show typical Rankine effic ratios; effic is not limited to these data, but it is difficult to justify higher values.

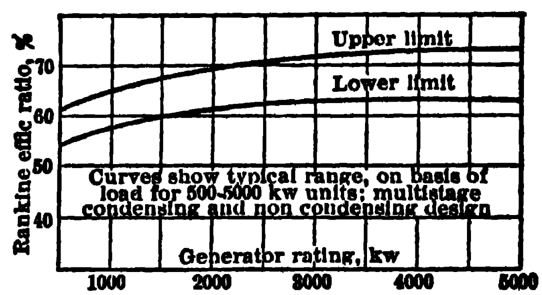

Fig 17. Rankine Effic Ratios of Steam Turbine Generator Sets

Table 14. First Cost of Turbine-generator Sets, 750° Steam Temp

A. Condensing units			B Non-condensing units			
Steam press, lb per sq in	Size, kw	Cost	Steam press, lb per sq in	Back press, lb per sq in	Size, kw	Cost
200–450	500–5 000	$17 000 + 18 6 × kw	450	0–215	500–5 000	$13 000 + 17 × kw
200–450	5 000–7 500	5 000 + 21 × kw	450	0–215	5 000–7 500	3 000 + 21 × kw
451–650	500–5 000	17 000 + 20 × kw	451– 650	0–265	500–5 000	16 000 + 20 × kw
451–650	5 000–7 500	5 000 + 22 5 × kw	451– 650	0–265	5 000–7 500	6 000 + 22 × kw

			651– 850	0–265	5 000–7 500	11 000 + 22.5×kw
			851–1 450	200+	5 000–7 500	21 000 + 23 × kw

Table 15. Effect of Size of Turbo-generators on Price (Clarke. Industrial Power, *Trans* ASME, 1939)

Rating, kw	Cost per kw, %	Rating, kw	Cost per kw, %
1 000	Base	7 500	0.625
1 500	0.850	10 000	0.687
2 000	0.775	15 000	0.652
2 500	0.730	25 000	0.623
5 000	0.635	50 000	0.462

Turbines are governed by throttling the steam supply, or cutting out nozzles on the first stage; the former is less expensive but less effic at light loads. Water rates at part loads, can be estimated if a Willans' line (Sec 39) is used with an intercept (no load) steam flow of 10–25% of full load flow. An internal governor may be built into the turbine to maintain constant press at a selected extraction point. For costs of turbine generator sets, see Table 14, 15.

6. STEAM ENGINES

Reciprocating engines compete with steam turbines in many services. Advantages of engines: low speed, high torque, and ready reversibility. Turbine advantages: high speed, minimum wt and space, and utilization of highest vacua. Max size for engines, 5 000 kw; for turbines, 200 000 kw. In sizes less than 250 kw, engines have better water rates than turbines. In large sizes turbines give max steam economy. Engines are suited to direct drive of air and refrigeration compressors, and piston pumps; turbines, to direct drive of elec generators, centrifugal pumps and fans, and turbo blowers.

Table 16. Steam Engine Diagram Factors* at Rated Load

Overall range, extreme conditions..	0.50–0.95
Usual range, normal conditions....	0.75–0.95
Simple, slide valve, small size.....	0.50–0.80
Simple, single valve, automatic, well maintained................	0.80–0.90
Uniflow..........................	0.85–0.95
Simple, four valve, or Corliss......	0.85–0.95
Compound, four valve............	0.75–0.85

* Diagram factor = Actual mep ÷ hypothetical mep

Engines are vert, horiz, angle, or inclined; single or multi-cylinder; simple or compound; condensing or non-condensing; uniflow or counterflow. Single-valve engines (D-slide, balanced, or piston valve) prevail on sizes below 100 kw, one valve controlling admission and release at both ends of the cylinder. Multiple-valves divide these functions among mechanisms such as oscillating plugs, plugs with trip gear (Corliss), or poppet valves. In uniflow designs, exhaust is through a central ring of ports, as in 2-cycle internal-combustion engines.

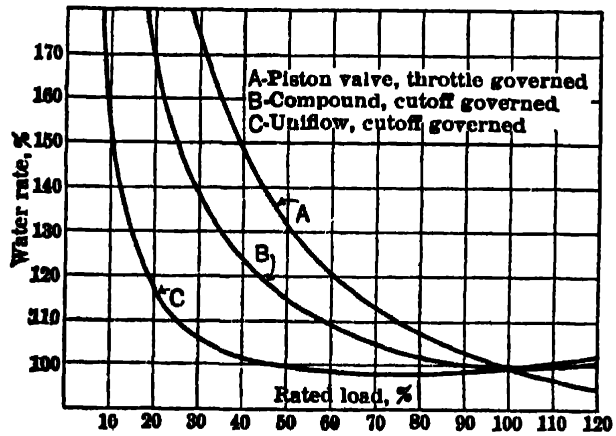

Fig 18. Typical Steam Engine Water-rate Curves

Mean effective pressure. Hypothetical values are calculated by thermodynamic methods (Sec 39). Actual values are obtained by using diagram factors (Table 16) as multipliers. Indicated hp (ihp) is then obtained by the equation ihp $= \dfrac{\text{mep} \times L \times a \times n}{33\,000}$, where mep = mean effective press, lb per sq in; L = stroke, ft; a = piston area, sq in; n = cycles completed per min. Mep is 50–100 lb per sq in for the usual steam press of 100–200 lb, and cutoff at 10–30% of stroke. The bore-stroke ratio ranges from stroke = 1 × bore, to stroke = 2 × bore, with 1.25 rather common. Commercial sizes are 4 to 36 in stroke. Speed is primarily a matter of machine design. Slide or poppet valves prevail in the 300-rpm group; plug and Corliss valves in the 100-rpm group. Piston speeds are 500–750 ft per min with the lower values on smaller engines.

Cylinder condensation and internal leakage cause higher actual water rate than computed from indicator cards; the increase may reach 50 or 75%; good maintenance reduces leakage. Use of superheated steam, and compound or uniflow designs reduce cylinder condensation; 10° superheat improves the water rate about 1%. The economy of a simple uniflow engine is nearly the same as that of a compound engine. The Rankine effic ratio of 500 hp condensing (5 in abs back press) engines is 60–70%; for non-condensing engines, the ratio is 5–10% higher. Smaller engines, especially slide-valve designs of less than 100 hp, show Rankine effic ratios of 30–50%, when operated non-condensing. The friction mean press is 8–10 lb per sq in, and results in mechanical effic of 85–95% at normal loads.

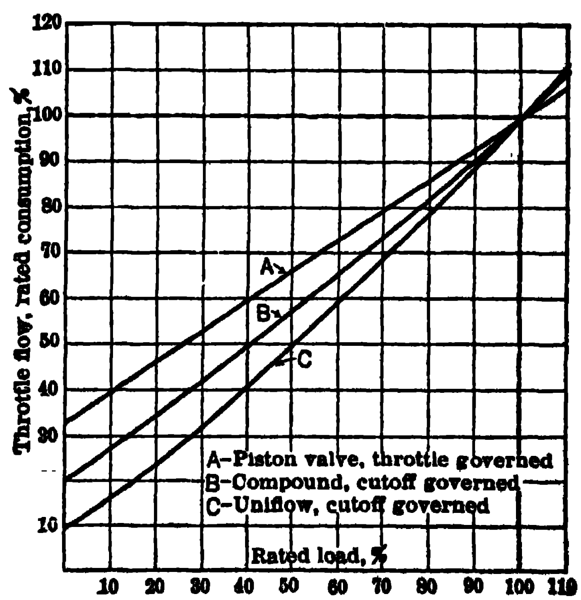

Fig 19. Some Typical Willans' Lines for Steam Engines

Governing and regulation, either for constant or variable speed, is obtained by throttling the steam, or varying the cutoff. Fig 18, 19 show comparative water rates, and Willans' lines for methods of governing different engines. Flyball and flywheel governors are not equally suitable to all valves and valve gear. "Automatic" engines have slide valves, and use flywheel governors to change the cutoff. Engines are made reversible by linkage mechanisms, which alter the valve eccentric position or its equivalent. Some first cost data on reciprocating engines are given in Table 17.

Table 17. First Costs of Reciprocating Steam Engines

Type	Size range, hp	Cost, dollars
Simple engines		
Single valve, automatic.	40– 320	930 + 11.7 × hp
Four-valve..........	150– 800	2 560 + 11.3 × hp
Corliss, slow speed....	107– 575	3 410 + 6 8 × hp
Uniflow.........	350–1 000	3 900 + 14.6 × hp
Four-valve, cross-compound.............	480–1 250	5 420 + 12.7 × hp
Corliss slow-speed, cross-compound.. .	400– 650	7 110 + 7.6 × hp

7. CONDENSING PLANT

The expansion of a lb of steam from boiler press to high vacuum produces approx twice the work that would be done by expansion to atmos press only. The condenser maintains the requisite vacuum. Engines can effectively utilize 25–26 in vacuum, while turbines realize the full benefit of 28 or 29 in (referred to 29.92 in, standard sea-level barometer). Condensing plants are not expensive, and are customary unless exhaust steam can be used for process heating purposes, or unless weight or bulk of equipment is prohibitive.

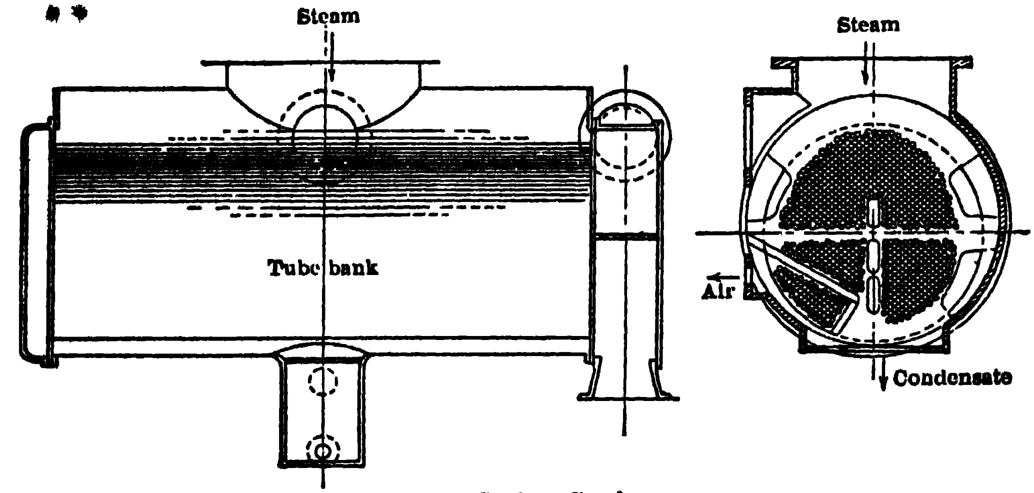

Fig 20. Surface Condenser

Condensers are of the mixture, contacting type, or surface, non-contacting (Fig 20, 21). Jets and sprays mix water and steam in the former; in the latter, a bank of tubes, less than 1 in diam, separate steam from water. In both, circulating pumps bring the cooling water to the condenser; hot-well pumps remove the condensate (or mixed condensate and circulating water), and air removal pumps abstract non-condensible gases which otherwise would accumulate and destroy the vacuum. A barometric leg may be substituted for the hot-well pump on a jet condenser to remove water by gravity. JET CONDENSERS will not maintain the highest vacua, nor preserve distilled condensate; hence, used only in small plants, with low steam press, and reciprocating engines. In SURFACE CONDENSERS, water generally flows through copper alloy tubes, steam surrounding the tubes, which are within a steel or C–I shell.

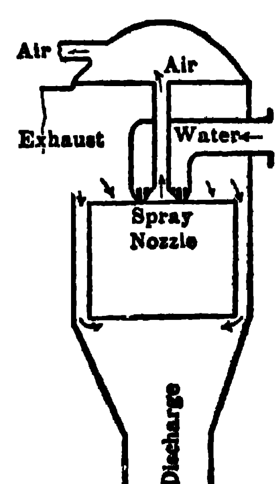

Fig 21 Jet Condenser

Vacuum is obtained in accord with the vapor tension curve for steam; lowest available temp is the atmos; latent heat of exhaust steam must be absorbed at this level. Water is preferable to air for cooling, due to its higher heat capac. Allowable temp rise of circulating water is limited to maintain

lowest practical steam temp. Fig 22 gives hypothetical water requirements for abstracting latent heat of dry steam at various vacua; actual condenser specifications often use 950 btu per lb latent heat with turbines, and 1 000 btu per lb with reciprocating engines. Allowable water temp rise is usually 10–20° F.

Heat transfer rates vary with water veloc, surface cleanliness, water and steam distribution, tube size and spacing, surface drainage, and air concentration. Heat transfer relation is $U = C\sqrt{V}$, where U = heat transfer rate, btu per hr per sq ft per deg F; V = water veloc, ft per sec; C (constant) = 251 for 1-in, and 270 for 0.75-in tubes. Heat transfer rates are 400–800 btu per hr per sq ft per deg F, with the veloc of 3–8 ft per sec. The surface required is usually 0.5–2 sq ft per kw of capac. The above formula (given by "Standards of Heat Exchange Inst," Condenser Section, p 7, edn 1939) is used by leading condenser makers.

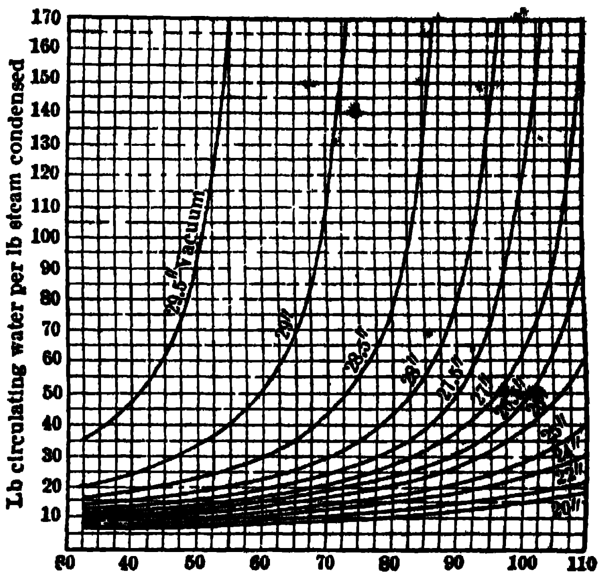

Fig 22. Hypothetical Condenser Circulating Water Requirements (29.92 in Barometer)

Condenser tubes are mounted in the tube sheets: (1) with ferrules and packings at both ends; (2) rolled at one end and packed at the other; (3) rolled at both ends with floating heads or bowed tubes. Tubes are kept clean by chlorination of circulating water, or by mechanical cleaners, as wire brushes or rubber slugs. ADVANTAGES OF JET CONDENSERS are cheapness, lower maintenance, less space, and fewer complications; surface condensers preserve pure feed, and give better vacuum.

Circulating pumps are of high capac (0.5–2.0 gal per min per kw) and low head (15–30 ft with surface condensers). The circulatory system is a syphon loop, the pump having only to provide for friction and veloc heads. Centrifugal and propeller types are best for this service, but direct-acting pumps can be used on small installations. Surface condenser, HOT-WELL PUMPS, have 0 01–0 04 the capac of circulating pumps; heads usually 100–200 ft. Centrifugal pumps prevail in larger installations. AIR PUMPS may be wet vacuum, removing both air and condensate, or dry vacuum, handling only air. The former are used only for small capac, and may be reciprocating or rotary; dry vacuum pumps may be reciprocating, rotary, hydraulic jet, or steam jet. The latter prevails because of small bulk and low cost, and is made in 1, 2 or 3 stages, with heat recovery condensers after each stage. Air pump capacities for 25 000 lb of steam condensed per hr are 0.25 lb dry air per min for turbines and 0.5 lb for engines. Atmospheric relief valves protect condensers from positive pressures due to interruption of the circulating water supply. Vacuum breakers prevent flooding the prime mover if the water level runs too high on a jet condenser.

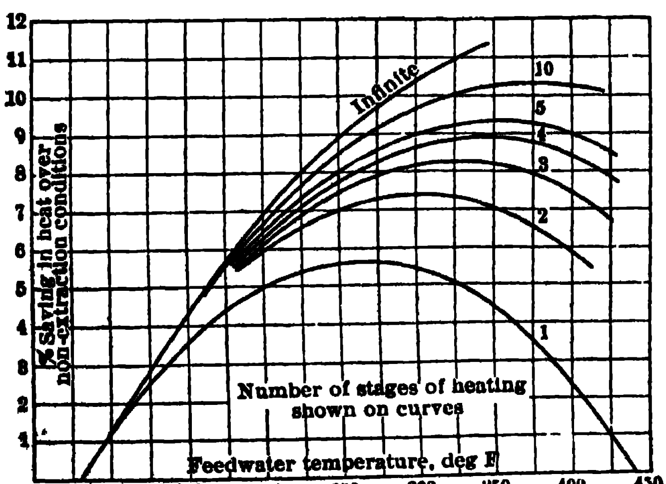

Fig 23. Feed-water Heat Saving by Extraction; Steam Conditions, 400 p, 700° F to 1 in Abs Back Pressure

Circulating water supply may be from natural or reclaimed source; it should be as cold as possible. The discharge should not mix with the cooler supply. Intake systems are protected by screens and racks to remove rubbish. If the natural supply is inadequate, reclaimed water can be used with an evaporation loss of 1–2%. Spray ponds and cooling towers increase power requirements, because of the 5–10 lb per sq in nozzle press and elevated head.

Cost of condensing systems, is $3–$6 per sq ft of condensing surface.

Feed water heaters are most important heat-saving devices. The use of exhaust or extracted steam for heating gives an approx 1% fuel saving for each 25 deg F; nearly all plants justify heating to 200° or 220° F. The greatest economy results when max work

is obtained from the steam before using it for heating. Main unit-extraction-stage heating gives max effectiveness (see Fig 23). OPEN HEATERS mix steam and feed by use of sprays and trays, with heat exchange rates of 200 000 btu per hr per cu ft of contact space. CLOSED HEATERS have a tube bank with water inside and steam outside the tubes. Tubes are less than 1 in diam and may be straight, plain, corrugated, U-shaped, spiral, or helical, with provisions for expansion and cleaning. Heat transfer rates are 250–750 btu per hr per sq ft per deg F, with terminal temp differences of 2°–10° F. Some advantages of open heaters are: (1) higher feed temp with same steam press; (2) convenient precipitation and removal of salts and scale; (3) degasification of feed, if properly vented. Closed heater advantages: are adaptability to any operating press; feed pumps can be placed before or after the heater; and contamination of otherwise pure feed by oily or dirty exhaust steam is prevented. Closed heaters vary widely in price, according to pressure; \$5–\$10 per sq ft being typical.

8. FEED-WATER HEATING AND PURIFICATION

Injurious substances occur in practically all water. They are detrimental either to the boilers or to their proper operation. Troubles from impure feed water are: formation of scale, corrosion, and priming or foaming. Solid matter may be precipitated as sediment, or may form scale on the heating surface. SEDIMENT causes little trouble; it is regularly drawn off at the blow-off. SCALE seriously retards heat transfer, and if allowed to accumulate the heat may weaken the metal sufficiently to cause rupture. CORROSION causes general weakening of the boiler, finally resulting in a breakdown at some point. PRIMING causes steam to carry with it more or less water, which, if it enters an engine cyl in sufficient quantity, may blow-out the cyl head. Substances causing these troubles may be natural constituents of the water, or be due to waste from a plant or factory at a higher point on the stream from which the water is drawn. Where the condensed steam from surface condensers is pumped back to the boilers the oil should be effectively separated. Condensed steam from turbines does not give trouble, as oil is used only in the bearings.

Water treatment. Scale-forming substances may be precipitated by heating or by adding chemicals to the water supply, and eliminated by filtration; or chemicals may be added to the feed water to cause the solid matter to form as a sediment instead of incrusting the heating surface. Anti-scale chemicals are known as BOILER COMPOUNDS. Substances causing corrosion or priming are treated in a similar manner. Electrolytic action, sometimes causing pitting and corrosion, may be neutralised by hanging zinc plates inside the boiler.

Table 18. Feed-water Purification

Trouble	Cause	Remedy
Incrustation	Sediment, mud	Filtration
	Readily soluble salts; Bicarb of magnesia; Lime, iron	Blowing off. Heating feed water and precipitating caustic soda, lime, and magnesia
	Organic matter	See Sewage, below
	Sulphate of lime	Sodium carbonate; Barium chloride
Corrosion	Organic matter	Precipitate with alum or ferric chloride and filter
	Grease, oil	Add slaked lime or sodium carb and filter
	Chloride or sulphate of magnesium; Sugars, acid	Sodium carbonate
	Dissolved CO_2 and O	Slaked lime, caustic soda; heating
	Electrolytic action	Zinc plates
Priming	Sewage	Precipitate with alum or ferric chloride, and filter
	Alkalies	Heat feed water and precipitate
	Sodium carbonate in large quantities	Barium chloride

Impure feed water should be analysed, to determine what it contains and the remedy, and also the wt of solids in a given wt of water and hence the proper wt of chemicals to be added for neutralising. Boiler compounds, if used in excessive quantity, may themselves cause boiler troubles. Avoid all secret preparations. They are either worthless or contain ordinary chemicals for which a higher price is charged under the name of a special preparation. In the latter case it is only a [illegible] chance that the chemicals are suited to the water. A number of concerns specialise in [illegible] impure feed water.

The importance of proper treatment is shown by the extensive purification systems installed at many large plants. EVAPORATORS. The most effective treatment of feed water is by using a closed system and adding only pure distilled water as make-up. On straight power cycles the makeup is only 1–3%. When make-up is too high, evaporators may be precluded. When used they are single or multiple in effect, and of submerged tube or circulating types. Cleanability of their surfaces is of prime importance. Dissolved oxygen in feed water corrodes steel parts of boilers and economizers; it is removed by DE-AERATORS, of either the chemical, or more generally the mechanical type. They resemble an open heater, but must have a scrubbing action, and not less than 30° temp rise to sweep the entrained O from the water. They operate at either positive or negative press. Good designs of condenser hotwells will give O concentrations as low as 0.03 cc per liter, but for greater purification a separate deaerator is necessary.

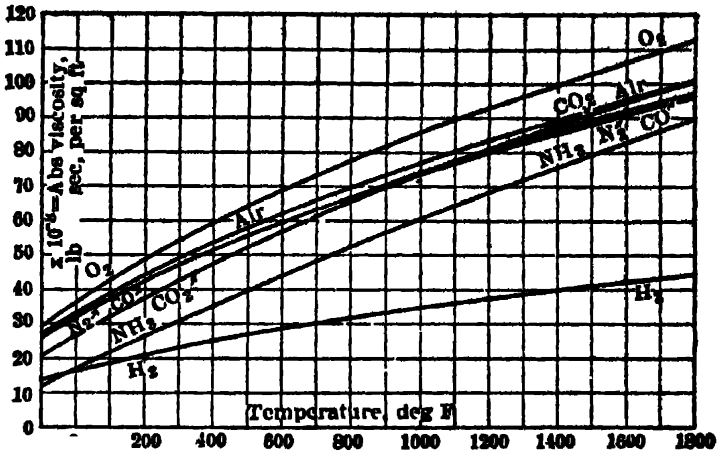

Fig 24. Viscosity of Gases, Calculated by Sutherland's Equation

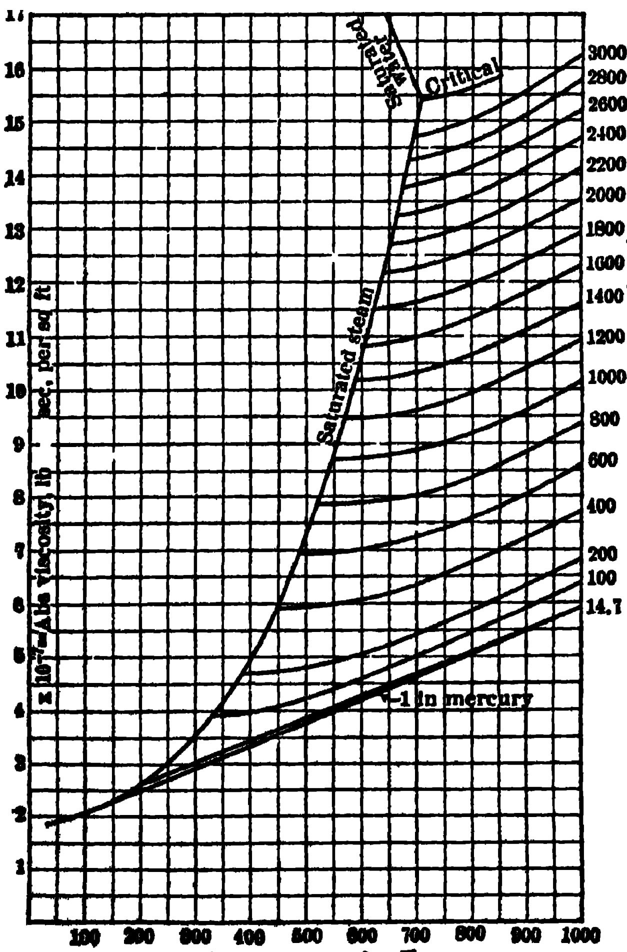

Fig 25. Viscosity of Steam

9. PIPING AND DUCT SYSTEMS

Selection of piping and duct sizes is a matter of balancing the operating cost, due to loss of energy by friction, against investment charges, to give the lowest total cost. Friction drops in straight pipe are determined by the relation: $\Delta H = C_D \frac{2Lv^2}{gD} = C_D \frac{Lv^2}{2gm}$, where ΔH = head loss due to friction, ft of fluid; L = length, ft; v = aver veloc, ft per sec; g = gravitational accel, 32.2 ft per sec²; D = pipe diam, ft; m = mean hydraulic depth, ft = $D \div 4$ for round pipe; C_D is the friction factor defining the flow pattern, and is a function of the "Reynolds' Number" (see Sec 39). The Reynolds' Number can be calculated from Fig 24, 25, 26. Data on C_D are in Fig 27. When an approx solution is sought, C_D can be taken as 0.005 or 0.006 for most duct and pipe installations. For the usual allowable piping veloc, see Table 19. The friction drop caused by fittings is generally expressed as $\Delta H = F \frac{v^2}{2g}$, where F = resistance coeff, for which typical values are given in Table 20, for approx estimates.

Expansion joints are necessary in pipe lines subject to temp changes. Piping must be so supported that no damaging thrusts will occur on connected equipment. They must be firmly anchored at intervals; supported by hangers, floor stands, or wall brackets; and have long-radius loops, U bends, sleeve, slip, or bellows joints for expansion and contraction. Hangers permit movement by swinging; brackets and stands have rollers.

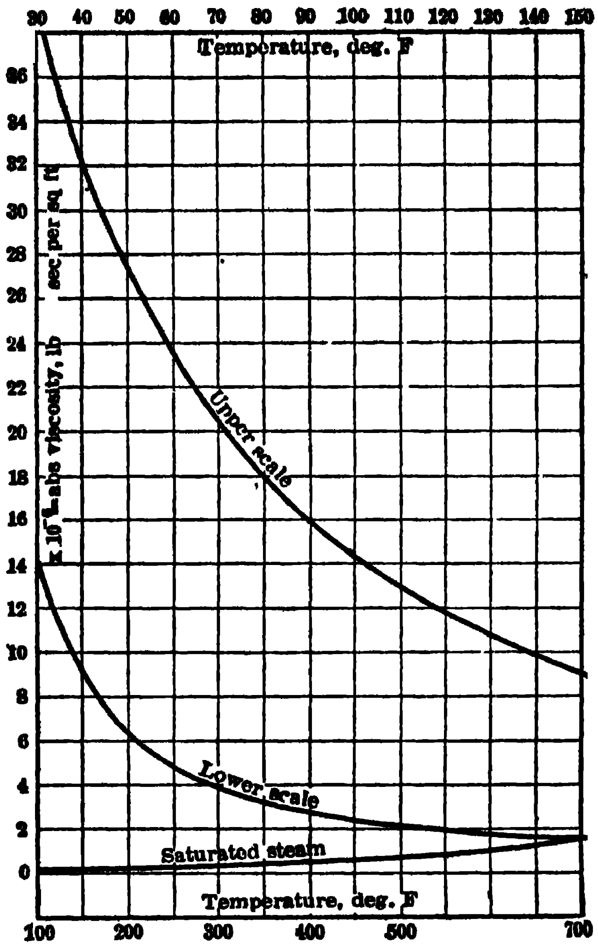

Fig 26. Viscosity of Water

Pipe insulating coverings. Cork, hair and felt are used for refrigeration and water pipes; waterproofed against external moisture condensation. Air-cell covering is satisfactory for steam temp below 250° F, while mixtures of magnesia and asbestos, in powdered or molded form with a cloth cover, are used for higher steam temp. Piping identification can be provided by color schemes, but instructional stencils on their surface are more effective.

Table 19. Allowable Velocities in Pipes and Ducts

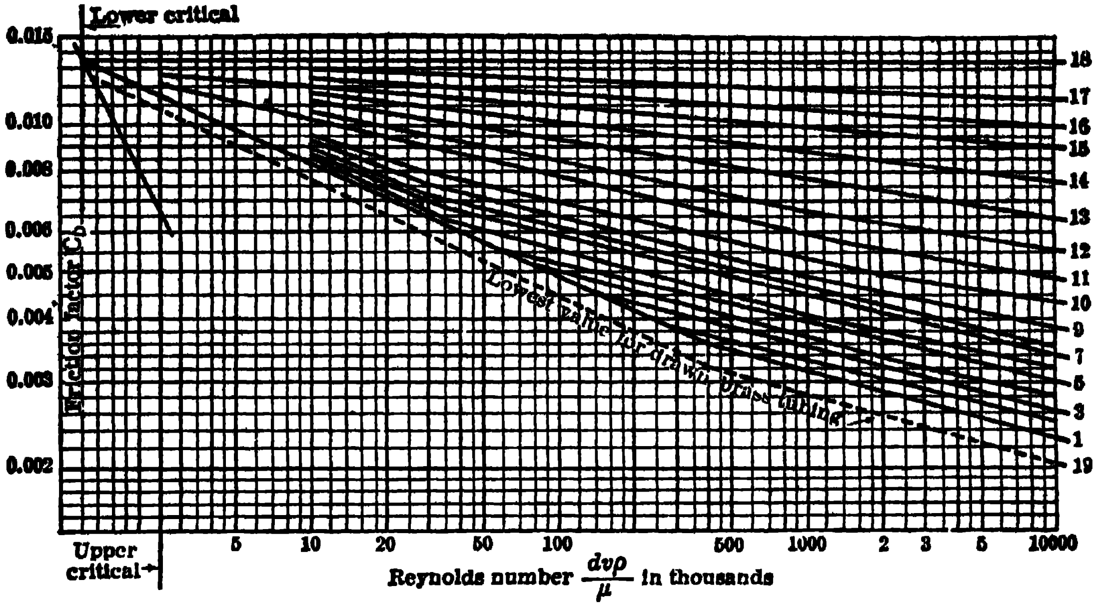
Service	Veloc, ft per min
Air ducts	2 000– 3 000
Comp air pipe	1 500– 2 500
High-press steam	10 000–15 000
Low-press steam	10 000–20 000
Water pipe	300– 600

Table 20. Friction Factors for Pipe Fittings

Fitting	Factor
Elbow, standard, 90°	0.75–1.00
Elbow, long sweep, 90°	0.20
Elbow, blade	0.25
Elbow, 45°	0.25
Gate valve	0.20
Globe valve	2.00
Orifice, sharp edge	0.04
Orifice, bell mouth	0.04
Re-entrant nozzle, L > 3 diam	1.00
Tee, straight run	0.25
Tee, turn	1.00–2.00

Drainage of steam lines prevents dangerous accumulation of condensate. Simple drainage chambers or drop legs may be used, with or without supplementary separators. SEPARATOR types: (1) reverse current; (2) centrifugal; (3) baffle plate; (4) mesh; (5) capillary.

Drainage chambers should have sufficient tankage, water gages, steam traps, and by-passes. TRAPS automatically remove drips, without allowing steam to escape; they comprise: float, bucket, gravity, differential expansion, thermostatic, and diaphragm. A manually operated by-pass is used when the trap is out of order. Drips are collected in a tank, hot-well, or open heater.



d = diam of duct, ft

v = mean velocity, ft per sec

ρ = fluid density = $\frac{\text{lb per cu ft}}{32.2}$

Fig 27. Flow of Fluids in Closed Conduits (Pigott)

10. WATER WHEELS

Water wheels function as demonstrated by Bernoulli's principle, relating the potential, press, and kinetic energy, at entrance to and exit from the wheel. The obsolete over-shot wheels directly utilize the wt of water as potential energy. Modern water-wheels, like steam turbines, function on the conversion of static into veloc energy. IMPULSE WHEELS (Fig 28). The veloc is generated in fixed nozzles, the emergent stream impinging on buckets mounted on the wheel periphery. With REACTION WHEELS (Fig 29) the nozzles are in the runner. There must be some accel in the speed ring, to bring the water to the wheel with proper entrance veloc; varying degrees of accel are therefore required in the

casings of different types of wheel. The vector diagrams of Fig 30 are illustrative. Fig 30(a) shows the impulse wheel, where the entire accel is in fixed nozzles; $v_1 = C_v\sqrt{2gH}$, where v_1 = jet speed, ft per sec; H = head, ft; and C_v = 0.98–0.99, the coeff of veloc. If the nozzle angle β were zero, and 180° reversal were attainable in the buckets ($\alpha_2 = 0$),

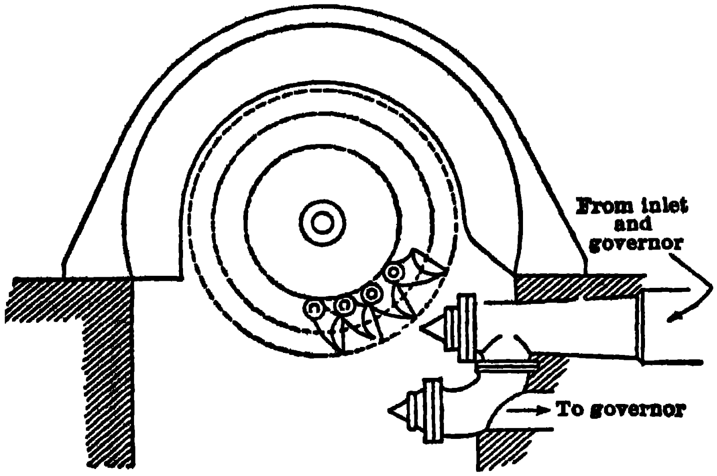

Fig 28. Impulse Water Wheel

then, for best energy utilization, bucket speed u would be half the jet speed v_1. As complete reversal is impossible in practice, impulse wheels operate with bucket speed = 0.42–0.45 × jet speed. If the conversion of head into veloc is only partial, in the fixed nozzles, and expansion completed in nozzles on the wheel, then vector diagrams, Fig 30(b), 30(c) obtain. With less expansion in the casing nozzles, the jet veloc becomes progressively smaller and the entrance vane angle, α is increased for max effic. The ratio of bucket to jet speed ($u_1 \div v_1$) is therefore about 0.9 in Fig 30(b), and may range to 1.5 to 2.0, as in Fig 30(c). Fig 30(a) is typical of Pelton wheels, Fig 30(b) of mixed press Francis runners, and Fig 30(c) of propeller wheels. The exit veloc triangles should always give minimum length for the final water veloc, v_2; attained when perpendicular to u_2, and only for one condition of flow. Effic curves must therefore show a peak value. In commercial designs the vector diagrams are more complicated, due to three-dimensional flow considerations.

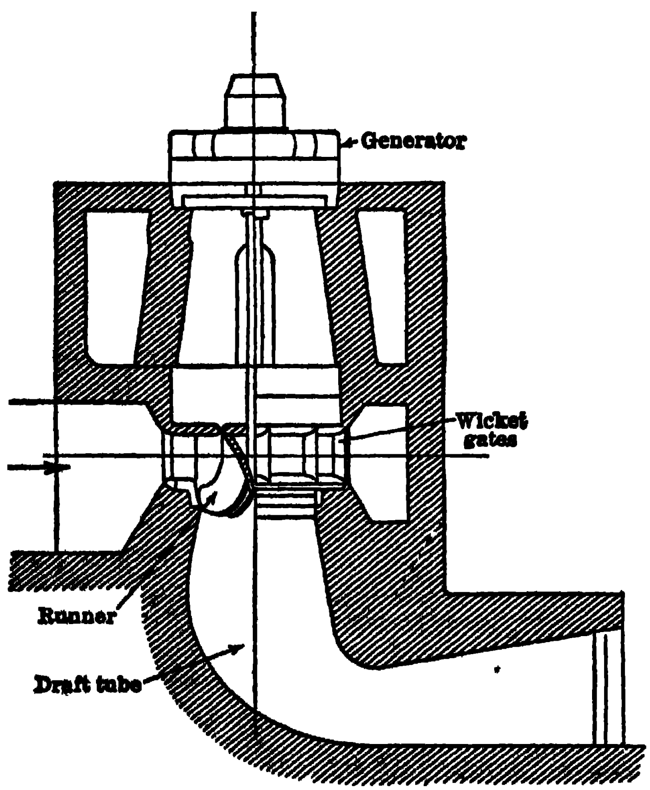

Fig 29. Francis Reaction Water Wheel and Setting

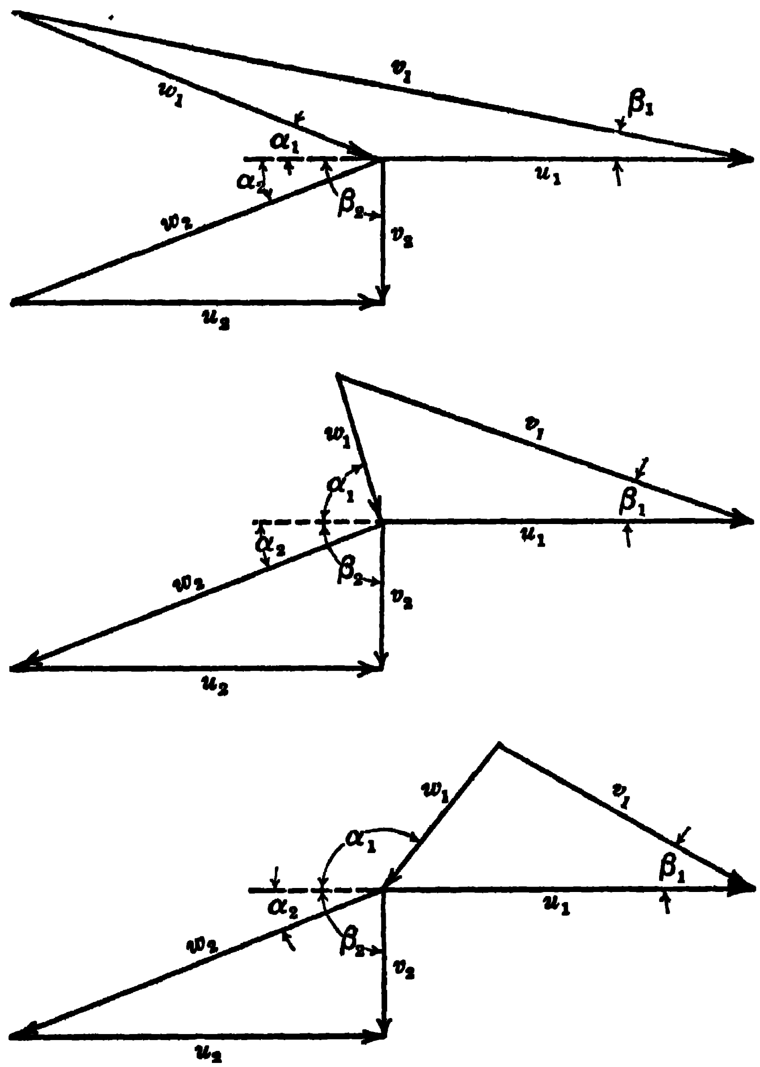
Pelton wheel (Fig 28) is the only impulse wheel of importance. The water jet is created in a stream-lined needle nozzle; only 1 or 2 jets are used per wheel. Governing and regulation is by use of a deflecting hinged nozzle, or a double nozzle, the lower one being for waste and opens only during load changes to avoid water hammer.

Reaction wheels operate full of water, as required by the criterion of a press drop through the runner. Fig 29 shows how the water is brought through a concrete, C-I, or steel-plate scroll to the gate ring and runner. The water is accelerated partly in accordance with vector requirements, and is directed by the speed ring to the runner passages.

The inward radial, and subsequent axial, flow complete the expansion. Water is discharged to a draft tube; thence to the tail race. Control and regulation are through the gate settings. Gates may be wicket, register, or cylindrical. FRANCIS RUNNER, with inward radial flow, predominates for heads of 50–500 ft. At less than 500 ft, the flow becomes more axial (Fig 31), ultimately reaching the propeller type. This results in high, sustained effic; see Fig 32, which includes other curves for comparison. Propeller wheels



Subscript 1, applies to inlet conditions; 2, to exit
v = abs water veloc;
u = abs bucket veloc;
w = relative veloc, water to bucket:
α = vane angle;
β = nozzle angle.

Fig 30. Water-wheel Vector Diagrams

are generally for heads under 100 ft. KAPLAN RUNNER vanes are adjustable and under governor control. SPECIFIC SPEED, N_s, defined by $N_s = \dfrac{\text{rpm} \times (\text{bhp})^{0.5}}{(\text{head})^{1.25}}$, where rpm = rev per min of the runner; bhp = brake hp; head = head of water, ft. Specific speed, a criterion that exactly classifies a runner (Fig 31), is the speed at which an homologous runner of proper diam would run in order to develop 1 hp under 1 ft head. It is usually given for the point of max effic, or at rating. High spec speed means a high-speed runner. With low heads, the practical problem is to make the rotative speed high enough. Hence, high spec speeds are for low-head service, and vice versa.

Fig 32 contains curves from numerous installations and authorities, to show the relations between spec speed and head. The spec speed of Pelton wheels is fixed by the ratio of wheel and

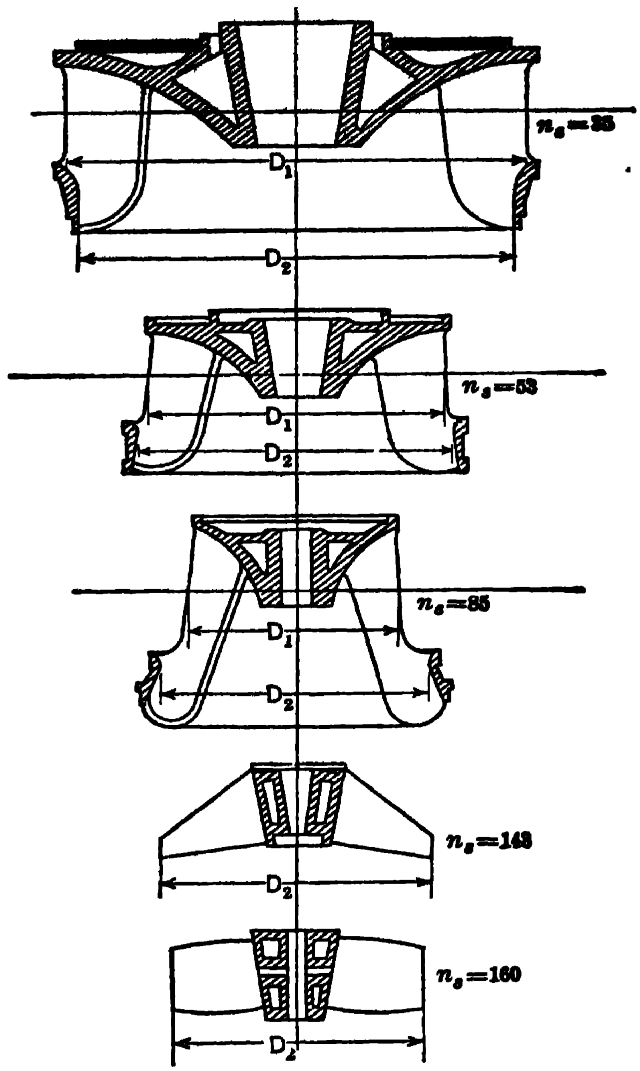


Fig 31. Comparison of Runners of Equal Power, but Different Specific Speeds (n_s)

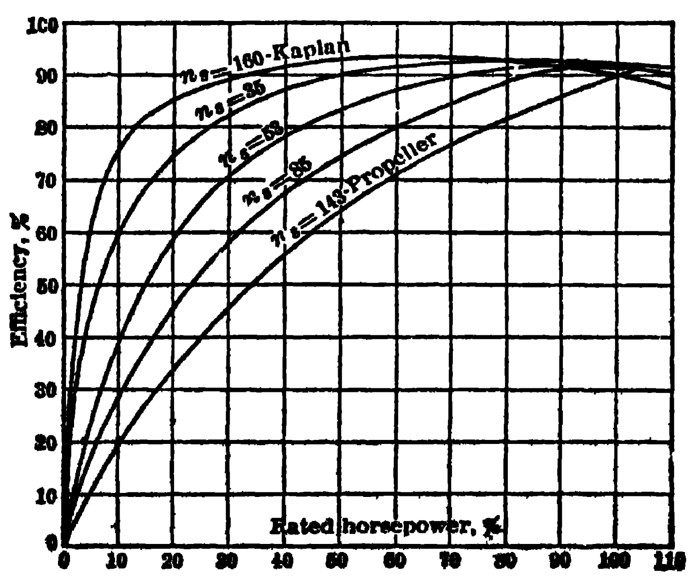

Fig 32. Water-wheel Efficiency Characteristics

jet diam, and is increased by the square root of the number of jets. Commercial spec speeds are: 3–8 on Pelton wheels; 15–50 on Francis; 50–100 on mixed-press wheels; and 100–200 on propeller and Kaplan wheels. All commercial runners except the Pelton operate full of water and hence require a continuous water column from head to tail race. The runner discharge connection is not a simple pipe, but a DRAFT TUBE, for the supplementary purposes of placing the machinery safely above tail water without loss of available head, and reducing to a negligible amount the loss incident to the discharge veloc from the runner. A plain cylindrical tube satisfies the first requirement, but a conical tube is needed for the second. While the theoretic height is the barometric (33.8 ft at sea level), the practical height is generally about 20 ft, because of veloc conversion, vapor press,

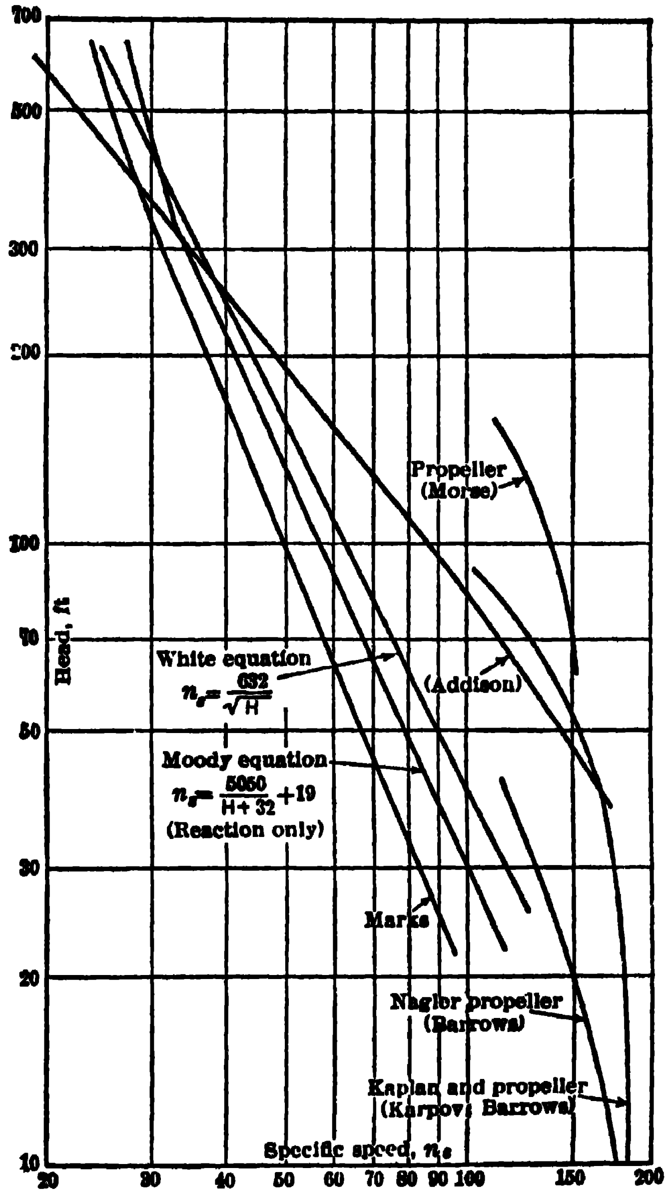

Fig 33. Water Wheel Experience Data; Specific Speed vs Head

air in solution, cavitation, and vibration. Draft tubes are usually of concrete, the design depending on site conditions. Draft-tube effic is the ratio of regain of press energy in the tube to veloc energy at its entrance; values run to 90% on the best designs.

Cost of hydraulic turbines varies widely, because most installations are of special design. Wheel and generator cost \$20–\$50 per kw; the lower prices for large size and high head. Turbine and generator usually represent only a small part of total cost of plant, which may be \$100–\$400 per kw of capac. Most of the cost is for structures, dams, spillways, head and tail works, land, and water rights.

11. PUMPS

Head. The TOTAL DYNAMIC HEAD of fluid (*TDH*) in ft delivered by a pump is given by: $TDH = h_s + h_d + \frac{V_d^2}{2g} - \frac{V_s^2}{2g} + d$, where h_s = suction head, ft, measured by a gage on the suction side; h_d = discharge head, ft, measured by a gage at foot of column pipe; V_s = veloc, ft per sec, in suction pipe at gage point; V_d = veloc in discharge pipe at gage point; d = vert distance, ft, between gage centers. SUCTION HEAD h_s = pipe entrance head loss + $\frac{V_s^2}{2g}$ + suction-pipe friction loss + suction lift. DISCHARGE HEAD h_d = static head at pump + discharge pipe friction loss to gage point.

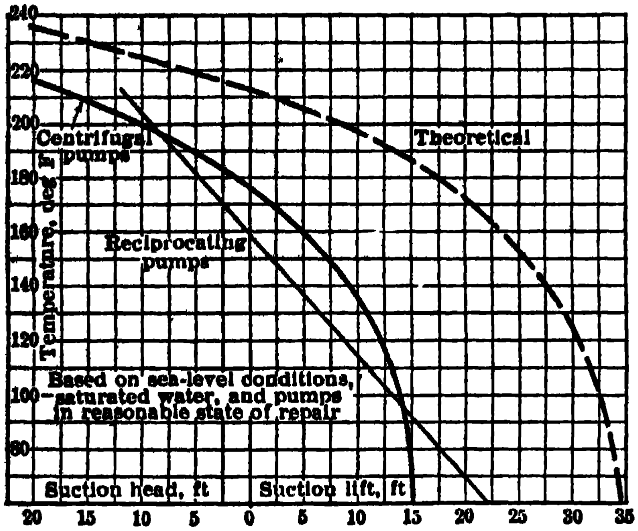

Fig 34. Theoretical and Practical Suction Lifts for Water at Various Temps

Water may be brought to the pump under negative press (suction lift) or positive press (suction head). With SUCTION LIFT, the fluid enters the pump by atmos press on the free liquid surface in the well or sump. Theoretical lift equals barom press in ft of fluid (33.8 ft at sea level). Actual allowable suction lift, h_s, is equal to this barom head h_a, minus the following: (1) h_{vp} = vapor press of the liquid; (2) h_v = veloc head in the suction pipe; (3) h_g = press of gas in solution; (4) h_f = friction loss in suction pipe. Conservative practice requires inclusion of a safety factor. In Fig 34 are given practical data. With liquids at or near the flash point, the fluid must be fed to the pump under positive head, to prevent separation in the column and cavitation. Thick liquids must flow to pumps under positive press.

Capacity is the net useful vol delivered per unit of time, expressed as gal per min (gpm). With positive pumps, piston displacement is sometimes listed as capac.

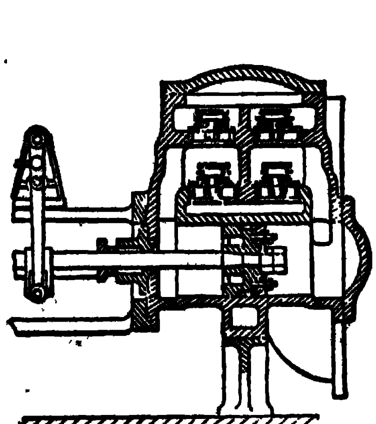

Fig 35. Water End of Piston Pump

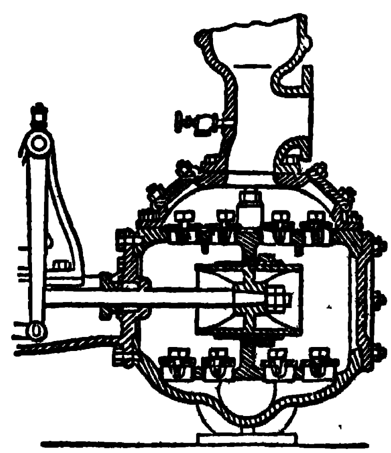

Fig 36. Piston-and-ring Pump

Hp and effic. Theoretical water hp is given by $whp = \frac{gpm \times TDH \times \text{sp grav}}{3\,960}$. Mechanical effic, $n_m = \frac{whp}{bhp} \times 100$, where bhp is brake hp. Standard density used for water is 62.318 lb per cu ft, at 68° F. DUTY of a pump is the ft lb of energy delivered to the water per million btu (the term is gradually being abandoned). SLIP is loss in displacement due to internal leakage and short stroking expressed as a percentage of displacement; usually less than 5%. SIZE designation. An 8 by 5 by 12-in direct-acting pump

has 8-in diam steam cyl, 5-in water cyl, and 12-in stroke. A 6-in pump, reciprocating or centrifugal, means 6-in nominal pipe size for discharge. CLASSIFICATION: (*a*) Positive displacement, including reciprocating, direct-acting and power pumps, and rotary pumps; (*b*) Steady flow, jet and vane pumps, including centrifugal and axial-flow propeller pumps.

Reciprocating pumps. Water-end classification comprises the simplex pump, having one water cyl; duplex, with 2 water cylinders in parallel; and triplex, with 3 water cylinders. A pump is single-acting when it takes water on one side of the piston only, and double-acting when it takes water on both sides.

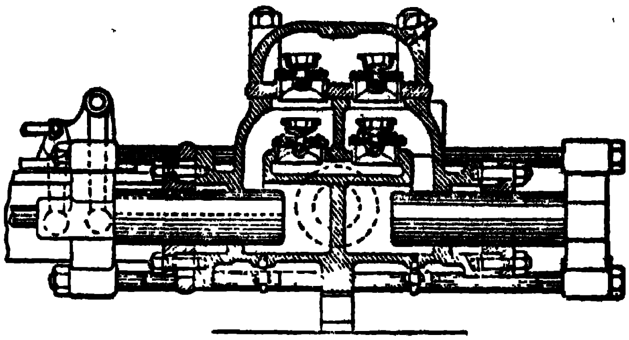

Fig 37. Outside, End-packed Plunger Pump

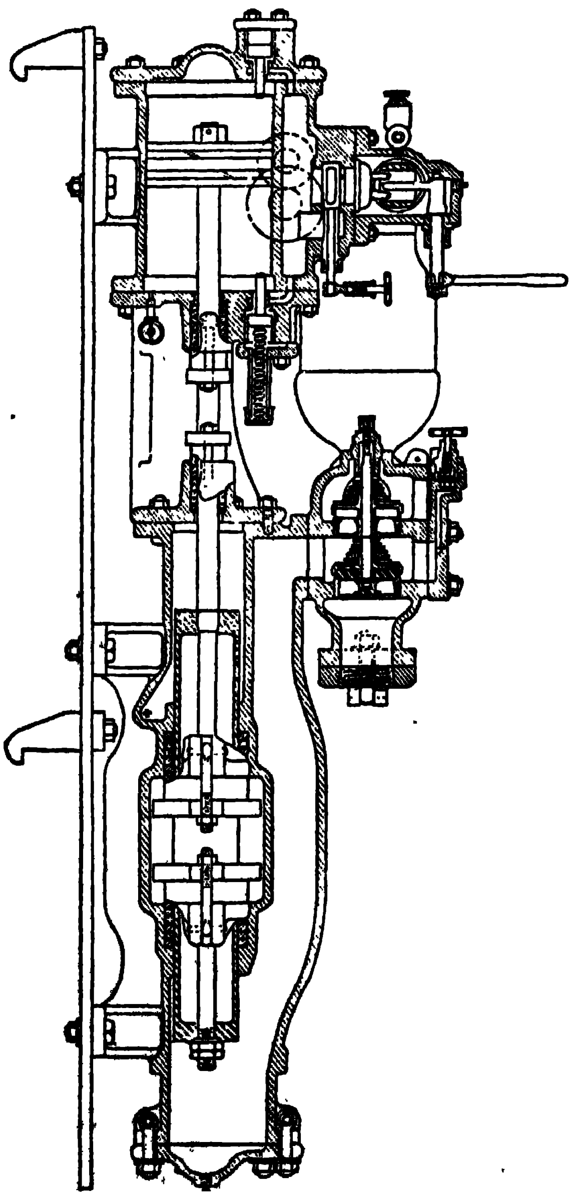

Fig 38. Vert Plunger Sinking Pump (Ingersoll-Rand)

The water cyl has a piston or plunger. A piston, making a loose fit in the cyl (Fig 35), is packed with hemp or metallic packing ring. Piston-and-ring pump (Fig 36) is a cheaper construction, but is apt to score with gritty water. Both types permit undetected leakage past the piston. They may be used for heads up to 150 lb per sq in. For pressures of 150–300 lb, outside-packed plunger pumps (Fig 37, 38) are recommended; for pressures exceeding 300 lb they are necessary. With outside packing leakage is readily detected, and stopped while the pump is running. Scoring (cutting) of the plunger is also plainly visible. Plunger pumps cost more than piston.

When both suction and discharge valves are above the barrel (Fig 35, 37), the pump is of the submerged type; when the suction valves are below (Fig 36) it is of the straightway type. Submerged type is used for hot liquids and condenser service, the pistons being surrounded by cool and de-aerated water, which protects the packing and improves suction action. But, as flow of water in the cyl is reversed at every stroke, it is not recommended for strokes over 14 in. Straightway type costs more, but the water has a more direct flow through the pump, and is therefore used for high water veloc.

Direct-acting pump has the water piston or plunger directly connected to steam end, through the piston rod. Steam-end classification: pumps are simple, compound, and triple expansion, according as each water cyl is served by a single steam cyl, a high and low-press cyl, or a high, intermediate, and low-press cyl. A crank shaft, connecting rod and flywheel are used in some steam designs. If motor-driven, the pump is called a POWER PUMP; Fig 39 shows a triplex pump of this type. Cylinders of all designs may be single, duplex or triplex. Water flow through a reciprocating pump is intermittent. Use of several cylinders and AIR CHAMBERS aids uniformity of flow and reduces shocks. Air chambers are generally mounted on the delivery side, and vacuum chambers are sometimes used on the suction side. Air chamber volume should be 6–8 times piston displacement on simplex pumps;

3-4 times, on duplex pumps; the chambers should have a gage glass and means for air charging.

Reciprocating pumps (Table 21-25) have 2 to 36 in stroke, the water cyl bore being 0.3-0.7 times the stroke. Actual stroke of steam pumps is 0.7-0.9 of rated stroke; power and crank-and-flywheel pumps do not short-stroke. Piston speeds and rpm are low, to reduce shock and cavitation. Fig 40 contains recommendations of Hydraulic Inst for standard pumps handling water, or liquids with viscosity less than 200, Saybolt Universal. Higher speeds are obtainable with positive suction feed.

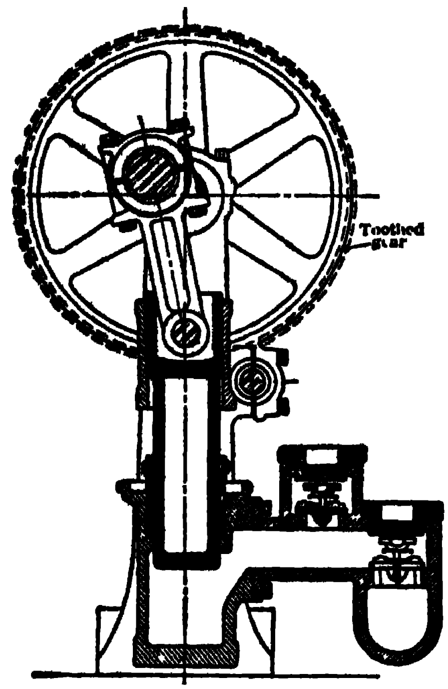

Fig 39. Triplex Power Pump

Commercial classification: REGULARLY-FITTED pump has a C-I plunger or piston working in a bronze ring, liner, or sleeve; piston rod is of steel, and valve seats, springs, and all inside bolts and nuts, are of bronze; valve disks, of rubber or bronze. BRASS-FITTED. Besides the bronze of regularly-fitted pumps, the rods are of "tobin bronze," piston is solid bronze or bronze-lined, and stuffing-box throats and glands are bronze-lined. In ALL-IRON FITTED pumps, for ammonia or tar, no bronze comes into contact with the fluid pumped. Valve seats are of malleable iron, springs of steel, the C-I piston works in the solid-bore of the cyl, and plunger nuts are iron. ALL-BRONZE pumps, for acids that attack iron, are entirely of bronze, which in some cases must contain no zinc. LEAD AND WOOD-LINED pumps. Large pumps, too costly if of bronze, may be made of iron, with the interior lined with an acid-resisting material, as lead, wood, or cement. By LARGE OPENINGS is meant that the valve seats are not obstructed by ribs. Ball or clack valves are of this type (see below).

"Special-fitted" pumps for different liquids:

"How fitted"	Liquid pumped	"How fitted	Liquid pumped
All-Iron................	Ammonia	Regularly-fitted	Calcium brine
"	Bichloride of mercury	" "	Calcium chlorate
"	Calcium chloride	" "	Citric acid
"	Caustic soda	" "	Cyanide of potassium
Brass-fitted............	Brine	Lead-lined, no zinc.	Hydrochloric acid
" "	Copper liquors	" " " ..	Hydrosulphite acid
" "	Glycerine; oils	All-bronze, or lead or wood-lined C-I, no zinc	Sulphuric acid
" " (large openings)	Sewage

18	12	20	8.5	510	3	8	103×41	6 080	.....

For boiler feed service, reduce these capacities by 50%.

Valves are almost always automatic, operating by unbalanced press on the two sides of a moving element. They include: (a) disk, for general service; (b) wing-guided, for high press; (c) ball,

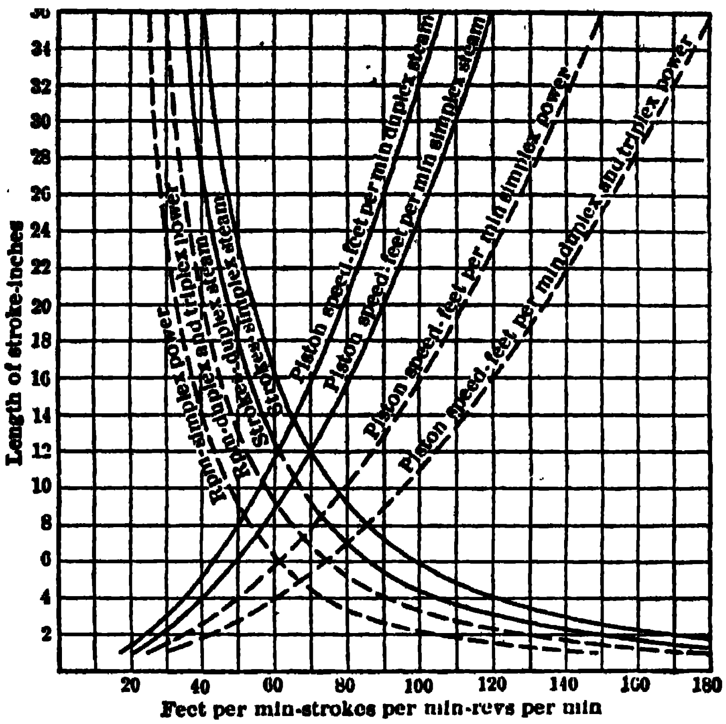

Fig 40. Basic Speeds, Simplex and Duplex Direct-acting Steam Pumps, and Simplex, Duplex and Triplex Power Pumps (Hydraulic Institute)

for viscous liquids; (d) clack, for lightest services. Disk valves, the commonest, seat on a bronze grid, and are spring-loaded on the downstream side. The disks are of medium or soft rubber, for press below 150 lb per sq in; hard rubber or composition, for hot water or press of 300 lb; metal for high press; standard diam, 3 to 4 in. Total valve area, 50–100% of piston area; highest for viscous liquids. Lift, 10–20% of valve diam; spring loading, 0.25–1.0 lb per sq in of valve area on suction valves, to 5 lb on discharge valves.

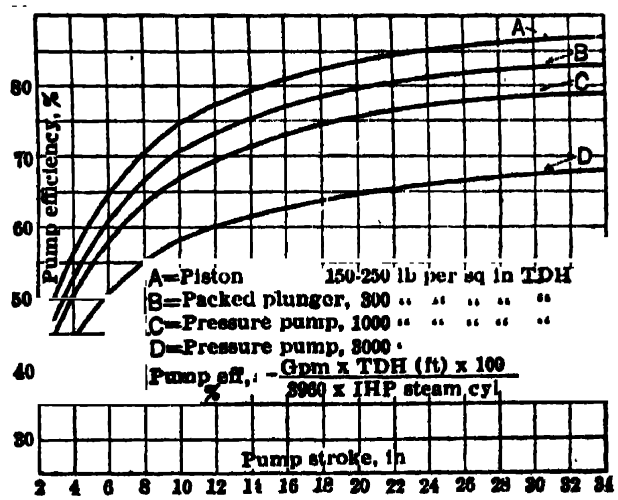

Fig 41. Efficiency of Direct-acting Steam Pumps

Efficiencies of direct-acting pumps are given in Fig 41. Performance is measured on basis of mean press, rather than mechanical effic. Friction losses, solid and fluid, are best expressed as equivalent mean press; which is practically constant, irrespective of operating head, and has decreasing effect as the head increases. STEAM CONSUMPTION is estimated by: lb per hr = $whp \times 90$; air consumption, by cu ft of free air per min $= 1.4\dfrac{asp}{p_a}$, where a = area of water piston, sq in; s = piston speed, ft per min; p = air press at pump required for water press, lb per sq in abs; p_a = atmos press, lb per sq in abs. See Tables 21–25.

Rotary pumps. Rotary motion may be used for an element within a fixed casing, to give positive displacement (Fig 42). The rotary element may consist of gears, lobes, screws, cams, vanes, or combinations of these. Rotary pumps are suited to direct connection with elec motors, and for oily liquids. Sizes are from the smallest to several thousand gal per min; heads, to 1 000 lb per sq in.

Centrifugal pump is essentially an impeller, with backward-curved vanes, rotating in a fixed casing. It may be volute or turbine (Fig 43); the former has a simple casing; the latter, a diffuser ring, with or without guide vanes, and also a concentric or volute casing. Impellers may be single or double suction (Fig 44, 45, 46).

24	8	18	15 6	33.3	525	4	6	16 0	4 10

These pumps are good for lifts up to 900 ft.

The pumps are vert or horiz; right or left hand, when viewed from the coupling end. Casings may be: (a) split, in a plane parallel to shaft; (b) drum or barrel, where impellers and diffusers are assembled in series from one end of a cylindrical case; or (c) ring, where successive stages are mounted from one end with through bolts. Shafts are supported in external bearings. End thrust, especially with single-inlet impellers, requires hydraulic balancing drums and thrust bearings. Stuffing boxes, with hard or soft packings, are suitable for heads of several hundred ft; high press requires supplementary labyrinth glands. Materials specification should be with the maker's advice. The impeller should be removable with minimum disturbance of pipe connections.

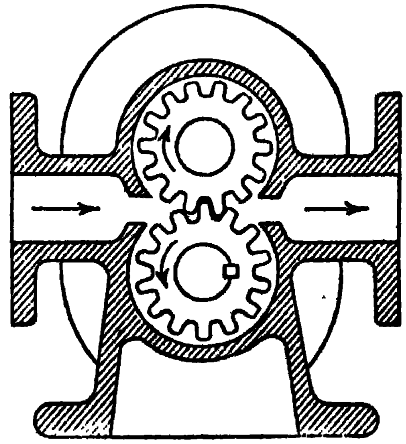

Fig 42. Gear Type Rotary Pump

Design and performance. Centrifugal pumps function as a combination of forced and free vortices. The static head theoretically $= U_2^2 \div 2g$, and total head $= U_2^2 \div g$: wherein U_2 = tip speed, ft per sec; g = gravitational accel, ft per sec^2. In practice, pumps give heads differing materially from the theoretic values, being influenced by blade

curvature at heel and tip, axial blade length, radial depth, number of blades, sidewall details, casing proportions, inlet form and proportions, fluid properties and friction. Variations in design are reflected in the CHARACTERISTIC CURVES (Fig 47), which are definitive. A pump can operate only on its characteristic. If excess head is developed (capac less than A in Fig 47), the difference must be throttled, or speed altered; the latter procedure economizes power consumption, but the carrying charges for speed-control equipment are not always justified. APPROX PERFORMANCE can be estimated at different speeds by the relations: (1) capac is directly proportional to speed; (2) head, directly proportional to speed squared; (3) hp directly proportional to cube of speed. These relations apply to the same point on the effic curve and give characteristics for different speeds. The relations are not exact, because they do not reflect scale effect or Reynolds' Number influence. The relations are sufficiently accurate for practical purposes. Fig 48 shows a set of curves from test. The characteristics may be plotted on the percentage basis (Fig 49), or on the dimensionless coeff basis (Fig 50).

Specific speed (Fig 51), $N_s = rpm \times (gpm)^{0.5} \div \text{head}^{0.75}$, where head is in ft per stage. It is rigorously fixed by the pump design, and is the speed (rpm) at which a geometrically similar impeller would revolve to deliver one 1 gal per min under 1 ft head. High-speed impellers have high values of N_s. Spec speed is useful in pump selection, because it relates head capac and pump speed for best effic and absence of possible suction cavitation. Fig 51 contains recommendations for double-suction, single-stage pumps. Usual spec speeds are: (1) less than 4 000 for single-inlet impellers; (2) less than 6 000 for double-inlet; (3) 4 000–9 000 for mixed-flow impellers; (4) greater than 9 000 for axial-flow pumps. Impellers for high heads have low spec speeds; those for low heads, high spec speeds.

Fig 51 shows that centrifugal pumps are sensitive to suction conditions. With liquids at or near the flash point, positive suction head is necessary to prevent cavitation in the impeller eye; as demonstrated by the hot-well pump characteristics of Fig 52. For very viscous liquids, pump makers should be consulted. Centrifugal pumps are generally limited to 200–400 ft head per stage, and a tip speed less than 150 ft per sec. Multistaging (Fig 46) is needed for higher heads. Actual head per stage is from 0.9 to 1.3 $\times \left(\frac{U_2^2}{2g}\right)$. Effic is 50–90%, the higher values for large pumps of few stages. Head characteristic curves may be flat, steep, or rising. Hp characteristics may be straight inclined lines; or curved, with concavity upwards or downwards; the last has advantage of a self-limiting feature and avoids over-motoring. Steep head characteristics are best for parallel operation, as they give equitable load division.

Axial-flow propeller pump (Fig 53) has high speed, low head and large capac. Spec speeds exceed 9 000. Its characteristic curves (Fig 54) differ from those for centrifugal pumps; showing decreasing head and hp for increasing capac; max power is required at shut off. They are especially suited to such low-head service as condenser circulating water and irrigation plant. For higher heads they are multistage, with guide vanes between stages. Axial-flow and centrifugal types often merge in a single mixed-flow design, where the impeller eye approx equals the diam of the outer periphery; this permits combining in a single unit the best features of both.

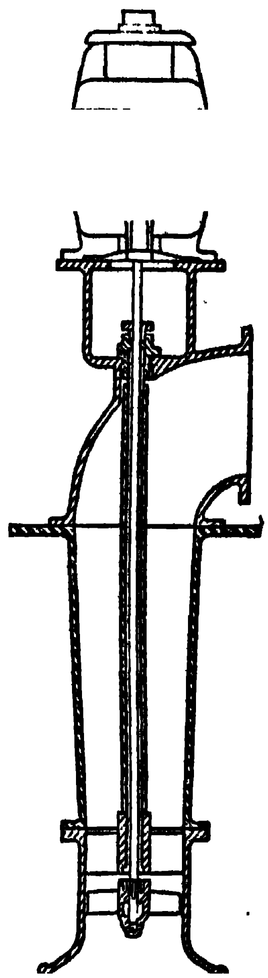

Fig 53. Axial-flow Pump

Cost of centrifugal pumps is affected not only by size or capac, but also by head pumped against, speed, number of stages, quality of construction, and commercial conditions (Table 26).

Cost of 4-in, single-stage pump. Single-suction: iron, \$200; brass impeller and brass-sheathed shaft, \$320; bronze ditto, \$425. Double-suction: iron, \$320; brass impeller and brass-sheathed shaft, \$575; bronze ditto, \$700.

Cost of 2-stage pumps is about 3 times that of single-stage, for same discharge and speed, but double the head. As number of stages increases, the cost approaches the number of stages × cost of a single-stage pump. For similar head, speed, and construction, cost varies directly as capac. Water-supply pumps cost about \$2 000 per million gal daily capac (DeLaval Steam Turbine Co).

Table 26. Average Cost of Iron Single-stage Centrifugal Pumps

Capacity, gal per min	A	B	C	D	Capacity, gal per min	A	B	C	D
100	$110	$160	$300	$400	1 500	$580	$840	$1 200	$1 400
200	180	270	400	500	2 000	675	1 000	1 425	1 575
500	300	430	660	800	5 000	1 325	1 800	2 375	2 600
1 000	440	650	1 025	1 150	10 000	2 600	3 800	......	......

Note.—*A* = low-head pumps, with iron impellers, single suction, belt-drive, and no performance guarantee. *B* = double-suction pumps, belt or direct-drive, but otherwise similar to *A*. *C* = pumps of better construction and heads up to 150 ft. *D* = pumps of fairly good construction, suitable for direct motor-drive.

For pumps suitable for high heads (as for mine drainage), the design is special and cost varies widely. Examples: 2 500 gal per min, 600-ft head, $10 000; 5 560 gal per min, 280-ft head, $50 000; 5 500 gal per min, 300-ft head, $55 000.

Cost per lb wt is nearly constant, decreasing slightly as size of pump increases; for small iron pumps, about 35¢ per lb; higher for brass and bronze-fitted.

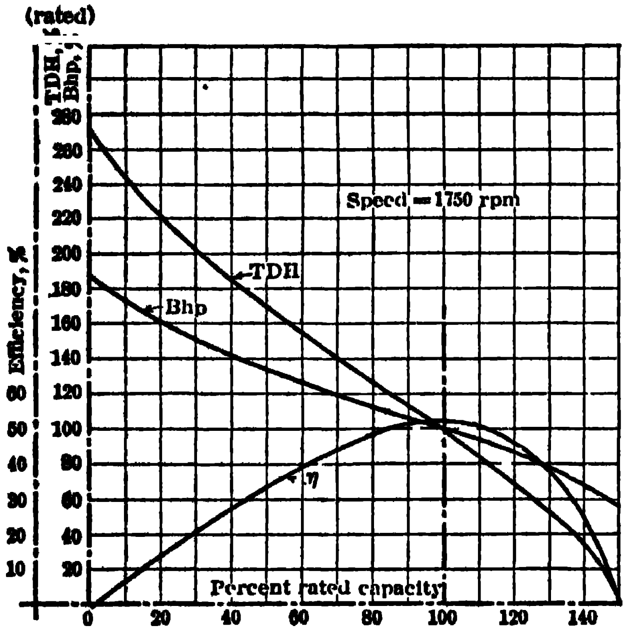

Fig 54. Characteristic Curves, Axial Flow, Propeller-type Pump, Percentage Rating Basis

12. INSTALLATION AND OPERATION OF PUMPS

Location. Pumps should be accessible, set on rigid foundations, with base slightly above the floor. Care must be taken in setting, not to exceed proper suction height (including losses in suction pipe), see Art 8. If bolted to foundations instead of being grouted, the base must be in perfect alinement when tightening the bolts. The pump shaft is alined with that of the driver by putting a steel scale on the coupling flanges. If alinement is accurate, the scale will rest on both flanges all around the surface. See that the clearance between the 2 half couplings is equal at all points of circumference. If bolts instead of grouting are used, make sure after the bolts are tight, that the pump and driver are still in line.

Piping. Piping should have as few bends as possible, and these should be of long radius. Introduce no unnecessary bends or other sources of friction in the suction line. Suction line must be free from air leaks, especially where it is long, or the pump is at some height above water level. Avoid air pockets in suction line; if any exist, provide means to get rid of the air.

Valves. In multiple-stage and single-stage high-press pumps, a CHECK VALVE is placed in the discharge line between gate valve and pump. Where there is a foot valve and possibility of water hammer, the discharge valve should be closed before shutting off power for stopping the pump. FOOT VALVE. Where the suction lift is not high, a foot valve is often advisable; it simplifies priming the pump. There must be a strainer to keep the foot valve from becoming choked. A foot valve is not advisable for a pump working against a high static head; on shutting off the power, the pump would stop suddenly, and the water rushing back might close the foot valve before the check valve could act, thus producing heavy water hammer. The foot valve should be of flap type, and of ample size to minimize friction.

Bearings must be cleaned before starting the pump for the first time, as foreign substances may get in during shipment or erection. They should then be filled with pure, clean mineral oil, which must be changed when it becomes dirty and the bearings thoroughly cleaned at same time.

Stuffing boxes and packing. Before starting the pump, the stuffing boxes should be carefully cleaned, and packed with enough packing back of the water-seal ring so that the inlet water for sealing is brought in at the ring and not at the packing. Piping supplying the water seal should fit tightly, so that no air can leak in; a little air entering here might cause the pump to lose its suction. If the water is acid or gritty, the sealing water must be obtained from some clear source.

of supply. Valves for the water seal must be open before starting up. If packing is too tight, it may cause burning of the packing and cutting the shaft. Packing-ring joints should be at angle of 45°, and the joints of the several rings staggered. On starting the pump, it is better to have the packing slightly loose (without causing an air leak); instead of putting too much press on it, place heavy oil in the gland until the pump works properly and then gradually tighten the gland. Since packing boxes are water sealed, see that the valves are open before starting; a slight leakage of sealing water through the gland is desirable.

Air in water may be liberated and collect in the pump passages. Hence, the air cocks on top of the casing should be opened occasionally; or, if much air, they may be kept partly open during operation, connecting them to drain pipes. If the delivery falls off without apparent reason, open the pump and examine its interior and the impeller passages, as foreign bodies may have been drawn into the pump.

Priming. Unless the water supply flows to the pump with sufficient head to fill the casing, the pump must be primed. PRIMING BY EXHAUSTER or ejector is convenient where steam or comp air is available. The discharge pipe must have a tight valve close to the pump, to allow air to be exhausted from casing and suction line. A foot valve is desirable on a steam exhauster, for priming the first time, or when the suction line has been emptied. PRIMING BY FOOT VALVE can be done where there is a supply of water available under pressure, by merely allowing the suction pipe and pump casing to fill. All pet cocks should be opened during the filling to allow escape of air. PRIMING BY VACUUM PUMP. Where steam is not available and it is impracticable to fill the suction line with water, a hand or power air pump may be used. A valve must then be placed on the discharge line. In priming multiple-stage pumps, the air must be exhausted thoroughly from each stage; if primed by exhauster, it should be connected to each stage.

Starting. The pump casing must be entirely filled before starting; if run empty, the clearance rings and shaft sleeves, which have very small clearances, will bind, heat, and cut. When first starting the motor, be sure that its direction of rotation agrees with that of the pump; pumps must run in the direction for which they are designed; this is usually stamped on the casing. After priming a centrifugal pump, the shaft should be turned over 1 or 2 rev, to allow all air to free from the impeller vanes.

13. INTERNAL-COMBUSTION ENGINES (see Sec 39)

Advantages for stationary power service: (1) when water supply is small or poor; (2) when coal is not available, or is high in price; (3) for small power requirements at high thermal effic, and with good reliability and reasonable first cost; (4) for poor load factors, because of low stand-by losses and quick starting.

Classification: (1) Otto, Diesel, or mixed cycle; (2) mixture or injection engines; (3) gaseous or liquid fuel; (4) volatile or non-volatile liquid fuel; (5) spark or compression ignition; (6) 2 cycle or 4 cycle; (7) air or solid (airless) injection Diesel engines; (8) high or low speed.

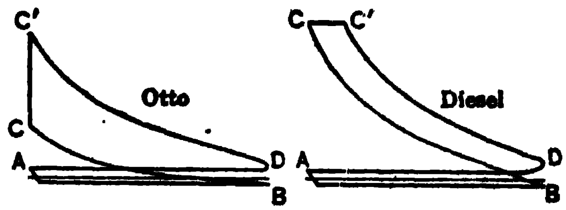

Fig 55. Otto and Diesel 4-cycle Indicator Cards

Four-cycle engine indicator cards for Otto and Diesel cycle (Fig 55). In the OTTO, a new charge is drawn into the cyl on suction stroke AB, and compressed into the clearance space on compression stroke BC, at or about the end of which it is ignited by an elec spark, and in burning causes the press rise CC', at approx dead center. The high-press gases formed by combustion expand during the third or expansion stroke C'D, driving the piston forward. On this stroke only is power delivered to the engine, enough being stored in the flywheel to run the engine until next power stroke. On exhaust stroke DA, the burned gases are forced out. In the DIESEL, a charge of pure air only is drawn in, AB, and compressed as in the Otto, but to a higher press, sufficient to raise the temp above ignition temp of the fuel, which is injected during the first part, CC', of next stroke, burning as it enters. Rate of injection determines slope of line CC', which should be nearly horiz. During remainder of stroke expansion occurs, followed by exhaust as in the Otto. The 4-cycle engine has 2 valves, inlet and exhaust, both mechanically operated.

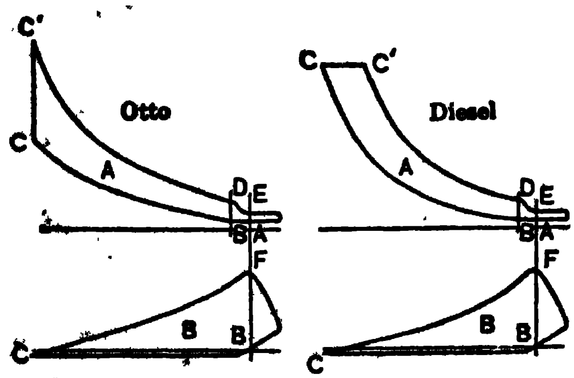

Fig 56. Otto and Diesel 2-cycle Indicator Cards

Two-cycle cards (Fig 56). A power stroke occurs once in each rev, the burned gases being removed, followed by a new charge during latter part of expansion and early part of compression strokes. Combustion occurs, CC', followed by expansion C'D, as in 4-cycle. At D an exhaust port is uncovered by the piston, allowing much of the gases to escape. A fraction of the stroke later, at E, a transfer port is uncovered, allowing a

new charge, previously compressed to 6–10 lb above atmos, to flow into the cyl, and thereby force out the products of previous cycle. On its return stroke, the piston closes transfer port at A and exhaust port at B, permitting compression to occur during remainder of stroke BC. During compression in the power cyl, suction BC occurs in the compressing cyl, followed by compression CF, while expansion occurs in the engine. Prior to admission to power cyl, the charge may be compressed in various ways: in small engines, by front end or step-piston compression; in large engines, by a separate compressor. Due to leakage at exhaust port during charging, 2-cycle type is generally limited to injection engines, in which fuel is not added until after compression is over, thereby eliminating fuel wastage through exhaust port. A 2-cycle engine, having twice the cycles for the same rpm, gives greater hp for same cyl size; but not twice as great, because the mep and effic are less than for 4-cycle. Chief advantages are: less piston area per hp, lighter flywheel due to greater frequency of impulses, and reduction of valves and valve gear; all resulting in smaller weight and cost.

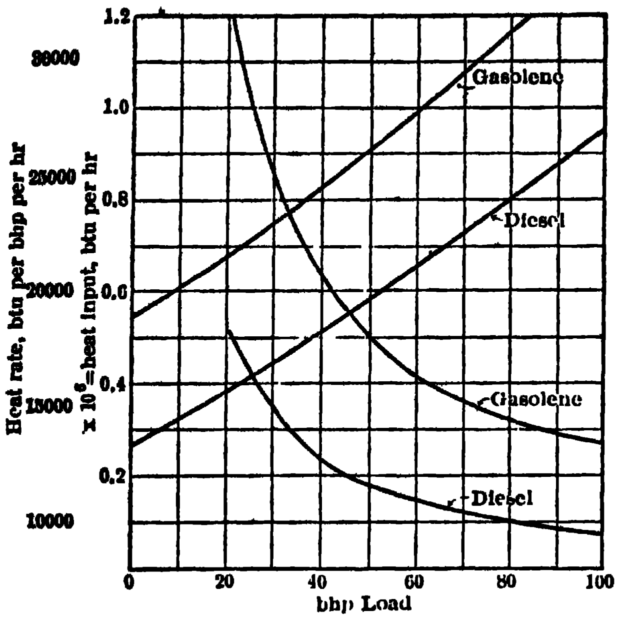

Fig 57. High-speed Gasolene and Diesel Engines. Comparative Performances (based on gasolene of 125 000 btu per gal; Diesel fuel of 142 000 btu per gal)

Externally-made-mixture engines operate on: (*a*) gaseous fuels, as natural, producer, or blast-furnace gas; (*b*) volatile liquid fuels, as gasolene, alcohol, benzol, or blends. The high speed, multicylinder, automotive engine, using gasolene, is the most important. Low and medium speed gas or gasolene engines are used in some stationary services.

Injection engines utilize non-volatile liquid fuel, wherein air only is compressed in the cyl and fuel injected near end of compression stroke; ignition is by the heat of compression. Low-compression, hot-wall engines were formerly used. Diesels now prevail; they may be solid injection (fuel directly injected by a pump), or, rarely, air injection (fuel injected by comp air at 1 000 lb per sq in). Air injection has been practically abandoned in favor of solid injection, due to trouble with high-press air, and improvements in solid injection fuel systems. The trend with all of these is away from low speeds and large cylinders, except where long life and minimum operating charges are sought. Multi-cylinder, high-speed design reduces wt and first cost. High-speed engines make little or no effort to follow Diesel or Otto cycle, but generally operate as a mixed cycle.

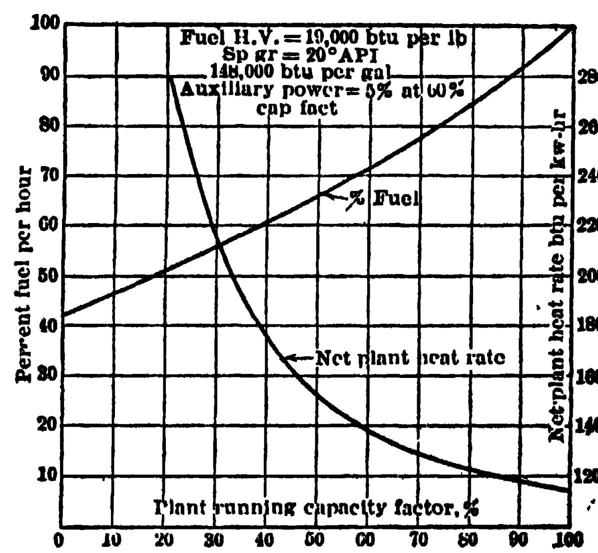

Fig 58. Diesel Plant Heat Rate

Power and efficiency. Analyses and heating values of fuels are in Table 10, Art 4; abbreviated ASTM Diesel fuel specifications, in Table 27. Performance data for different classes of engines are given in Table 28, and Fig 57, 58 show performance curves for stationary Diesel and gasolene engines. Lubricating oil consumption of Diesel plants is reflected by the relation: Gross kw-hr generated per gal lubricating oil = 24 × (plant running at capac factor, %).

Costs vary widely, due to differences in design and to competition. Prices of gasolene and kerosene stationary engine are: 1–6 hp, \$50–\$60 per hp; 6–10 hp, \$35–\$50; 10–25 hp, \$25–\$40 per hp. Vert, multicylinder medium speed, natural gas engines, \$35–\$40 per hp.

High-speed Diesel engine generator sets (10–100 kw). \$50–\$90 per kw. Low and medium speed Diesels, 4 cycle, \$50–\$75 per hp; 2 cycle, \$40–\$60 per hp.

Table 27. Diesel Fuel-oil Classification (ASTM abbreviated)

	Grade of Fuel

14. OPERATION OF INTERNAL-COMBUSTION ENGINES

Governing. External-mixture engines are practically all controlled by throttling the mixture on its way to the cyl, manually or by governor; injection engines, by varying amount of fuel injected.

Ignition for external-mixture engines is always by elec spark, the commonest system being the jump-spark, in which the secondary circuit of an induction coil is led into the cyl through the insulated terminal of a spark plug. At the proper moment the primary circuit is closed and a series of sparks jumps a gap in the secondary circuit at end of plug. Injection engines require no

ignition system, except in the hot-wall type, where an uncooled portion of the cyl heats the fuel to ignition point.

Starting devices. Large engines are started by admitting comp air to one or more cyls at proper time, until a mixture has been drawn into and fired in one of them, whereupon the air is shut off. Small engines are started by turning them over by hand until an explosion occurs, or by elec motors. Automobile engines have elec starters, which become generators and supply current for ignition, storage battery, and lighting.

Cooling is by water jacketing the cyl, except in very small sizes where, by ribs on the cyl, enough radiating surface is obtained for cooling. In larger sizes, the exhaust valves, and in double-acting engines, the pistons and rods, are also water-cooled. Cooling water must not deposit much salt on heating; dirty or hard water fills the jackets with mud or scale, causing overheating. Water may be allowed to go to waste, or artificially cooled; 3–5 gal per hr per hp are generally sufficient.

Carbureters prepare explosive mixtures from gasolene or alcohol. Strictly speaking, the term carbureter is limited to apparatus where no external heat is applied, those requiring heating being called vaporizers. But, with the use of heavier grades of fuel, many so-called carbureters now have means for applying heat, from engine-jacket water or exhaust. Carbureters proportion the fuel and air, vaporizing the fuel to some extent and mixing the two, by allowing fuel to flow from a reservoir, in which the level is kept constant, into the air-inlet pipe. As the press in this pipe drops with increase of air flow, more fuel will flow. If air and fuel followed the same law of flow with press drop, a carbureter adjusted for any condition of load or speed would be correct for all conditions. But, flow of fuel increases faster than that of air, tending to cause too rich a mixture at heavy loads or high speeds. Most carbureters use a manual or automatic device, or a combination of these, for introducing extra air when conditions normally cause a rich mixture. The fuel reservoir is called the float chamber, when the liquid level in it is regulated by a float. This device is limited to engines in which the supply is under a gravity or press head. For stationary engines insurance regulations usually forbid its use, in which case a pump forces fuel to the reservoir in excess of the engine demand, surplus returning to the tank. The fuel flows from the reservoir through a spray nozzle, controlled by a needle valve.

For light fuels the heat in the atmos suffices for vaporization; for heavier grades, heat is applied by drawing the air partially or wholly from a jacket on the exhaust pipe, or by allowing the engine-jacket water to pass through a jacket on the carbureter. Excessive heating is bad, as engine power is proportional to density of the charge. Incomplete vaporization, especially in multi-cyl engines, is apt to cause a non-homogeneous mixture. For mixing action, carbureters depend chiefly on the throttle and valve obstruction, and on bends in the supply pipe.

15. GAS PRODUCERS

Construction. A gas producer is a metal shell, lined with fire brick and having provision for supporting the fuel bed and blasting it with air or a mixture of air and steam. Fuel bed is 4 ft or more thick, comprising a zone of ash at bottom, next a high temp zone of burning fuel and finally a layer of fresh coal. The bed may be supported on a grate, fixed or revolving; or on a concrete pier rising from a pool of water, into which the sides of the producer extend, thus forming a water seal through which ash is raked out. Fuel is charged through a hopper, to prevent outrush of gas or inrush of air.

Operation consists in roasting off volatile matter, and then oxidizing the carbon to CO or CO_2 by the O in the air and steam; H of the steam is set free, and the ratio of CO to CO_2 depends on temp and thickness of the bed. Steam reduces the temp, the exothermic reaction of the oxidation of the C being partly neutralized by the endothermic reaction of breaking down the steam. Without steam the hemp is usually high enough to fuse the ash, forming clinker and preventing flow of air through the bed.

Fuels. Though any fuel rich in carbon may be used, those containing much volatile are disadvantageous, due to variation in gas quality and difficulty in removing tar and soot formed by reduction of the heavier hydrocarbons. Coking coal is unsatisfactory, as it tends to block the flow of gas like clinker; some producers have mechanical pokers to break up the cake. Fuels used in producers: anthracite or bituminous coal (non-caking), coke, lignite, charcoal, oil, wood, peat, and waste products.

Blast may be forced through the bed by building up press before the bed is reached, as in PRESSURE PRODUCERS, or by creating a deficiency of press beyond the bed, as in SUCTION PRODUCERS. In press producers (commoner in the larger sizes), the blast is caused by a steam jet or positive blower (usually the former, as steam is required in the blast and the blower serves as a good mixing device). In the suction type, the engine piston draws the blast through the producer (a small auxiliary blower being used for starting). Though this type requires no gas holder, it is disadvantageous to employ the engine for producing blast, and a rotary blower or fan is generally used to draw gas from the producer and deliver it to the engine. The suction producer is limited to the better grades of fuel, as anthracite and coke, but is safer, because, as leaks are inward only, the burning of some gas in the producer is all that can result; whereas leak in a press producer allows escape of CO_2, or may form an explosive mixture in the room or building. The draft may pass up through the bed, UP-DRAFT PRODUCER; downward, DOWN-DRAFT PRODUCER; or both ways, COMBINED-DRAFT PRODUCER. In the two latter cases, the volatile matter passes through the combustion zone and is reduced to staple forms or is completely burned.

Producer auxiliaries. The term PRODUCER SET covers producer, auxiliaries, and engine. The most important is the cleaning and purifying device, usually comprising a scrubber and filter or tar extractor. The SCRUBBER is a chamber filled with coke or similar material, through which the gas rises while water passes down; sometimes it is a pipe, up which the gas travels, passing water sprays at short intervals. FILTERS, of saw dust, excelsior, or mineral wool, extract tar and other liquids, but are only partially successful. TAR EXTRACTORS, other than filters, are centrifugal fans or beaters for churning the gas and water, causing tar particles to collect in drops, which float away. A recent filter depends on static elec action in causing minute particles of tar to coalesce into drops large enough to fall by gravity in an ordinary separator; tar so recovered is water-free, and has value as a by-product. Suction producers must also have apparatus to supply steam for humidifying the blast. As no press is required, the steam may be made in the producer jackets, or in an evaporator heated by the gas on its way to the scrubber. Proportions of steam and air must be controlled; best done by saturated air, but of different temp. For a press producer, a separately fired boiler generates steam for the blower.

Mond producers recover ammonia from the coal. An excess of steam is supplied to the producer, reducing the temp of the reaction and hence increasing the CO_2 content, but preventing breaking down of the ammonia. After purification the gas passes to a scrubber supplied with dilute H_2SO_4 instead of water, which absorbs the ammonia as sulphate, and upon evaporation solid sulphate is obtained.

Rating of producers is more uncertain and difficult than that of boilers; the term horsepower of a producer is incorrect, as no mechanical work is done. However, a producer is usually designated as being of a certain hp, meaning that it will supply gas for an engine of that hp. On the basis of 1–1.5 lb coal per hr per engine hp, and a rate of combustion of 7–10 lb per sq ft of producer grate surface (figures realized in aver units of both types), a producer will supply about 7 hp per sq ft of grate.

Table 29. Producer Dimensions (Smith)

Hp rating	Coal per hr, lb	Space required, ft			Hp rating	Coal per hr, lb	Space required, ft		
		Length	Width	Height			Length	Width	Height
50	65	12	7	20	175	220	15.5	9.5	22
75	95	12.5	7.5	20	200	250	16	10	22
100	125	13	8	20	250	315	17	11	22
125	160	13.5	8.5	20	300	375	18	12	22
150	190	14	9	22	.....	......	. .	..... .	......

Producer costs. Following figures are from actual installations before 1917:

Suction producers, up to 300 hp,	$252 + (14 \times hp)$	**Note.**—For approx 1938 costs, double the figures obtained from above formulas.
Pressure " " " 300 "	$860 + (15 \times hp)$	
Suction " and auxiliaries, 0–200 hp,	$570 + (46 \times hp)$	
Suction producers and auxiliaries,	$150 + (11 \times hp)$	
Pressure " " " to 200 hp,	$1\,000 + (16 \times hp)$	
" " " " over 200 hp,	$2\,000 + (15 \times hp)$	

16. APPARATUS FOR TESTING POWER PLANTS

Codes governing the testing of power-plant machinery are published by Amer Soc Mech Engs. Following suggestions, as to methods and procedure, may assist in laying out and running tests.

Preparation. Define the object of test, and decide upon the limit percentage of error allowable in the results. Determine quantities to be measured, by analysing the expressions denoting the final results (generally compound units) into quantities of a single dimension, since there are very few methods or instruments for measuring quantities of more than one dimension. Thus, the determination of water rate calls for the wt of dry steam per hr per ihp, and the measurements necessary are: wt of steam used, dryness factor, length of run, mep in the cyl, length of stroke, area of piston, and strokes per min.

Choice of instruments and methods of measurement depend upon the limit percentage of error allowable. If an aggregate error of 20% is permissible, apparatus of extreme accuracy is unnecessary, but, if results will be worthless unless accurate within a very few per cent, it is useless to proceed except with accurate methods.

After deciding upon the method, a DIAGRAMMATIC SKETCH is made of the machine to be tested, with all instruments shown in their relative positions. This is a guide in setting up the apparatus. A log of all of the readings is then drawn up, with a column for each variable and space for each constant. The log should also contain spaces for description of apparatus, date of test, names of observers, and remarks concerning unusual occurrences. Completeness of the log and sketch

should be proved by seeing that there is a place for every instrument reading, and that the formulas used for calculating final results can be fully satisfied for the log readings.

Pressure measurements. Ordinary press units are: lb per sq in, in of mercury, in and ft of water. 1 lb per sq in = 2.0359 in mercury at 32° F = 27.71 in or 2.309 ft water at 62°. Lb per sq in is used for all ranges of press, except vacuum and press to 10–15 lb above atmos, which are expressed in inches of mercury. Furnace draft, press in ventilating ducts, and other small pressures, are expressed in inches of water. For hydraulic work, ft of water are used almost exclusively.

Pressure gages of the Bourdon tube type, with scales ranging from 30 in vacuum (15 lb press) to several thousand lb, are of indicating or recording form. Gages should be CALIBRATED before and after use. The most reliable gage tester is the "dead-weight" tester. Measurements by mercury manometer, of either U-tube or cistern form, are standard if the mercury be pure. Density of mercury is altered by dissolving tin in it; evidence of such adulteration is found by subjecting mercury and water columns to the same press, and comparing the ratio with that for the pure liquids. Pure water should be used in water manometers, but ordinary impurities in fresh water will not materially affect readings. For measuring very small press at temp below 32°, other liquids may be used. Such readings should be transposed into inches of water, by direct comparison with a water manometer, or by measuring the sp gr of the liquid by a hydrometer. Very small press may be measured by a water manometer with tube inclined at a considerable angle to the perpendicular, thus causing large longit travel of the surface of the liquid for small change in elev.

Temperature measurements are made by the Fah scale by engineers, though chemists use the Cent scale. 1° F = $^5/_9$° C. Temp in °F = temp in °C × $^9/_5$ + 32. (For conversion table, see Sec 37.) The mercury thermometer, generally used for measuring temp, has a range of scale from −40° to 1 000° F. Indicating and recording instruments are also made, in which the actuating portion is a bulb filled with liquid or gas, connected by a flexible tube to a Bourdon tube which moves the recording pen. Elec pyrometers, indicating or recording, are of the thermo-couple or resistance type, for all ranges of temp to 3 000° F. Optical and radiation PYROMETERS are for measuring temp from 1 000° F up. High temp is sometimes gaged by the fusing of materials having well-defined melting points. The temp of a gas flowing through a flue may vary considerably in different parts of the cross-sec, and the true aver is hard to determine. Also, the instrument must not be exposed to radiation from some object at a temp higher than that of the gas. Failure to shield the instrument from such radiation may cause very large errors. As gases are transparent they will not radiate heat, and, if optical or radiation pyrometers are used, a solid object must be placed in the gases at the point where temp is to be measured and upon which the instrument is sighted. Such an object should be dark colored; all optical or radiation pyrometers are calibrated for a black object.

17. MEASUREMENT OF WEIGHT, DIMENSIONS, SPEED AND POWER

Measurement of wt is made by lever or spring balance. Spring balances are often more convenient, but their length of scale is limited and percentage error relatively high. After long use their accuracy is more questionable than that of lever balances. Wt may be determined indirectly by measuring the vol of an object when its sp gr is known.

Length, area, and volume. Small irregular areas on drawings may be measured directly by a planimeter. Irregular volumes may be determined by weighing in air and immersed in water; from which volume is computed. Differences in altitude may be determined by measuring the difference in press in a water pipe running from one point to the other. The water must not be flowing when measurement is made.

Speed. Many types of stroke or revolution counters are used. Some are attached to the machine; others for hand use. They are the most reliable for general service, when the speed varies. TACHOMETERS indicate or record directly rev per min. They operate by the centrifugal force of solids or liquids, voltage of an elec generator, or synchronous vibration. They should be calibrated before use in important work, and their readings checked by a revolution counter. They are unsatisfactory for variable speeds, because averages must be estimated. Chronographs make a graphical record of each rev, with simultaneous time record.

Power measurements. Standard unit in the U S is the hp = 33 000 ft lb per min = 0.7457 kw. Power developed in cyls of engines, pumps, or compressors is indicated horsepower (ihp). It is measured by an engine INDICATOR, a special form of press gage which records on a piece of paper wrapped on a drum, caused to follow the motion of the piston. In nearly all indicators the press-recording mechanism is driven by a spring-opposed piston, the cyl of which is connected with the engine cyl. Springs have a wide range of strength, and the scale marked on the spring indicates that the recording pencil will rise 1 in for that unit press. Mean effective cyl press (mep) is the aver height of the recorded diagram, inches, multiplied by scale of spring used. The indicator drum, usually 1.5–2 in diam, is driven from the engine crosshead, with the necessary reducing motion. The indicator is connected to the cyl through a special cock, which has a standard 0.5-in pipe thread on one end, the other end being special for each make of indicator. Indicators are often used for recording rapidly fluctuating press in pipes, the drum being designed so that a continuous roll of paper is passed over it.

Power output of machines is measured by absorption or transmission dynamometers. The absorption dynamometer or PRONY BRAKE is easily made in any shop, the details of its design being governed by the work to be done. Fig 59 shows a Prony brake made of wood blocks held together by steel bands. The arms are of pipe or bar iron. Friction,

is adjusted by the handwheel. Bhp = $2\pi L \times$ rev per min $\times W + 33\,000$, where W = lb wt registered on the scale, less the unbalanced wt of the brake and its support, and L = length of brake arm, ft.

Prony brakes are seldom used to absorb more than 50 or 75 hp, the limitation lying in the difficulty in removing the heat generated; this may be met by water-cooling the brake, but best by using a brake pulley with an internally-flanged rim, which when running will hold a body of water in contact with the pulley rim. Another absorption dynamometer is the ALDEN BRAKE, made with a rotating steel disk surrounded by a casing. Within the casing are copper plates, pressed against the disk by water press. Power is determined by measuring the torque of the casing, the heat generated being carried off by the water.

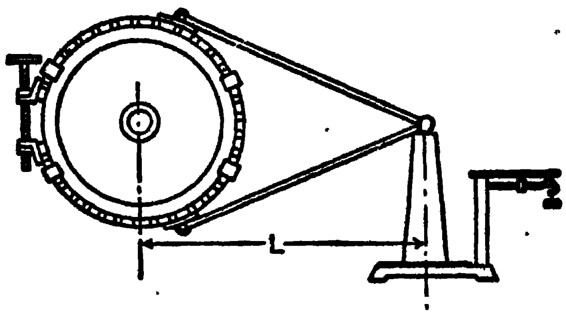

Fig 59. Diagram of Prony Brake

A number of HYDRAULIC BRAKES are on the principle of a centrifugal pump, with vanes on both casing and motor. Power is absorbed by the eddy-current friction, and measured by the torque of the casing. These brakes have been made to absorb over 5 000 hp. At low speeds their capac is low, but increases about as the cube of the speed.

An elec generator may be used for measuring power, if its effic is known. ELECTRIC BRAKES are on this principle, with the generator stator hung on ball bearings, so that the torque can be measured. By running them as motors they will accurately measure power input to a machine.

18. MEASUREMENT OF FLOW OF WATER AND STEAM

Measurement of water or other liquids. The most accurate mode of weighing liquids is in tanks on scales. When measured volumetrically, by change of level in a calibrated tank, the area of the water surface should be as small as possible at the points where depth measurements are taken, so that a small error in depth will not make a large error in vol. Flowing water is measured by weirs, Venturi meters, pitot tubes, orifices, and nozzles. Piston and disk meters, also used for small and intermittent flows, should be set up for easy calibration. Disk meters will not handle hot water.

Measurement of steam flow should be made in the form of water, either before it is fed to the boiler or after it leaves a condenser. STEAM METERS operate on the pitot tube, Venturi meter, orifice, or float principle. Chief source of error is in the recording or indicating device, which, for accuracy, should correct for press and moisture content or superheat. A steam meter is calibrated by placing it in a steam line from a boiler, the feed water being weighed, or in the line to an engine exhausting to a condenser.

Measurement of gas flow is more difficult than that of steam, as the meters are not so easily calibrated. Small quantities of gas can be measured in gasometers or gas holders, and wet or dry gas meters give fair accuracy for small flow. But, large quantities of gas must be measured by a RATE-FLOW METER. Pitot tubes, Venturi meters, orifices of various forms, and anemometers, are used. The standard meter for measuring gas is the Thomas elec gas meter, in which the gas is heated by an elec resistance coil and amount of current measured. The wt of gas flowing can then be computed from the rise in gas temp and the specific heat of the gas. The apparatus is expensive, and is generally used for calibrating the simpler and less costly forms of meters.

Steam calorimeters. For most work a throttling calorimeter is best. It consists of a thoroughly lagged metal chamber (often made of pipe fittings), with a thermometer cup at the top and an opening to the atmos at bottom. It is connected close to the steam line and steam flows into it through a small orifice. Total heat in the steam is computed from amount of superheat indicated by the calorimeter thermometer. As the principle of operation depends upon the difference in total heat, the range of this instrument is limited, about 4% moisture being the max at 100 lb steam press and 5.5% at 200 lb press. For very wet steam a separating, or combination separating and throttling calorimeter should be used. The chief source of error in steam calorimetry lies in the difficulty of obtaining a truly representative sample of steam; hence care should be taken in placing the sampling nipple.

Fuel calorimeters comprise those which operate continuously and those operating on single charges. Continuous calorimeter is used for gas and light fuel oils. The common form resembles a small fire-tube boiler, set vertically, with an internal fire box. The fuel burner is placed within the fire box, air for combustion being drawn in at the bottom. Water circulates around the tubes, and the heating surface is sufficient to allow gases of combustion to be cooled to atmos temp. The relative quantities of water and fuel are so adjusted that the rise of water temp is 20–30° F. The btu per lb or cu ft of fuel are computed from measurements of amount of fuel burned, wt of water heated, and the rise in water temp. The discontinuous type of calorimeter (bomb calorimeter),

is for solid fuels and heavy oils. A weighed amount of fuel is placed in a heavy chamber or bomb, together with O gas under press, or a chemical containing O to support combustion. The bomb is placed in a fixed wt of water, in an insulated chamber, and the charge fired by an elec spark. The rise of water temp measures the heat units set free.

19. CONTRACTS

When contracts for power machinery contain a clause guaranteeing the performance, the wording should be such that its meaning can not be mistaken, and that the operating conditions are clearly specified under which the performance is to be made. Unless otherwise agreed upon, the acceptance test is run by the engineers of the purchaser. The contractor is allowed to have a representative present, who shall have access to all readings, though without right to interfere in the running of the test; but he may see that the machine is properly adjusted before the test is begun, and in case of boiler tests he is generally permitted to direct the firing, but not to furnish the firemen. The engineer in charge is responsible for maintaining the operating conditions for which the guarantee is made. When there may be difficulty in maintaining such conditions, some agreement should be reached by the contracting parties as to allowances made in fulfillment of the guarantee on account of such variations of conditions. When it is necessary to make measurements by other than generally accepted methods, a mutual agreement on the matter should be reached before the test begins. All readings should be entered upon the official log sheet, which should be retained in its original form, because, in case a lawsuit develops upon the results of the test, that sheet alone has a legal standing in court as evidence.

MECHANICAL ENGINEERING MISCELLANY

BY

H. L. PARR

PROFESSOR OF MECHANICAL ENGINEERING, COLUMBIA UNIVERSITY

MECHANICAL ENGINEERING MISCELLANY

1. GEARING

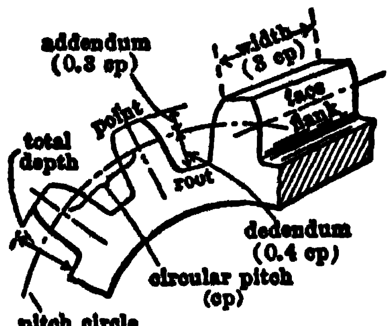

Fig 1. Involute Gear Teeth

Characteristics. The term as here used means tooth gearing; friction gearing and other special forms will not be considered. According to the shape of tooth, gears are divided into involute and epicycloidal; former has many advantages, and the latter is little used. PITCH CIRCLE (Fig 1) is the base to which all gear calculations are referred. The pitch circle diams of 2 intermeshing gears are equal to the diams of 2 equivalent cylinders, rolling in contact without slipping. CIRCULAR PITCH is the distance measured on pitch circle from center to center of teeth; hence cir pitch $= \frac{\text{pitch circumference}}{\text{no of teeth}} = \frac{\pi d}{N}$, where d = diam of pitch circle and N = number of teeth in the gear. Circular pitch is not convenient for determining number of teeth or pitch diam; hence, the DIAMETRAL PITCH is used, which is the number of teeth per in of diam, and is either a whole number or a simple fraction. Then, no of teeth = pitch diam × diametral pitch, and cir pitch $= \frac{\pi d}{N} = \frac{\pi d}{d \times \text{diametral pitch}} = \frac{\pi}{\text{diametral pitch}}$ In this way gear proportions are readily calculated. Thus, for a 2 diametral pitch, if the wheel has 20 teeth the pitch diam is 10 in; or, if a wheel has 60 teeth and the pitch diam is 20 in, the diametral pitch is 3, and the circular pitch is $3.1416 \div 3 = 1.05$.

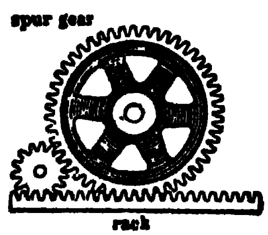

Fig 2. Spur Gears and Rack

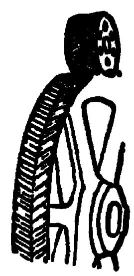

Fig 3. Herringbone Gears

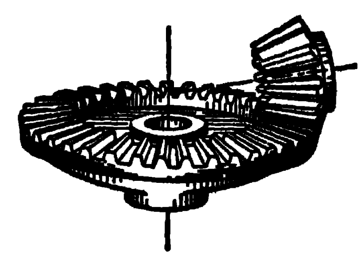

Fig 4. Bevel Gears

Spur gears are gears in one plane, with their axes parallel. If the radius of pitch circle is infinite, the circle becomes a straight line, resulting in the RACK. Spur gears having the same pitch are interchangeable (Fig 2). HERRINGBONE GEARS are used when end thrust on shafting is to be avoided. Their teeth are cut at an angle with the axis (Fig 3).

Bevel gears are those of which the axes are in one plane and intersect; they are called miter gears if both are of the same diam. Bevel gears are not interchangeable for the same pitch, but must be made in pairs (Fig 4).

Worm and worm-wheel gears are gears with axes at right angles and in parallel planes (Fig 5). They must be made in sets.

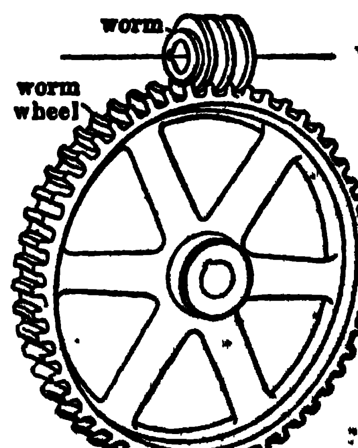

Fig 5. Worm and Worm-wheel

Construction. Metal gears are usually of C I or steel; brass, white metal, raw-hide, paper, and cloth, are used for special cases. Teeth cut in the solid rim give the most perfect form of tooth,

and are known as CUT GEARS. If cast in a sand mould the tooth outline is less accurate than in the cut gear; in operation they are noisy, noise increasing with speed. Small gears are cast in steel moulds under pressure, known as diecasting. They are accurate in form, but can be made only of soft metal and commercially must be duplicated in large quantities because of the expensive dies. Gearing is also made of the inserted tooth type. The teeth, of maple wood, are inserted in a C-I rim; one wheel of a pair has wooden teeth, the other, ordinary metal teeth (Fig 6). Advantages: they run quietly and in case of accident the wooden teeth, which are the ones to be damaged, are readily replaced. Wooden teeth are made in coarse pitches only. They are wider on the pitch circle than iron teeth, in the proportion of 0.6 circular pitch for the wooden to 0.4 circular pitch for the iron, making strength and wear more uniform. Gears of large sizes are made in halves or sections, bolted together, and can therefore be placed anywhere on a shaft, not necessarily at the end.

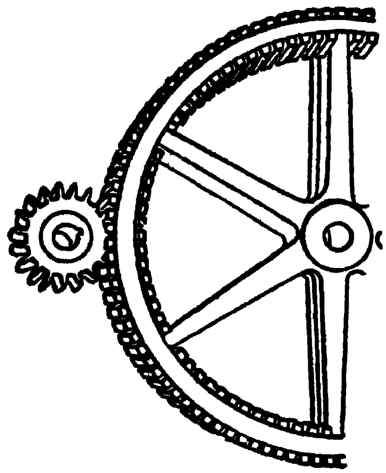

Fig 6. Wooden-tooth Gear

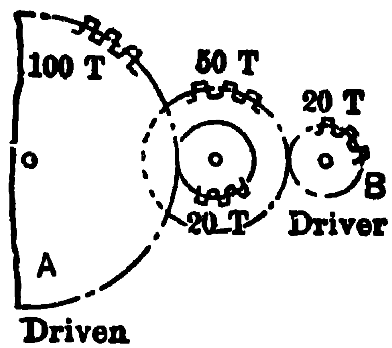

Fig 7. Compound Gear Train

Spur-gear ratios for single reduction of speed seldom exceed 6 : 1; in some special cases as high as 10 : 1. When greater reduction is required, gear trains may be used; in that shown in Fig 7 the driver has 20 teeth and meshes with a 50-tooth wheel, giving a 2.5 : 1 reduction; attached to the same shaft as the 50-tooth wheel is a 20-tooth wheel, forming a COMPOUND GEAR. The latter wheel meshes with a 100-tooth wheel, giving a 5 : 1 reduction, or a total of $2.5 \times 5 = 12.5 : 1$.

A handy rule for calculating gear ratios in compound trains is $\frac{\text{Product of the drivers}}{\text{Product of the driven}} =$ gear ratio; in which diameters, numbers of teeth, or rev per min may be used. Where single reductions of 3 or 4 : 1 are made, the teeth on small gears wear much faster than those on the large. To equalize wear, the smaller or pinion gear is made of harder metal, as steel, while the larger is of C I. When the number of teeth are exact multiples, any tooth on the pinion will always mesh with the same tooth on the large wheel, and, in case there were opposed hard and soft spots in the teeth, wear would be rapid. But, where exact gear ratios are unnecessary, as for triplex pumps, the larger gear has an extra tooth called a HUNTING TOOTH; thus, if the pinion has 20 teeth and the large wheel 101 teeth, every tooth on the pinion will come in contact with every tooth on the large gear, thus distributing the wear more evenly over both wheels.

Fig 8

Strength of gear teeth. Weakest part of a tooth is at the root in the smallest wheel (a, Fig 8), the root being bounded by the radial lines, as shown. Formulas for strength of teeth are constructed upon this basis, the smallest number of teeth being 12. Stub tooth gears have overcome this objection and even 5-tooth pinions can be cut. The root width a and the strength increase with the number of teeth. Width of face for good contact is generally assumed to be 3 times the circular pitch (sometimes exceeded). Spur and bevel gears are obtainable of almost any size, stock sizes having pitches from 0.5 to 46 diametral pitch. Selection of proper pitch depends upon size of gear and power transmitted; in general, the larger the gear the greater the power transmitted and the coarser the pitch. WORM-GEAR REDUCTIONS are much greater than for other types of gearing. If the worm is a single thread, for each revolution of worm the worm-wheel moves 1 tooth; for a double, triple, or quadruple thread, the wheel advances 2, 3, or 4 teeth. The wheel should have at least 25 teeth, and as the diams of worm and worm-wheel have no influence on the gear ratio, the correct proportions must be carefully worked out for efficient operation. In makers'

catalogues, ratios of 15 : 1 for quadruple threads, or 129 : 1 for single thread, are quoted. In all gearing the ratios are positive; there is no slipping as with belting.

2. BELTING

Principles of pulley and belt transmission. Since slippage always occurs, exact speed ratios can not be obtained. Resistance to slippage depends upon the coeff of friction, area of surface in contact, and pressure on pulley face due to belt pull. The effective pull is equal to the difference between the tensions on the tight and slack sides of the belt. The angle over which contact takes place is the angle of wrap. Coeff of friction depends upon the materials in contact and the condition of the two surfaces. For ordinary iron or wooden pulleys and leather belting, the coeff is 0.3 to 0.4 aver for dry surfaces, and say 0.15 to 0.2 for wet or oily surfaces.

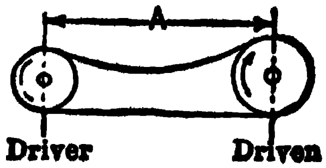

Fig 9. Favorable Belt Drive

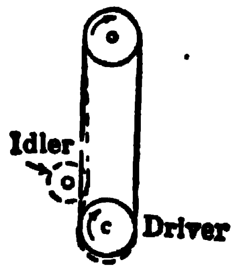

Fig 10. Unfavorable Belt Drive

For efficient operation the friction coeff must be as large as possible. It is evident that the best drive is that shown in Fig 9, that is, with the tight side below, since any stretch in the belt increases the angle of wrap, one of the power factors. The worst condition is shown in Fig 10. The lower pulley being the driver, any stretch in the belt causes slipping and excessive wear. In practice this form of drive requires an idler pulley to maintain proper tension.

Power transmitted by a belt depends first upon the difference in tension between tight and slack sides, and second upon the belt speed. With surfaces in good condition, and 180° angle of wrap, the ratio of tension on tight side (T_n) to tension on slack side (T_0) averages about 2.5, that is, $T_n \div T_0 = 2.5$. This ratio varies from 2 in small sizes to 3 in large, the pulley diams being equal or nearly so. To solve this formula either T_n or T_0 must be known. T_n is obtained by finding the breaking strength of a piece of belting, from which is determined the safe working stress. Since belting varies in thickness, the tension per in of width is generally given, rather than tension per sq in of cross sec.

Belt speed. Increase in speed, other conditions unchanged, increases power delivered, up to a certain limit. But, as the belt travels over the pulley, centrifugal force throws it away from the pulley face and partly neutralizes the driving force. The limit is reached at a speed of about 5 000 ft per min; any further increase of speed decreases the power transmitted. Hp = [pull of belt (lb) × veloc (ft per min)] ÷ 33 000. In practice, 3 000 to 4 500 ft per min are aver speeds. Velocity must sometimes be sacrificed, due to the large diam of pulleys required for given rev per min of shafting, and the belt width is increased to transmit the required hp. Belting is usually of leather, or several plies of canvas covered with rubber and pressed together. Woven belts, or thin steel bands, are also used.

Leather belts are of single, double, or triple thickness. Makers' catalogues give tables of the hp transmitted by different kinds of belting at given speeds, the figures being based upon an arc of contact of 180°, and an aver working tension per in of width found satisfactory in practice, viz: 40 lb for single, 70 lb for double, and 100 lb for triple thickness. Thus, if a belt running at 3 000 ft per min is required to deliver 60 hp, the total pull would be $P = 33\,000 \times 60 \div 3\,000 = 660$ lb. For a double belt a pull of 70 lb per in of width is allowable, giving $660 \div 70 = 9.5$, or say a 10-in belt. It is good practice to design a belt drive capable of transmitting 25% excess power for small sizes and 5% excess for large drives. One maker recommends the following rule, which includes reserve power: for single-thickness leather belt, the hp per in of width = belt speed in ft per min ÷ 800; for double thickness, divide the speed by 500.

Leather belting should be cleaned and dressed with a reliable compound to keep it soft and pliable, and be systematically inspected. Belts exposed to dampness or acid fumes require special treatment in manufacture. If a belt is stretched to its limit to transmit a given hp, its life is short. Since tension produces a heavy pull on shafting and bearings, causing friction and wear, it should be a minimum for the work to be done. Low tension gives long life and increased first cost; high tension, a short life and lower first cost, but with more stoppages for belt repairs. Shafts can be driven at almost any angle, if provided with idler or guide pulleys. DISTANCE BETWEEN SHAFT CENTERS: if ample, the weight of belt on slack side produces the necessary tension, and stretch increases

angle of contact; if short, the belt must be stretched for necessary tension. Slippage, which will occur after a short time, due to increased stretch, can be overcome by an adjustable idler pulley on slack side, close to the driving pulley, so as to increase arc of contact. Short-center drives, capable of heavy power transmission, are now built with special type of idlers. If the distance between pulley centers is excessive, the tight side will sag, decreasing the angle of contact, and the belt is liable to flap, causing the faces to rub on each other. To get proper tension when putting on new belting some makers recommend cutting out 2 in of belt for every 10 ft of tape line measurement. For running shafts in opposite directions, crossed belts (Fig 11) are used, but should be avoided if possible, because the belt rubs at point of crossing. For other types of belt drive, the makers should be consulted. Leather belting can be had from 0.5 in to 72 in wide; widths from 0.5 to 1 in vary by 1/8 in, from 1 to 4 in by 0.25 in, 4 to 7 in by 0.5 in, 7 to 26 in by 1 in, 26 to 40 in by 2 in, and above 26 in by 4 in.

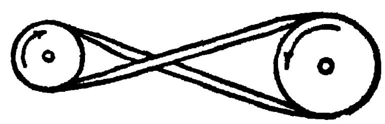

Fig 11. Crossed Belt

The figures in Table 1 are based on first-class short-lap belting, made from backs of pure oak-bark tanned leather, run under ordinary conditions and on pulleys of medium and equal size. When the driven pulley is smaller, the power transmitted will be as much less than the tabulated values as that part of the surface of the driven pulley which is covered by the belt is less than half its surface.

Rubber belts consist of several plies of canvas covered with rubber. They can be used in damp or wet places, or in drives exposed to the atmosphere or to acid fumes.

Table 1. Hp Transmitted by Leather Belts, American Leather Belting Association (1939)

Horse power per inch of width

Belt speed, ft per min	Single ply		Double ply			Triple ply	
	11/64″	13/64″	18/64″	20/64″	23/64″	30/64″	34/64″
	Medium	Heavy	Light	Medium	Heavy	Medium	Heavy
600	1.1	1.2	1.5	1.8	2.2	2.5	2.8
800	1.4	1.7	2.0	2.4	2.9	3.3	3.6
1 000	1.8	2.1	2.6	3.1	3.6	4.1	4.5
1 200	2.1	2.5	3.1	3.7	4.3	4.9	5.4

Minimum pulley diam. — Belts under 8″ wide	3″	5″	6″	8″	12″	20″	24″
Minimum pulley diam. — Belts 8″ and over wide	5″	7″	8″	10″	14″	24″	30″
	These are the minimum allowable pulleys for the above thickness belts						

For belt speeds over 6 000 ft per min consult a leather belting manufacturer

Quality of rubber determines grade of the belt, new rubber being better than reclaimed product. Strength depends upon the wt of canvas used, which is given in oz per sq yd of canvas duck. Rubber belting is cheaper than leather. Makers advocate a difference of tension of 60 lb per in of width for 4-ply belts, made of new rubber, with minimum pulley diam of 24 in. Smaller pulleys can be used, but the life of belt will be shortened, due to bending over the pulleys, the outside layers being stretched, while the inner are compressed, thus causing working of the layers on one another. On this basis makers give the following figures, 3 or 4-ply rubber belts being rated as the equivalent of single-thickness leather, and 5 or 6-ply the equivalent of a double leather belt transmitting about 50% more power than a single. The arc of contact is taken as 180°.

4-ply	rubber	belt,	60-lb	tension per	in of width,	min diam	of pulley,	24 in
5 "	"	"	80 "	"	"	"	"	30 "
6 "	"	"	100 "	"	"	"	"	36 "
7 "	"	"	120 "	"	"	"	"	42 "
8 "	"	"	140 "	"	"	"	"	48 "

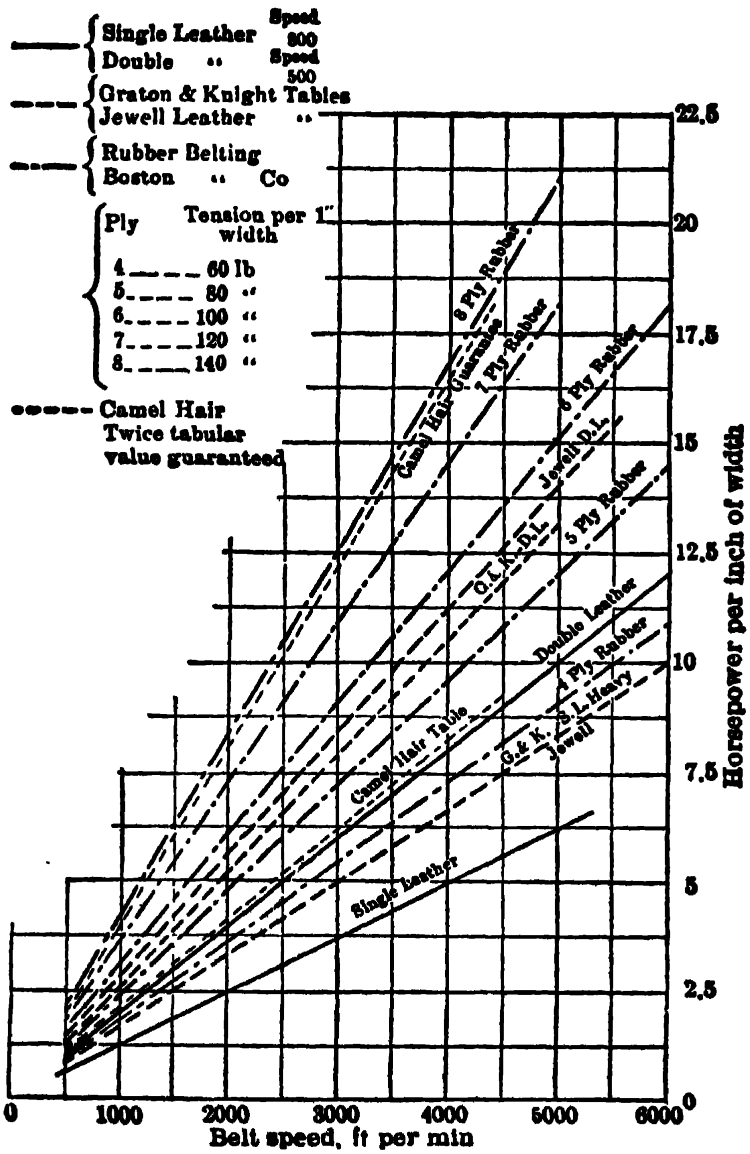

Fig 12. Belt Speeds and Horsepower

Some engineers estimate the aver value for tension at 20 lb per in of width per ply of canvas, which is higher than the values given above. In laying out belt drives, ample clearance must be given between machine frame and the walls of wooden buildings; the belt rubbing against a timber may produce enough heat to cause a fire, besides destroying the belt. If the outside rubber coating is damaged, moisture or fumes will penetrate the

canvas and destroy the belt. Application of resinous substances to pulley faces to increase adhesion also destroys belting by tearing the rubber. Power transmitted (Fig 12), based upon previous formula for 180° arc of contact, is $hp = P \times V \div 33\,000$; if the arc is 240°, allow 150%; if 120°, allow 60%; if 90°, allow 30%. An allowance of 1/8 to 0.25 in per ft of tape line measurement for stretch in rubber belts is recommended by makers. CANVAS BELTS are made by sewing plies of canvas together; woven belts by a weaving process as for cloth, animal fiber being used in some cases. In using this class of belting the tension must be the same over the entire width, otherwise the belt will not run true. CAMELS-HAIR BELTING is guaranteed to transmit twice the power of a leather belt, based upon the increased coeff of friction and strength of belt.

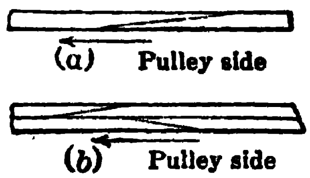

Fig 13. Scarf Joints, Leather Belt

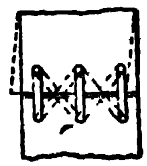

Fig 14. Belt Lacing

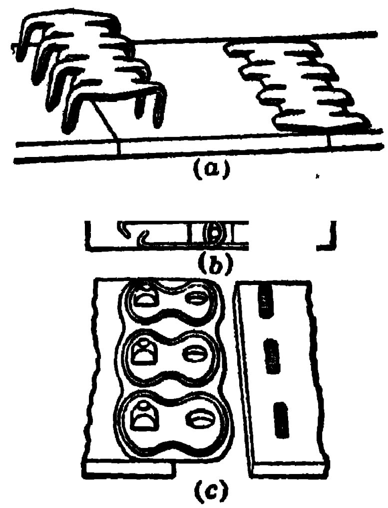

Fig 15. Metal Belt Fasteners

Belt fastenings. For leather belting, joints are made by scarfing and gluing the ends together, making an endless belt. Some machines are designed to be shifted on their frames to take up slack, but when the limit is reached the belt joint must be made over. For single leather belts the joint should be as in Fig 13 *a*; for double belts, as in Fig 13 *b*. Rubber belting can be similarly spliced. After the surfaces are covered with a rubber cement and allowed to dry they are stitched together with narrow rawhide lace. LACING should have uniform tension; it is straight on pulley side but crosses on the back; for narrow belts, the holes are in one line; for wider, they may be staggered. In lacing a belt the 2 ends must meet square and in line; if offset, as shown by dotted lines, Fig 14, the edges will be damaged. Metal fasteners are good and are made in many designs. For canvas and woven belts, the maker generally recommends some special type, best adapted to his own belting. In the fastener shown in Fig 15 *b* the wire is inserted by a special machine, the ends being held together by a rawhide pin. It is a hinge joint and can be readily taken apart and replaced.

3. PULLEYS

Pulleys for belt drives are of C I, wood, fiber, or pressed steel. C-I pulleys are solid, or in halves bolted together. A solid pulley must be installed by slipping it over the end of the shaft; split pulleys can be set anywhere on the shaft by bolting them in place.

Principal dimensions for ordering pulleys are bore, diam, width of face, and size of keyway (Fig 16). The face may be crowned or flat (Fig 17). With a CROWNED PULLEY, if the tension is not equal on both sides of belt, or the shafting is slightly out of line, the belt will seek the highest veloc, which is at the middle of the face, and is thus made to run true. Crowning is generally about 1/8 in per ft of width; if excessive, it damages the belt by overstretching it in the center. Flanges on the pulley face to keep the belt from running off should be avoided, as they wear the edges of the belt. If the belt becomes slack it may ride up on the flange and tear. Untrue running of belts is caused by unequal tension or poor alinement of shafting. Machinery that must be started and stopped frequently is sometimes fitted with crowned TIGHT AND LOOSE PULLEYS, the belt being shifted from one to the other to start or stop the machine. The driving pulley has a flat face, and a width equal to the combined widths of the 2 driven pulleys. BELT SHIFTER should be placed on the side where the belt leads on to the pulley. Very wide C-I pulleys may have double spokes or arms (Fig 18). C-I pulleys are heavier than other types. They vary from 3-in diam and 2-in face to 120-in diam by 60-in face. (For details, see

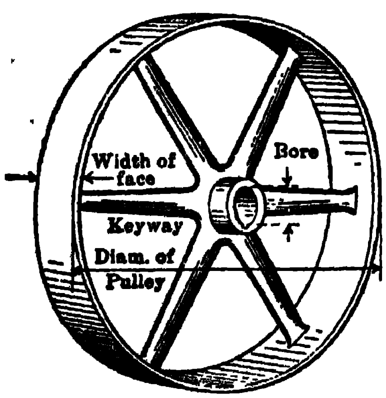

Fig 16. Cast-iron Pulley

Fig 17. Flat and Crowned Pulleys

catalogues.) Solid C-I pulleys for single-thickness belt are the cheapest. Split C-I pulleys cost about 50% more for small sizes, to about 20% more on medium sizes. C I (with the foundry scale attached) withstands action of acid fumes or dampness better than steel or wood. PRESSED STEEL PULLEYS (Fig 19) are made in halves, with double sets of arms when necessary. Sizes vary from 6-in diam by 2-in face to 120-in diam by 36-in

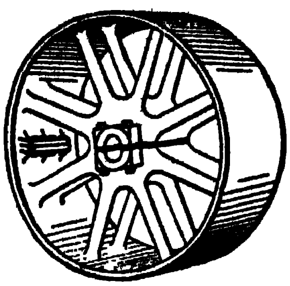

Fig 18. Double-arm Pulley

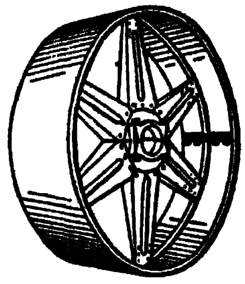

Fig 19. Pressed-steel Pulley

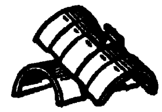

Fig 20. Pulley Bushings

face, prices averaging about the same as C-I split pulleys for single belts. Fig 20 shows a set of bushings which adapts this type of pulley to several sizes of shaft. WOODEN PULLEYS are made by gluing together strips of wood so arranged as to avoid warping. They should not be used in damp places. They are light in wt, and have the same advantages as the pressed-steel pulley. Sizes are from 3-in diam by 3-in face to 120-in diam by

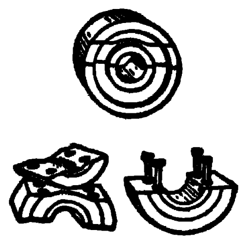

Fig 21. Small Wooden Pulley

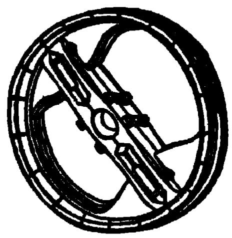

Fig 22. Large Wooden Pulley

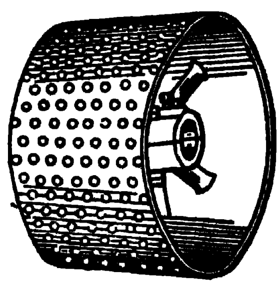

Fig 23. Pulley with Inserts for High Coeff of Friction

24-in face (Fig 21, 22). Prices of wooden pulleys for double belts aver slightly less than solid C-I pulleys. Catalogues give information as to special types and sizes. If the coeff of friction can be increased, the tension on tight side can also be increased, and more power transmitted; hence, the pulley face is sometimes covered with leather, canvas, or cork inserts (Fig 23), increasing the power transmitted for the same drive.

4. SHAFTING, HANGERS, AND BEARINGS

Shafting is of steel, turned and ground, or cold-rolled. The latter has a hard surface, which, if damaged by the cutting of a keyway, may warp the shaft. Shafting is carried in stock in sizes from $^3/_{16}$ to 1.5-in diam, in lengths from 1 to 24 ft, and from $1\,^9/_{16}$ to 7 in diam, in lengths from 5 to 24 ft. Diam always increases by $^1/_{16}$ in. Where longer shafts are required, stock lengths are joined by couplings.

Hangers and bearings. Shafting is carried in bearings mounted in adjustable hangers attached to the ceiling, walls, floor, or posts of a building. Special fittings are required for steel-frame buildings. Hangers are of C I or pressed steel. Fig 24 is a ceiling hanger, which can be reversed and made a floor stand. In Fig 25 the bolts *c* pass through slotted holes to permit adjustment; the bearing can be raised or lowered by screws *d*, which support it. The bearing in Fig 26 has a spherical seat

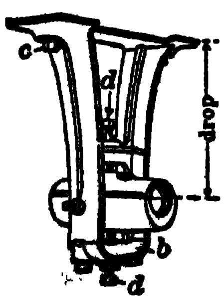

Fig 24. Ceiling Hanger

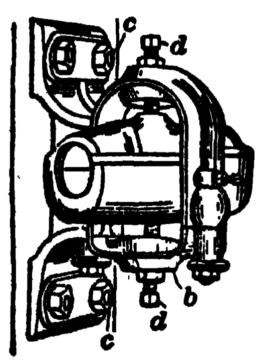

Fig 25. Adjustable Post Hanger

at *a*, for alining in any direction about its center. The lower cap *b* (Fig 25) can be removed, the box taken out, or shafting removed, without interfering with the hanger; shafting can be assembled on the floor, hoisted into position in the hangers, and bearings and caps readily put on; convenient for heavy work. Boxes should be ring-oiled and dustproof, to minimize attendance. The points for ordering hangers are: style of hanger, drop or distance from center of shaft to the base (Fig 24), and diam of shaft. When in places difficult of access, shafting and bearings are apt to be neglected. When hangers are attached to ceiling beams, the spacing of these determines the distance between bearings; 8 to 10 ft is considered good spacing; if greater, heavier shafting should be used to prevent bending. Length of bearings is given in terms of diam of shaft; for diam less than 2 $^3/_8$ in bearings are 5 diam long; for heavier shafting, 4 diam long. Shafting is subjected to torsion, due to the power transmitted, and to bending, due to wt of the pulleys, its own wt, and the wt and tension of the belts. All pulleys should be as close to the hangers as possible, and heavy drives placed near the point where the power is received. For good service, shafting should be carefully alined, with a small end play (say $^1/_8$ in), and with collars to prevent any excess end motion. Where the power is received, collars should be placed on both sides of one hanger, leaving the ends of the shaft free to expand and contract with temp changes. Motors driving shafting in dusty places can be enclosed, and a slight increase of air press above atmos maintained on the inside, to prevent entrance of dust. Bearing pressures are determined per sq in of projected area (diam × length of bearing). The aver allowable press, varying with load conditions, speed, lubricant, and method of lubrication, is about 60 lb per sq in of projected area.

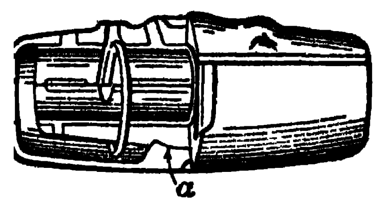

Fig 26. Hanger with Spherical Seat

5. ROPE DRIVES

Hemp or cotton-rope drives are of two kinds: continuous or American, and multiple or British. American system. The rope is wound around the pulleys as many times as the power to be transmitted requires; it then passes over a tension carriage (see below), which keeps the rope at constant tension and returns the last wrap to the first groove of driving sheave. This drive has only one splice, which is the weakest part of the rope. Breakage of the rope causes a complete shut down, usually avoidable by careful inspection. This system is best for vertical or angular drives, and can be used for heavy powers with short center distance. British system has separate ropes for each loop, and hence has as many splices as ropes. Maintenance of constant tension in all the ropes is difficult but important. If 1 or 2 should fail the others will transmit the power until repairs are made. Low tension lengthens life of the drive, which should average 8 to 10 years.

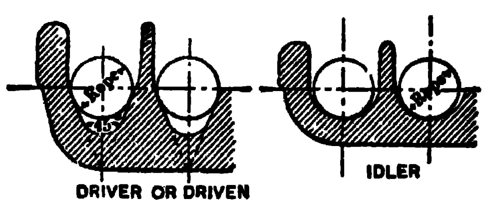

Fig. 27. Sheave Grooves, British Rope Drive

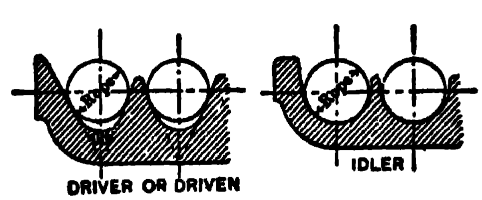

Fig 28. Sheave Grooves, American Rope Drive

Sheaves and rope. Fig 27 shows shape of grooves for main sheaves and idler, of the English system; Fig 28, for the American system. Grooves must be accurately machined, with surfaces free from imperfections; sand holes cause rapid wear on ropes. Being necessarily heavy, the sheaves act as fly-wheels for variable loads, and should be well balanced. Minimum sheave diam is 36 times rope diam; 40 times is better. Rope must not touch bottom of grooves of driver or driven sheaves, otherwise no wedging action occurs. Some makers design the groove to cause the rope to rotate on its axis, and so produce uniform wear.

Cotton ropes are softer than hemp, cost more, and are more used in Great Britain than in U S. Hemp transmission ropes are laid with internal lubricant to reduce wear. Manila rope has 3, 4, or 6 strands (Fig 29). Diams from 0.75 to 2 in increase by $^1/_8$ in; from 2 to 2.5 in by 0.25 in. (For strengths and wt of hemp rope, see Sec 12.) To lie properly in sheave grooves, splices must not increase the rope diam. Strength of a good splice is about 85% that of the rope.

In the American drive (Fig 30), constant tension is maintained by a TENSION CARRIAGE, to compensate variation in length, from stretch or shrinkage due to moisture. A tension carriage will take care of 3 000 to 3 500 ft of rope.

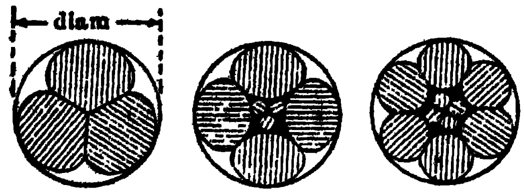

Fig 29. Drive Ropes

Power transmitted by rope drive depends upon the same elements as for belting. The friction between the ropes and sides of grooves can be increased by an increase of tension, and the difference between the 2 tensions and centrifugal force is the pull in lb. Rope speed is generally the same as for belting; but, since rope weighs less than belt, the tension can be increased at high speeds to offset effect of centrifugal force; 80 ft per sec is an aver speed.

Driving force is $P = T_n - T_0$, where T_n = tension on tight side, and T_0 is the resultant of the tension on slack side (taken as $0.5\ P$) and centrifugal force C. Hence, the power may be written, $P = T_n - (C + 0.5\ P)$, reducing to $P = {}^2/_3(T_n - C)$, and the hp $= {}^2/_3(T_n - C) \times V \div 33\ 000$, where V = rope veloc, ft per min. The expression for centrifugal force is $C = Wv^2 \div 32.16$, W being the wt of rope per ft and v the veloc, ft per sec. With fixed rope speed and min diam of sheave it is more difficult to design rope than belt drives. If the desired rev per min can not be obtained with a certain rope diam, the rope diam may have to be reduced, so as to use a smaller sheave. To transmit the same power, this requires more ropes, increasing wear and maintenance. It is good practice to use few ropes of large diam; 1.75-in rope is a good commercial size.

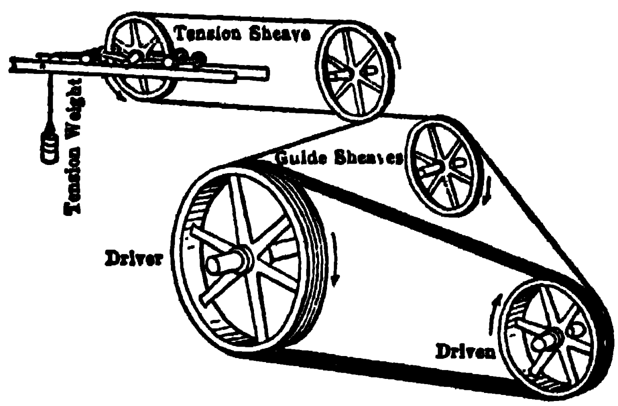

Fig 30. American Rope Drive

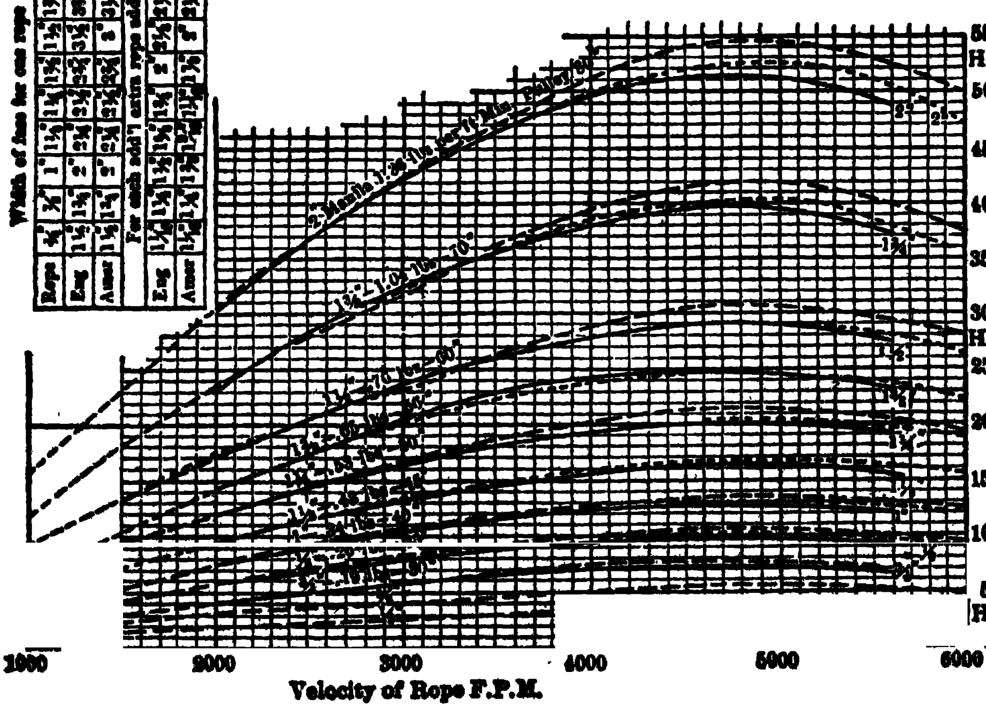

Fig 31. English (Multiple) Hemp Rope Drives (C. W. Hunt Co, broken lines; G. V. Cresson Co, dotted lines; Rice & Sergeant, full lines). L. DeG. Moss

Comparison of power drives. Gearing is used for minimum center distances; it gives a positive drive, but is noisy. Chain drives are positive, and special forms can be run at high speeds; center distances are greater than for gears, less than for belts. The elements of chain drive are given in Sec 27. Belts can be shifted from one pulley to another, can be run at high speeds or at any angle, require good alinement of shafting, are not noisy, but produce electricity, which is sometimes objectionable. Rope drives, used for max center distances, are quiet in operation, produce no electricity, do not require accurate alinement of shafting, can be run at any angle, occupy less space than belts, and are cheaper than belting for heavy power and long center distances.

Wire-rope drive (Fig 33), consisting of a single loop of wire rope around a pair of pulleys, can be used for distances of 70 to 400 ft between sheave centers. The sheave grooves are "filled," and the rope should not touch the sides of the grooves, thus requiring good alinement.

Driving power depends upon coeff of friction between rope and sheave filling (see below). (For wire ropes, see Sec 12.) 7-wire rope will stand more wear, but requires larger pulleys. Steel rope is stronger and has a longer life, but the size can not be reduced, due to the wt required; a small rope must have more tension and damages the pulley filling. Bending stresses (Sec 12) generally exceed those due to direct pull. Speed limit is 5 000 ft per min. If the rope lashes at high speed, the direct tension may be momentarily doubled, and, if the sheaves are small, the bending stresses plus the tension may strain the rope beyond the elastic limit.

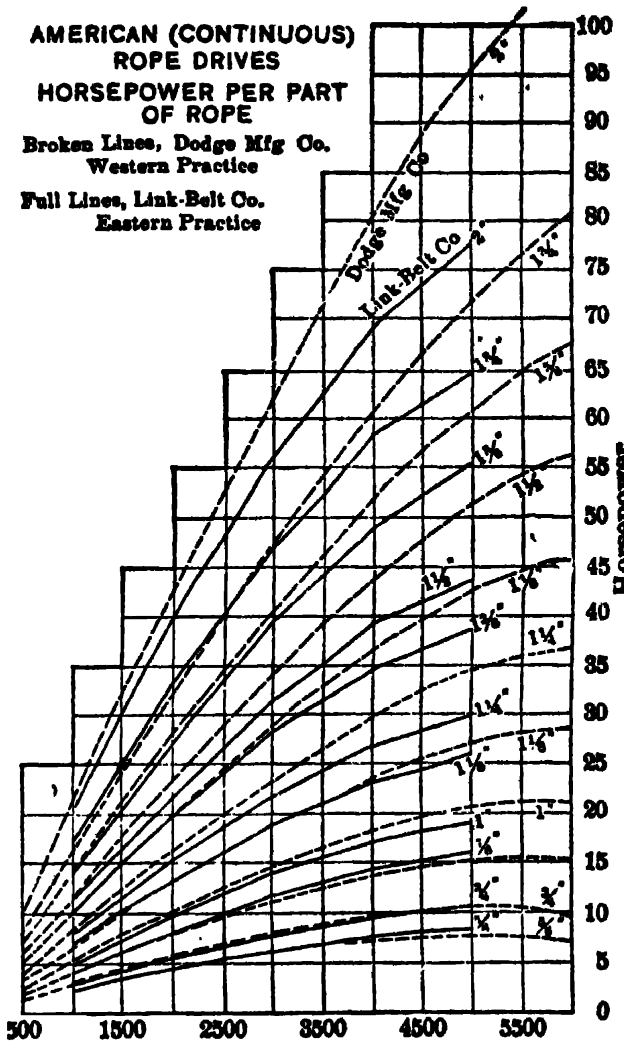

Fig 32. (L. DeG. Moss)

Sheaves should be as large as practicable, to give high rope speed and hence permit use of min diam of rope. Fig 34 shows sheave groove and filling. Filling consists of alternate blocks of leather and rubber; rubber has high coeff of friction, while the leather has resisting qualities. Hard-wood blocks are sometimes used. 5 000 ft per min rim speed is about the safe limit for C-I sheaves or for the filling. Sheaves must be accurately

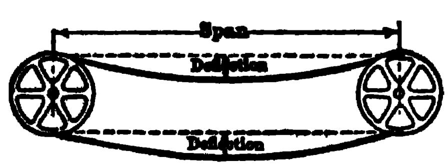

Fig 33. Wire-rope Drive

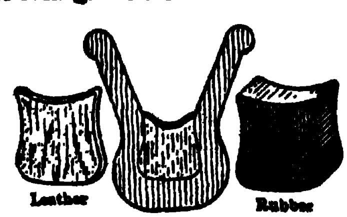

Fig 34. Filling for Wire-rope Drive Sheaves

balanced, to prevent lashing of the rope. At less than 70 ft center distance, tension becomes excessive, increasing wear on rope and filling. For spans greater than 400 ft, multiple loops may be employed. Where there are sudden variations in load, a flywheel can be attached to the sheave shaft. For changing direction of the drive, bevel or friction gears are used. The heavier the rope, the greater the tension and farther apart may the

sheaves be placed, with smaller sag or deflection. Makers advise a sag of $^1/_{36}$ the span in both ropes when idle; in operation, the sag on tight side is about 0.02 the span and on the slack side 0.04. This makes the tension ratio about 2 : 1; or difference in tensions may be computed by taking the wt of 1 rope between sheaves and multiplying by 3. The hp can then be found: hp = $T \times V \div 33\,000$, T being difference in tensions and V veloc, ft per min. No deductions are made for centrifugal force, or bending stresses, as they are negligible under usual conditions. Idler sheaves may be used to prevent the rope from striking obstructions. When on the following side, they are 0.5 the diam of the driver or driven wheel; if in the middle of a span, the tension and power transmitted will be halved. Tightener sheaves may be placed on short spans, but are not recommended. Sheaves are sometimes mounted on movable bearings, for taking up slack without resplicing. Catalogues of makers give tables of hp transmitted, center distances, diam of sheaves, and rev per min for different size ropes.

6. LUBRICANTS

Requirements. Lubricant must have sufficient BODY at the probable temp to which it will be subjected, to prevent it from being squeezed out by press between bearing surfaces; it must not decompose nor evaporate at ordinary working temp; it must contain no acid, which may injure bearing surfaces; its coeff of friction must be low; it must be as fluid as is consistent with the required body; and it must not freeze at any temp to which the bearing may be exposed.

Ordinary lubricants: animal fats, vegetable and mineral oils, flake graphite, soapstone, powdered mica.

Animal fats or oils are often used for bearings subjected to low temp, but are generally mixed with mineral oils. They decompose at moderate temp and set free acid. Vegetable oils are used where the bearing press is light and temp low. Mineral oils are obtainable to suit practically all conditions of lubrication; they do not easily decompose and contain no acid. Greases are mixtures of mineral oil and animal or vegetable soap; useful for slow-moving bearings under heavy press.

Solid lubricants, used alone, fill the pores of the bearing metal and form a film on it. They are commonly mixed with oil or grease, and generally improve lubrication. They must not be used for ball bearings, as they build up a surface on the ball race which often splits the bearing.

Testing lubricants. The value of ordinary tests is relative rather than absolute. Two oils, showing approx the same characteristics, will probably serve equally well in the same bearing. Oils are tested for the following characteristics. Special machines are used for coeff of friction tests. Other tests are for adulteration and presence of acids. VISCOSITY, or degree of fluidity, is a measure of the body of an oil. It is determined by viscosimeters. Nearly all operate on the principle of finding the time required for a given volume of oil to flow through an orifice. Their design varies greatly, and 2 different instruments may give widely different results for the same oil. Viscosity is generally expressed as specific or as relative viscosity (Table 3), which denote the relation between the times required for the same volume of oil and water to flow through the orifice. Tests are made at different temps. FLASH POINT is the temp at which an oil will give off enough vapor to ignite and flash, when a flame is held over the surface. The heating should be done slowly. Types of apparatus are the open cup and closed cup. The closed cup has an opening in the cover, closed by a slide. As the oil is heated the slide is periodically removed, and a flame inserted until the flash point is reached. During tests a thermometer is hung in the body of the oil. BURNING POINT is the temp at which an oil will give off enough vapor to ignite and continue to burn. CHILL POINT is the temp at which an oil freezes. Best determined by placing the oil in a test tube with a thermometer. The oil is then frozen by an ice and salt mixture. After freezing, the test tube is removed from the ice and the temp observed at which the oil melts. FRICTION TESTS are made by special machines, designed to reproduce working conditions, and to measure the temp of the oil and coeff of friction. The speed and press between bearing surfaces may be fixed at will. The simpler machines give only comparative results, but valuable data have been obtained from specially designed apparatus.

Table 3. Characteristics of Lubricating Oils

Kind of oil	Specific viscosity, 70° F	Specific grav, water = 1	Flash point, deg F	Burning point, deg F
Heavy engine and machine	185	0.875	400	445
Ordinary engine and machine	180	0.873	410	460
Light machine	100–150	0.870	400	440
High-grade cylinder	175–200	0.903	600	650
Ordinary cylinder	185	0.899	570	615
Gas engine	300	0.893	320	350
Automobile cylinder	195	0.877	430	485

Detection of adulterants. High-grade oil is sometimes adulterated with low-flash mineral oil, which is detected in flash-test apparatus. Presence of vegetable or animal oil in mineral oils is determined by mixing a sample with a solution of sodium or potassium hydroxide and heating to about 200° F. Animal or vegetable oils will saponify and separate from the mineral oil. Presence of mineral oils in animal or vegetable oils is determined by the same process, as the mineral oil will not saponify. Acids are detected by litmus paper.

Most of the above oils have a chill point slightly below freezing point of water. Oils may be obtained the chill point of which is considerably lower.

Selection of lubricants. For engine cylinders using high-press steam, high-grade cyl oil; for engine cylinders using steam below 100 lb press, second-grade cyl oil; for stationary gas engines, a heavy oil with high flash and burning points (it should preferably have a liquid base); for air compressors and high-speed internal combustion engines, a liquid-base oil with a relatively low viscosity and a high flash point. Engine and machine oils are sold in many grades to suit all conditions. For slow-moving bearings under heavy press, use grease. If the press is exceptionally heavy, add graphite to the grease.

7. PIPING

List sizes of welded W-I or steel pipe indicate the nominal inside diam. Actual diam varies considerably from the nominal, especially in standard wt pipe of small sizes. Outside diam of all weights is the same, so that the threads may be uniform for same nominal size. Added thickness of metal reduces the internal diam. Ordinary welded pipe is of mild steel. If iron pipe be desired, it should be specified. Tubes are listed according to their actual outside diam. Pipe is regularly supplied in random lengths, from 18 to 22 ft, threaded on both ends, and 1 coupling is furnished with each length. An extra charge is made for pipe in equal lengths. Prices vary with the metal market, and the place of sale.

List prices rarely change, and those in following tables hold good for 1938. List prices are subject to large and varying discounts and prevailing rates should be obtained from manufacturers before cost estimates are made.

In the following tables a fairly complete list of pipes and fittings is given, but valves and cocks are omitted, as they are made in too great variety to be listed here. Dealers' catalogues should be consulted regarding them.

Table 4. Line Pipe, for Oil, Gas, and High-press Mains

Tubes may be obtained in other thicknesses and larger sizes than those given above.

Table 6. Root's Spiral-riveted Pipe

Black and asphalted pipe is in lengths of 25 ft or less, galvanized in lengths of 20 ft. Wt is approx for black pipe only; asphalted and galvanized weight 10 to 20% heavier. Prices, $ per linear ft, with plain, crimped, or sleeved ends. Sleeves when furnished are included in linear measurement.

Extra strong and double extra strong will be shipped in random lengths and plain ends unless otherwise ordered. For pipe fitted with threads and couplings, extra charge will be made above regular. For cut lengths, extra charge will be made above random. For galvanized or asphalted, extra charge will be made above black.

Weights given are standard, but can be changed when pipe is made to order. Coated inside and out, and tested 300 lb per sq in, hydrostatic press. Made in 12-ft lengths, 440 lengths per mile.

Use of welded joints, instead of screwed or flanged joints, is rapidly gaining favor, especially for high pressure and high temperature piping. Particulars concerning welded

joints and accepted codes governing use of piping of various types and materials will be found in Kent's Mechanical Engineer's Handbook, Vol II, Power, 1936.

12	12	19	28.00	31.00	12	24	19	40.50	45.00

Mineral wool prices (net) per ton in 1939:

	Car-load lots	Less than car-load lots
Loose.....	$47.00	$53.00
Granulated	63.00	69.00

Temperature limit, 1000° F. Mineral wool is also made in blanket form, felted between metal fabric, asbestos paper or other materials. Mixed with various binders, it is in form of blocks, or special shapes to suit requirements.

10. SPRINGS

Formulas relating to springs are based on torsion formulas, modified according to form of spring and cross-section of the wire or rod used. Following brief notes relate especially to springs of mine hoisting cages.

Helical spring, of round wire, is shown in Fig 35; Fig 36 illustrates its action. A load, P lb, is attached by a cord to the rim of a pulley, of a diam D = mean diam of the spring coils, and produces torsion in the rod. A line AB, originally straight, becomes a helix AC, length of rod being l. Angle between AB and AC is the angle of shear ϕ, and angle $BOC = \theta$, is the angle of twist. For equilibrium the external and internal moments must be equal, hence (Fig 36) $P\dfrac{D}{2} = f_s Z_p = f_s \dfrac{\pi d^3}{16}$, where Z_p equals section modulus (Sec 43, Art 4) derived from the polar moment of inertia, and d equals diam of wire or rod. From the equation, the load P which the spring will carry can be determined for any given fiber stress f_s by transposition, $P = \dfrac{2\pi d^3}{16D} f_s = \dfrac{\pi d^3}{16R} f_s$, all dimensions being in inches. The length of a coil of the spring is generally taken as πD; accurately, it is $\sqrt{(\pi D)^2 + p^2}$. On applying the load, the rod is twisted through an angle θ; or through a length of arc measured on the circumference of $D = \delta$, which is the moment of the weight P. If the distance from B to C measured on the rod circumference $= x$, then

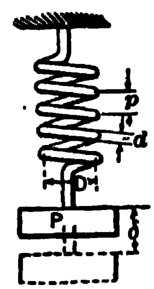

Fig 35. Helical Spring

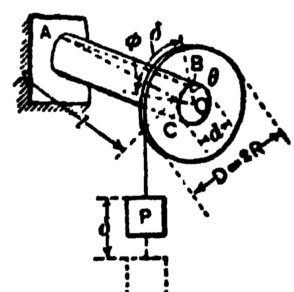

Fig 36

$$\frac{x}{l} = \frac{\text{Shear stress}}{\text{Modulus of rigidity}} = \frac{f_s}{G}.$$

Angle $\phi = x \div l$ and angle $\theta = x \div r$ or $2x \div d$; hence, $\theta = 2f_s \div Gd$, and $\delta = R\theta l = 2f_s l \div Gd$. Since $f_s = 16PR \div d^3$, $\delta = 32PR^2 l \div Gd^4$, which gives the deflection of the spring, where $l = 2\pi Rn$, if n = the number of complete coils. The resilience = 0.5 PS, providing the spring is not too open.

For rectangular wire or rod, the max stress occurs at centers of the longer sides. If b = thickness and h = width of section of wire,

$$I_p = \frac{b^3h^3}{3(b^2 + h^2)}, \quad \text{and} \quad Z_p = \frac{b^2h^2}{3\sqrt{h^2 + b^2}}.$$

Following the same analysis, $P = \dfrac{f_s}{3R}\dfrac{b^2h^2}{\sqrt{b^2+h^2}}$, and $\delta = \dfrac{3PR^2l}{G} \times \dfrac{b^2+h^2}{b^3h^3}$.

For wire of square section, $b = h$, $I_p = b^4 \div 6$, and $Z_p = b^3 \div 3\sqrt{2}$.

Flat spiral spring (Fig 37). In this the center is fastened to an arbor, the other end being attached to the framework. The formulas are correct if the spring winds uniformly and the center remains the center of gravity. If the load is applied at B, the greatest bending stress may occur at a point diametrically opposite A, or at the spindle if the curvature is great. For the first condition the external moment $= P \times 2R$ and $f = 2Pr \div Z = 12PR \div bh^2$; in the second case, $f = 6PR \div bh^2$. The load is $P = fbh^2 \div 12R$ (first case), or $fbh^2 \div 6R$ (second case).

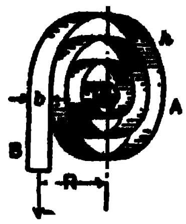

Fig 37. Flat Spiral Spring

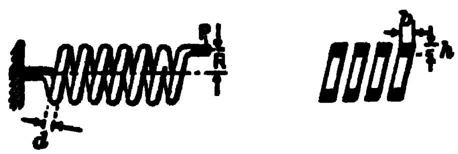

Fig 38. Round and Flat Helical Springs

From the theory of the elastic curve, the angle of deflection $\beta = PRl \div EI$, and $\delta = \beta R = PR^2l \div EI = 12PR^2l \div Ebh^3$, and resilience $= 0.5PR^2l \div EI$, and $I = bh^3 \div 12$.

Round and flat helical springs (Fig 38). For a spring subjected to a force P, tending to twist the spring at a radius R, the load $PR = fZ = f\pi d^3 \div 32$ for the circular section, and $PR = fbh^2 \div 6$ for the square section; also $\delta = 64PR^2l \div Ed^4$ for circular section, and $\delta = 12PR^2l \div Ebh^3$ for square section; the resilience being determined as above.

ELECTRICAL ENGINEERING

BY

WALTER I. SLICHTER

PROFESSOR OF ELECTRICAL ENGINEERING, COLUMBIA UNIVERSITY

ELECTRICAL ENGINEERING

1. DEFINITIONS, UNITS, AND STANDARDS

Potential (E or V), or DIFFERENCE IN POTENTIAL between two points, is theoretically the work required to move a unit quantity of electricity from one point to the other. It is analogous to difference in pressure, or head, of a current of water. The practical unit is the (International) VOLT, or electrical pressure which, when steadily applied to a conductor, the resistance of which is 1 ohm, will produce a current of 1 ampere. Difference of potential is measured in practice by a VOLTMETER (Art 4). For comparison and calibration the Weston Normal Cell is used, the electromotive force (e m f) of which is 1.0183 volt at 20° C. These cells are calibrated by Bureau of Standards, Washington. A millivolt is 0.001 volt.

Current (I) expresses the quantity of electricity flowing past a given point in 1 sec; it is analogous to gal per sec of a current of water, or to the miner's inch. The practical unit is the (International) AMPERE, or the unvarying electric current which, when passed through a solution of $AgNO_3$ in water, in accordance with standardized specifications, deposits silver at the rate of 0.001118 gm per sec. Current is measured by an AMMETER (Art 4). A milliampere is 0.001 ampere. DIRECT CURRENT (d c) is officially one which always has the same direction, though it may pulsate in value; but the term is popularly applied to a unidirectional current of constant value, officially called a CONTINUOUS CURRENT (c c). ALTERNATING CURRENT (a c) is one which changes its direction and amount in regularly recurring periods.

Resistance (R) in an electric circuit is similar to friction in mechanics. It is the property by which a circuit limits the amount of current caused by a steady voltage. The (International) OHM is the practical unit of resistance, and is the resistance offered to an unvarying electric current by a column of mercury, at temp of melting ice, which is 14.4521 gm in mass, of constant cross-sec and a length of 106.3 cm. Resistance is usually determined by computing the ratio between volts and amperes in a circuit according to Ohm's law (Art 2).

Power unit is the watt or kilowatt (kw). A watt equals 10 million units of power in the centimeter-gram-second system, and in practice equals the product of 1 volt by 1 ampere, or is the rate of expenditure of energy by 1 ampere in a circuit of 1 ohm. A KILOWATT is 1 000 watts; a horsepower (U S) = 746 watts.

Energy. The theoretical unit is the JOULE, which is 10 million ergs; in practice, equal to 1 watt times 1 sec. Commercial unit is the kilowatt-hour (kw-hr), equal to 3 600 000 joules. A circuit taking 10 amperes at 100 volts receives 1 kw of power, or 1 kw-hr of energy per hr; hence 1 kw-hr = 2 655 000 ft lb.

Coulombe is the unit of quantity of electricity (corresponding to a gallon of water), or the quantity transferred in 1 sec by a current of 1 ampere.

Capacity is the ability of an electric circuit to store energy in the space between conductors, measured in coulombes or quantity of electricity. A condenser is a device to provide capacity. FARAD (C) is the unit of capacity; or the capacity of a condenser which will be charged to a potential of 1 volt by 1 coulombe of electricity. A microfarad is one-millionth of a farad.

Maxwell (ϕ) is the unit quantity of magnetic flux, and is equal to 1 line of force.

Gauss (B) is the unit of magnetic flux density, and is equal to 1 line or 1 maxwell per sq cm.

Gilbert (F) is the unit of magneto-motive force (m m f), and is that m m f which will produce 1 line or 1 maxwell in a path in air having a cross-sec of 1 sq cm and a length of 1 cm. One gilbert = 1.257 ampere-turns.

Oersted is the unit of magnetizing force or magneto-motive force per unit length of path, expressed in gilberts per centimeter, or $0.4\pi NI \div 1$.

Reluctance. The practical unit is defined as the reluctance of a magnetic circuit in which a magneto-motive force of one ampere-turn produces a flux of one weber.

Weber is the practical unit of quantity of flux and is equal to 10^8 maxwells.

Henry (L), the unit of inductance, is the inductance of a circuit in which a variation in current of 1 ampere in 1 sec will induce an e m f of 1 volt.

Hysteresis. When iron or steel is magnetized by an electric current, the value of magnetic flux does not vary directly with the current. An increasing current does not produce the same flux for a given current as a decreasing current. This lagging of the

flux behind the magnetizing force is called hysteresis, and may be considered as the effect of friction between the molecules of iron which, in alining themselves with the flux like little magnets, rub against each other. Hysteresis causes loss of energy and heating of the iron, when the direction or magnitude of flux is changed. If the magnetizing force varies through complete cycles, positive and negative, the power lost in hysteresis is:

$$\text{Watts} = k_1 f V (B_m + 1\,000)^{1.6} \times 10^{-6}$$

where $k_1 = 6$ to 18, depending upon quality of iron; f = frequency in cycles per sec; V = volume, cu in; B_m = maximum magnetic density in lines per sq in.

Eddy currents are local currents induced in any conducting material located within the influence of any varying magnetic field. The term is especially applied to currents set up in the iron core of a machine, or in a conductor carrying an a c. These currents cause heating and loss of power and energy.

Effective resistance of a circuit carrying an a c is found by dividing the total loss in watts due to the combination of true resistance, eddy currents and hysteresis, by the square of the effective value of the current.

Series. Two circuits are in series when the same current passes through both successively.

Shunt. A circuit is in SHUNT, in MULTIPLE or in PARALLEL, with another when they form a divided circuit, so that a part of the total current passes through each, while the potential across them is common.

Constant potential circuit is one across which the potential is kept as nearly as possible constant, irrespective of the current flowing. It implies a supply from a circuit of low resistance. Most house lighting (incandescent), motor supply, and transmission systems are of constant potential type.

Constant current. Certain systems of lighting by arc lamps require constant value of current in all the lamps, which are therefore connected in series and the voltage across the whole circuit is varied to suit the number of lamps in operation. A special type of generator or transformer is required. In Europe the Thury system of long-distance transmission employs a constant d c, the voltage generated being varied with the load.

Conductance (G) of a circuit is that quantity which, if multiplied by the voltage, will give total current if voltage is unvarying, and which will give the component of current in phase with voltage ($I \cos \phi$) if voltage is alternating. For d c, conductance is the reciprocal of resistance. For a-c conductance, see Art 7. Conductance is used in analyzing multiple circuits. 1 volt applied to a circuit of 1 MHO conductance will cause 1 ampere to flow.

Rating of an electrical machine is the load in kw which it will give for a specified period of time without injury to itself. There are several limitations to the output, but the one most frequently met and inferred is injury to insulation by the heat developed. The limit is the temp of the hottest part of the machine, and the allowable temp depends upon character of the INSULATING MATERIALS. These are divided into 3 classes: (*a*) cotton, silk, and other fibrous materials, not so treated as to increase their heat-resisting qualities; (*b*) similar materials, but treated and impregnated, including enameled wire; (*c*) mica, asbestos, and other materials capable of resisting high temp. Temp of machines is usually determined by thermometer or by resistance measurements. Since neither method gives the temp of the hottest spot, it has been agreed to assume the temp of the hottest part as 15° C higher than indicated by a thermometer on the surface, and 10° C hotter than indicated by resistance measurement. Temp of surrounding air (ambient temp) influences directly the temp of the machine. Provision must be made that, when the air is at its highest possible temp (assumed at 40° C), the machine will not become excessively hot. This is done by specifying that the rise in temp above surrounding air shall be such that, if operating in a room of 40° C, its hottest spot shall not exceed certain established values. CONTINUOUS RATING is the load in kw which a machine will carry continuously without exceeding the above temp rise. INTERMITTENT RATING, or short time rating, is the load in kw a machine will carry for a short specified period (up to 2 hr) without exceeding these limitations. Unless otherwise specified, continuous rating is understood (Art 6).

Table 1. Temperature Conventions (Standard Rules of Am Inst Elec Engs)

Class of insulation	Highest permissible temp	Limiting temp by thermometer	Limiting temp rise	Limiting temp by resistance	Limiting rise by resistance
a	95° C	80° C	40° C	85° C	45° C
b	105	90	50	95	55
c	125	110	70	115	75

2. PRINCIPLES

Electric circuit. OHM'S LAW: $E = IR$, where I = current, amperes; E = e m f or difference of potential, volts; R = resistance, ohms. Used for solution of all simple d-c circuits and for a-c circuits having no reactance. For an a-c circuit having reactance, $E = IZ$, where I and E are effective values and Z is impedance in ohms (Art 7).

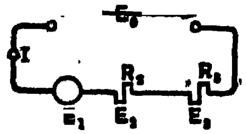

Fig 1. Series Circuit

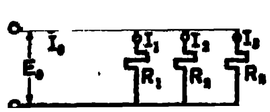

Fig 2. Multiple Circuit

Kirchhoff's laws are for solving any combination of series, multiple, or series-multiple circuits. FIRST LAW, for series d-c circuits: $E_0 = E_1 + E_2 + E_3$, where E_0 = generated e m f, E_1 = counter e m f (motor), and $E_2 = IR_2$, etc, are the drops in voltage in different resistances (Fig 1). Special case: $R_0 = R_1 + R_2 + R_3$. SECOND LAW (for multiple d-c circuits): the algebraic sum of all currents meeting at a point = 0 (Fig 2). $I_0 = I_1 + I_2 + I_3$, where I_1 may be found by $I_1 = E \div R_1$, whence

$$I_0 = \frac{E}{R_1} + \frac{E}{R_2} + \frac{E}{R_3}; \text{ or, in general, } \frac{1}{R_0} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3}$$

Magnetic circuit is calculated similarly to electric circuit: $\phi = \dfrac{\text{m m f}}{\text{reluctance}}$ where ϕ = flux in maxwells, m m f is in gilberts and reluctance $= l \div \mu A$, where l = length of path, cm; A = cross-sec of path, sq cm; μ is permeability of the material, varying from 1 for air to 3 000 in some steels.

Permeability. Since μ varies greatly with different materials, and with different densities in same material, it is more practical to calculate a magnetic circuit by means of magnetisation curves, which show relation between m m f per unit length of path and flux density in maxwells or lines per sq cm. Such a curve must be made for each different material used. In U S it is customary to plot the magnetisation curve between the ampere turns per in length of path and maxwells or lines per sq in (Fig 3). To determine the current to produce a given flux, divide number of lines of flux by cross-section of circuit in sq in, and find required magnetic density in lines per sq in. Referring to magnetisation curve (Fig 3) of the particular material to be used, the number of ampere turns per in of path is obtained for this particular density. Multiplying this number by length of path (in) gives total ampere turns required, which may be divided into any number of amperes or any number of turns, the product of which will give the required number. For a path in air, or in any non-magnetic material, the ampere turns per in = 0.313 times the density in lines per sq in.

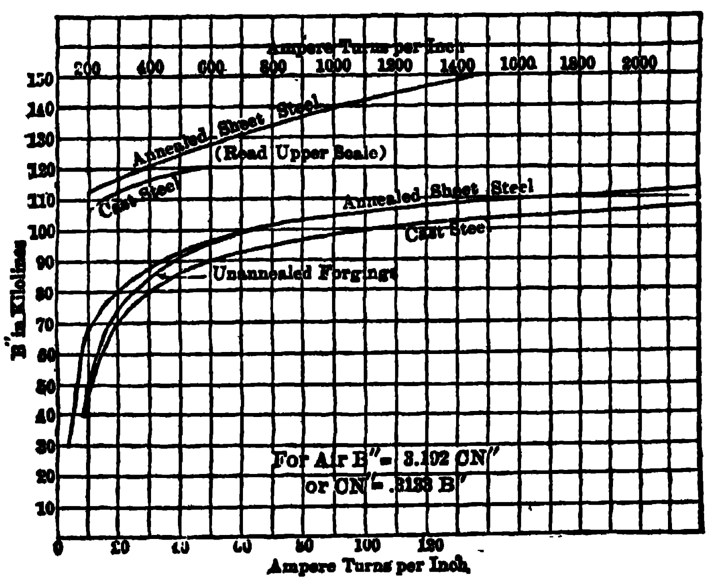

Fig 3. Typical Magnetisation Curves

Force on a conductor. Experiment shows that if a conductor carrying a current I and having a length l is placed in the magnetic field of density B gausses, at right angles to the direction of lines of force, a mechanical force will be exerted on the conductor, at right angles to the conductor and to the flux, the value of which will be $f = BlI$, where f = dynes, if the other quantities are expressed in c-g-s units. Practical form of this equation is $F = 0.89\ BlI\ 10^{-7}$, where F = lb, B = lines per sq in, l = in, I = amperes. This relation is basis for calculation of torque of any motor. In this case l must be the length of conductor in the active field only. The pull of any magnet is given by equation:

$$P = B^2A \div 72\,134\,000$$

where P = lb, B = lines per sq in, A = cross-sec of core, sq in. This is the case when 2 magnetic elements are in contact; when separated, the average gap density must be used.

Generation of an electromotive force (e m f). When a conductor is moved in a magnetic field so that it cuts lines of the field, an e m f is generated, numerically proportional to rate of cutting the flux. When conductor cuts 10^8 lines per sec, one volt is generated. If Z conductors are connected in series, as is usual in practice, $E = Z\phi \div 10^8 T$, where E = average volts generated and ϕ = flux cut in T sec. In the armature of any machine the relations are:

$$\text{Average } E \text{ of a d-c machine} = (4PNS\phi) \div (120 \times 10^8)$$

$$\text{Effective } E \text{ in an a-c machine} = (4.44PNS\phi) \div (120 \times 10^8)$$

where P = number of poles, N = rev per min, S = turns in series between terminals, ϕ = flux per pole, maxwells.

3. CONDUCTORS

Copper is generally used, iron and aluminum being next in importance. Though all metals are conductors, only these 3 are of commercial value, since their cost is reasonable and loss of energy is low. SILVER is the best conductor, but is too expensive for practical use. COPPER is nearly as good as silver, and is best economically. ALUMINUM is next; in the form of solid wire it is as cheap as copper, but lacks uniformity in mechanical strength. It is better when in form of stranded cables, but is then more expensive than copper of equal conductivity. IRON and STEEL approach copper in economic value, and for small-diam conductors are preferable due to their mechanical strength. An INSULATOR is a material used to prevent flow of current, but the division between insulators and conductors is not sharp; all insulators conduct some current. Common insulators are air, glass, porcelain, rubber, cotton, paper, and dry wood.

Table 2. Relative Characteristics of Conductors of Equal Resistance and Length

	Cross-sec for equal resistance	Wt for equal resistance
Copper	1	1
Aluminum	1.6	0.48
Iron, steel	8	7.1

* Steel being an alloy has varying spec resist. Steel used for track rails has approximately the value given in table, while for the "third" or conductor rail a special composition is used with lower spec resist.

Resistance of any conductor is given by: $R = \rho L \div A$, where R = resistance, ohms; L = length of conductor, ft; A = cross-sec of conductor, circular mils; ρ = specific resistance, or resistance of a conductor of unit cross-sec and length. Though the cm and sq cm are the more scientific units, it is convenient to use the circular mil for unit of cross-sec and the foot for unit of length, as adopted for commercial wires. A circular mil is the area of a circle having a diam of one mil (0.001 in). A circle 1 in diam has an area of 1 000 000 circ mils, and 1 sq in = 1 270 000 circ mils. Hence, in above equation, if length be 1 ft and A = cross-sec in circ mils, then ρ has values given in Table 3

Specific resistance ρ varies directly with the temp. Table 3 gives a constant for determining the percentage of increased resistance per deg C in excess of 20° C. General law of increase in resistance of copper with rise in temp is $R_t = R_0\,(1 + 0.0042\,t)$, where R_t = resistance at any temp, t° C; R_0 = resistance at 0° C; t = temp above 0° C.

Wire gages. Standard classification of wires in the U S is the Brown and Sharpe or American wire gage (Table 4).

B & S gage sizes have definite relations, readily remembered: A wire 3 sizes larger than another has nearly half the resistance, twice the area, and twice the wt per unit length. Thus, No 7 has

half the resistance of No 10. A wire 10 sizes larger has 0.1 the resistance and 10 times the area and wt. No 10 is approx 0.10 in diam, has area of 10 000 circ mils, resistance of 1 ohm per 1 000 ft at 20° C, and weighs 32 lb per 1 000 ft.

Resistance and wt of standard sizes of wire of other materials are found by using following ratios: ALUMINUM, multiply resistance given for copper by 1.61 and the wt by 0.301. IRON telegraph wire, resistance is 5.96 and wt 0.877 that of copper. STEEL wire, resistance is 8.82 and wt 0.883 that of copper.

Birmingham wire gage (B W G), also known as Stubbs, is largely used in Great Britain and somewhat in this country. Metric system is used in France and Germany. Roebling table is used in the U S for steel wires and cables (see Sec 41, Art 9).

Table 5. High-resistance Wires

* Manganin is used in electric meters because of its low temp coef.

4. MEASURING INSTRUMENTS

Solenoid. Simplest form of measuring instrument is the PLUNGER TYPE of solenoid. It consists of a coil of thick wire carrying current to be measured, and a soft steel plunger which is pulled into axis of coil by effect of the current acting against weight of plunger,

or against a spring. Operates with both d c and a c, but is not accurate with either. MAGNETIC VANE is a special form of solenoid instrument. Inside the coil carrying the current is a thin steel vane, pivoted in center of coil, and a fixed vane of triangular cross-section. When current flows in the coil, both vanes are magnetized alike and repel each other; hence, pivoted vane moves away from fixed vane, moving force being proportional to square of the current. Used both for d c and a c, but its accuracy varies with frequency and wave shape. INCLINED COIL solenoid instrument is very generally used to measure a c. A cylindrical coil of wire carrying current to be measured is set inclined to a spindle or axis carrying a steel vane. When no current flows, the vane is held in plane of coil by a spring. When current flows, the magnetic field is perpendicular to plane of coil and the pivoted vane, in moving to set its longer axis in the line of flux, rotates the spindle to which pointer is attached. Force is proportional to square of the current. Used for d c and a c, but is affected by wave shape and frequency. D'ARSONVAL PRINCIPLE, used in almost all instruments for d c, employs a coil of fine wire placed in the field of a permanent magnet, suspended so that it can rotate. Current to be measured, or a definite part of it, passes through the movable coil, causing a torque which is resisted by a spring. The force is directly proportional to the current. Only operative with d c, and is affected by stray magnetic fields.

Hot-wire instruments may be used to measure both d c and a c. The current is passed through a wire, which it heats and lengthens. Increase in length is taken up by a spring or weight, the movement of which is proportional to square of current.

Dynamometer consists of 2 coils, fixed and movable, so arranged that their magnetic fields act upon each other. The current, passed through the two in series, develops a torque (as in a series motor) proportional to square of the current. Movement of the coil is resisted by a spring and indicated by a pointer. As no iron is present, this instrument is accurate for d c and a c of all frequencies. The principle is used in the Siemens dynamometer, in some a-c voltmeters and ammeters and in all wattmeters. In wattmeters one coil is in series with the line and the other coil across the load, receiving current through a high resistance proportional to the potential.

Induction-type instruments utilize the fact that, if a coil carrying an a c has within it a piece of copper or aluminum, eddy currents will be induced in the metal, and these will react on the main current, giving a force or torque. The torque is proportional to square of current. Instrument operates only on a c, and is affected by varying frequency.

Ammeter operates on any one of above-mentioned principles. Its electrical circuit must have very low resistance, and usually the measuring coil carries only a small though definite part of the current. In parallel with working circuit, there is usually a metallic "shunt," which has such resistance that the maximum current to be measured causes a drop of about 50 millivolts (Art 1, par 1) in the shunt. Some meters have interchangeable external shunts, while others have shunts placed inside the case and permanently connected in the circuit.

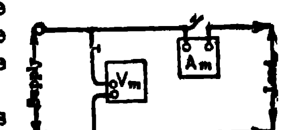

Fig 4. Connections of Voltmeter, Ammeter, and Protecting Switches

When the instrument is used with an external shunt it is sometimes called a MILLIVOLTMETER, its scale being marked in millivolts. An ammeter must never be left connected in the circuit without its shunt. Most ammeters for measuring d c operate on the d'Arsonval principle, as it gives the most accurate results. For a c, the inclined coil is in most general use. Most a-c meters will indicate as correctly on d c as on a c, but not as accurately as an instrument of the d'Arsonval type (Fig 4).

Voltmeter resembles an ammeter and in reality measures current, but its electrical circuit has a high resistance connected in series with it, to limit the current to a reasonable value. Since, in accordance with Ohm's law, with a constant resistance the current is proportional to the potential across the circuit, the scale deflection will indicate volts. The resistance must be non-inductive, and must not vary with temperature. When the resistance coil is separate from voltmeter the coil is called a multiplier.

The dynamometer type voltmeter is to be preferred for a c, and a potential transformer may be used instead of a multiplier if required to measure a voltage higher than the range of the voltmeter proper. ELECTROSTATIC VOLTMETER, a special instrument for measuring very high voltages, utilizes the force exerted between two charged bodies. A moving vane is connected to one side of the circuit, a fixed vane to the other. As the high potential charges these vanes, a force is exerted between them causing the movable vane to rotate. This instrument is used for either a c or d c.

Wattmeter is used on both a-c and d-c circuits for measuring the true or active power in watts; EI in d-c circuits, $EI \cos \phi$ in a-c circuits. In d-c circuits a voltmeter and an ammeter may be used to measure power, the product of the volts and amperes giving true

power, but in an a-c circuit this is not true. The wattmeter has a potential coil connected in parallel with the load (like a voltmeter), and a current coil connected in series with the load (like an ammeter). If the needle shows negative deflection, the terminals of one coil or other must be reversed. Range of the wattmeter must be selected with reference to the volt and current capacity of its coils. A "multiplier" may be used in the potential coil and a current transformer in the circuit of the current coil.

Watt-hour meter measures energy by recording watt-seconds. Coils are arranged to form a motor, which causes a disk to revolve at a velocity proportional to the power. A counter registers number of revolutions of the disk, and this number represents energy. Watt-hour meters for a-c circuits are constructed differently from those for d-c. (Art 11.)

Power-factor meter determines the phase angle (ϕ) between voltage and current of an a-c circuit. Since in practice the power factor is the more important, the scale is graduated in $\cos\phi$. Instrument is constructed like a wattmeter having 2 coils, one for potential and one for current.

Frequency meter indicates the frequency in electrical cycles per second of the circuit voltage. The two common types are the vibrating reed and the induction. They are connected to the line like voltmeters.

Recording meters are often used in power stations to provide a continuous record of voltage, current or power. A pen, attached to the indicating element, rests on a strip or disk of paper, and draws a line as the paper moves by clock work.

5. DIRECT-CURRENT GENERATORS

Application. Direct-current (which is officially named continuous current) apparatus is used for short transmission distances. For long distances the a-c system (Art 7) is preferable, because the transformer (Art 13) permits transmission at very high voltages. However, since the d-c motor is more convenient and more easily controlled than the a-c motor, the d-c system is used whenever possible. It is often found advisable to generate and transmit by means of a-c, which is then converted to d c at the place where the motors are located. Thus, most generating stations produce a c, though many of the motors supplied by these stations use d c provided by synchronous converters or rectifiers.

Fundamental principle of a dynamo is the production of e m f (Art 2) in one or more conductors by the motion of these conductors in a magnetic field. In most machines the e m f is alternating; first positive, as conductor passes a north pole, then negative, as it passes a south pole. For use as a d-c machine a commutator must be provided to rectify voltage and current. The commutator is the distinguishing feature between d-c and a-c machines. Small machines are usually of the bipolar type, with a more or less enclosed frame of cylindrical shape. Large machines are multipolar; that is, having a large number of inwardly projecting radial pole pieces. Commutating pole or INTERPOLE machines have small auxiliary poles placed alternately with respect to the main poles and excited by a few turns in series with the load. Effect of these poles is to improve the commutation of the machine. Machines are divided generally into belt-driven and direct-connected, the former having the higher speed.

Shunt machine, either generator or motor, is one in which the entire field excitation is derived from a circuit of many turns and high resistance, connected in shunt or multiple with the armature circuit (Art 6, Fig 8). The characteristic of a shunt generator is poor regulation; that is, voltage decreases as load increases, and hand regulation of a rheostat in the field is necessary to provide steady voltage.

Compound-wound machine has on each field pole, in addition to its shunt winding, a few turns of thick wire which carry the load current and are known as series winding (Fig 5, 6). This causes excitation to increase as load increases, and tends to keep the terminal voltage constant or even to increase it. If the field windings are proportioned to cause a higher voltage at full load than at no load, the machine is over-compounded. A flat-compounded machine has the same voltage at full load as at no load; an under-compounded machine has a lower voltage at full than at no load. A compound-wound machine may be connected either in short shunt (Fig 5), which is usual practice, or in long shunt (Fig 6), in which the field winding is connected from outside of the series field to outside of the armature.

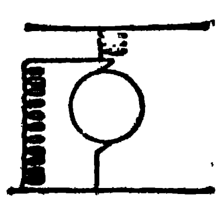

Fig 5. Short Shunt Connections

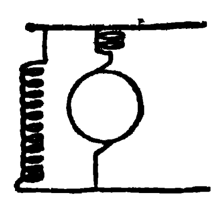

Fig 6. Long Shunt Connections

Constant potential vs constant current. In constant-potential type an endeavor is made to maintain a constant potential across the load. For particular purposes machines sometimes have their field connected in series with the armature, and with a special regulating device for giving constant current irrespective of load. These machines were formerly much used in arc lighting, but are not now built.

Installation. In installing and erecting a d-c machine, certain features must receive careful attention, so that the machine shall operate properly and not deteriorate too rapidly. The most important considerations are: (*a*) For large machines the base is bolted to the foundation in accordance with the drawings. (*b*) Bearings are lined up, cleaned, and oiled. (*c*) Field coils are tested for open circuit and wrong connections. Test is made with a compass for correct polarity. For a self-excited generator there is one particular connection of the field to the armature for each direction of rotation. (*d*) Armature must be properly centered so that the air gap is correct at all points. Gap is measured by taper wedges. (*e*) Magnet frame is bolted to base. (*f*) Commutator is smooth and polished; use sand paper, never emery paper, to polish commutator. (*g*) Brushes are properly and accurately spaced around the commutator, sandpapered and fitted to its curvature, and their pressure adjusted to the correct value, usually 1.5 to 2 lb per sq in of contact surface. (*h*) Field connections are adjusted for correct direction of rotation and substantial connections made. (*i*) Machine must be protected from moisture during shipment; if it be damp it must be dried out by heat before starting.

Operation. In starting a single generator it may be necessary to CHARGE THE FIELD by exciting the shunt field separately for a moment to set up residual magnetism. To cause the machine to PICK UP, or generate voltage by self-excitation, the rheostat connected in series with the shunt field must be cut out, or short-circuited. If total resistance of shunt-field circuit exceeds a certain critical value the machine will not "pick up," however much time is allowed.

Parallel operation. For economical operation of a power station there must be a number of machines, whose aggregate capacity equals the maximum demand on the station. As the demand varies the number of machines in operation is adjusted so that those running are operating at a load near their rating, and therefore at good efficiency. To operate SHUNT GENERATORS in parallel (that is, feeding the same bus-bars); it is only necessary to adjust all to the same polarity and voltage, connect them to the bus-bars, and adjust division of load by strengthening the field of the underloaded machine if voltage of the bus-bars is low, or weakening the field of the overloaded machine if voltage is high. To operate COMPOUND GENERATORS in parallel there must be an equalizer connection, making a common connection on all the machines at the point between the armature and the series field (Fig 7). The equalizer divides the load current in proper proportion between the series fields of the different generators, preventing the machines from acting as series generators or differential motors, which would cause short-circuits. For successful operation of compound machines in multiple all those connected to one set of bus-bars must have same amount of compounding, and same voltage at no load. The compounding curves of machines must be investigated before they are operated in parallel. With unlike curves, one machine may be overloaded while another is underloaded, unless the field current of one of them is adjusted.

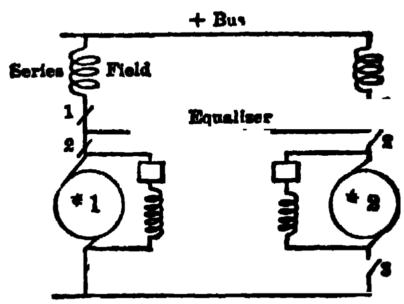

Fig 7. Parallel Operation of Compound-wound Generators

If a machine is to be connected in parallel with those already in operation it must have proper polarity and voltage, the equalizer circuit must be made, and the switches are closed in the order 1, 2, 3, as in Fig. 7. With any other order the effect is the same as having no equalizer. In shutting down one machine, switch No 3 must be opened first; then No 2 and No 1. For MANAGEMENT, see Art 6.

Testing. D-c machines are tested for regulation, commutation, and heating, by subjecting them to a load, but their efficiency is best determined by the separate loss method, for which the machine need not be run under load. Customary commercial tests are:

(*a*) **Resistance measurements** are made on armature winding, shunt field, and series field, at known temp, before the machine is run and again after the heat run (*d*). Resistance of a lap or multiple winding is found by measuring between two diametrically opposite points on commutator. If this resistance be R', then the actual armature resistance is $R_a = 4R' + p^2$, where p = number of poles on machine. Resistance of a series-wound armature is found by measuring between two commutator segments, separated by a distance equal to periphery of commutator divided by number of poles. Resistance of the brush contact can not be accurately measured by any simple means, as its value is affected by value of the current, speed of commutator and pressure of brushes. An accepted method is to assume a total loss of 2 volts in all brushes.

(*b*) **Core loss and friction (stray power).** Machine is run as motor without load, field current being held at proper value and the voltage applied to armature adjusted to give desired speed. Input to armature is measured; subtracting from this the calculated I^2R of armature circuit, the net value of input = core loss + friction.

(*c*) **Load runs.** Machine is run and the excitation adjusted to give proper voltage at no load. Load is then added and terminal voltage noted. If E_0 = voltage at no load and E = voltage at full load, the regulation is $(E_0 - E) \div E$. Brushes must be set in proper position for commutation, which is judged by observing action of brushes at no load, full load, and 150% load.

(*d*) **Heat runs** are made by operating at full load until the temps of the various parts that can be noted during operation become constant. The greater the machine's capacity, the longer is the testing time required. Heat runs are sometimes made at 1.25 or 1.50 times rated load for 2 hr. Heat runs may be made either by the DEAD-LOAD METHOD, in which a resistance load such as a water rheostat is connected to the terminals and full rated load power is required to drive the machine; or by the Hopkinson or PUMPING-BACK METHOD, in which 2 machines of similar characteristics are run in multiple, one acting as a generator to supply electrical power to the other as motor, which in turn drives the first by a belt or equivalent mechanical connection. For this test a LOSS SUPPLY is required, which may consist of a source of either electrical or mechanical power. The power required is from 10 to 20% of the rating of one machine. During a heat run, thermometer readings are taken at stated periods, showing temp of frame, field-coils, bearings, and surrounding air. After the run thermometers are placed on various parts of the machine, the bulbs being protected from radiation by small cotton pads, and the temps are noted of armature core surface, ventilating ducts and winding, commutator surface, pole-tips, field-coils, bearings, frame, and the room. Resistance of the elec circuits should be measured, and average temp of the copper calculated from: $t_1 = (R_1 \div R_0)(234 + t_0) - 234$, where R_1 and R_0 are the hot and cold resistances, and t_1 and t_0 are the hot and cold temps.

(*e*) **Compounding test.** To adjust the current in series field so that a compound-wound generator will give specified voltages at no load and full load, the machine is first operated at no load and current in shunt field adjusted to give desired no-load voltage. Load is then put on, and it will usually be found that the terminal voltage is too great. Strips of German silver or other resistance metal are then connected across the series field terminals, until by shunting current from the series field the machine voltage is reduced to desired value. This "series-field shunt" is then insulated, and made up into permanent form. Before making the no-load adjustment, it is advisable to over-excite the shunt field for a moment to overcome hysteresis.

(*f*) **Insulation tests.** After the heat run the insulation is tested, first by measuring its resistance and then by applying a high-potential test. INSULATION RESISTANCE is found by connecting one terminal of a 500-volt d-c circuit to the windings through a 500 voltmeter, and connecting the other terminal of the 500-volt circuit to the machine frame. If voltmeter resistance is R_v and the deflection during above connection is x, then insulation resistance in ohms is: $R = R_v\,(500 - x) \div x$. The value of R should be approximately one megohm (1 000 000 ohms) for each 1 000 volts of rated potential of the machine. HIGH-POTENTIAL test is made by applying an alternating high potential between each winding and the frame of the machine for 1 min, in accordance with specifications adopted by Am Inst Elec Engs. This test is usually made only at the factory and should be under supervision of an experienced person.

6. DIRECT-CURRENT MOTORS AND MOTOR-GENERATOR SETS

Shunt motor (Fig 8) has only one exciting winding, which is connected across armature terminals, and is in parallel or shunt with the armature. Field winding consists of a large number of turns of fine wire on each pole, and all poles are usually connected in series in one circuit. Field current depends upon line voltage and resistance of field winding. Resistance of field winding is made high, so that the field current will be between 1% (large motors) and 5% (small motors) of the full-load current of motor. The characteristic of the shunt motor is a fairly constant speed for all reasonable load values.

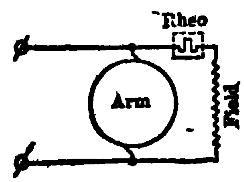

Fig 8. Shunt-motor Connection

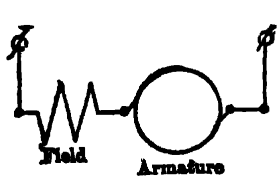

Fig 9. Series-motor Connection

Series motor (Fig 9) has only one exciting winding, which is connected in series with the armature, and all the current flows through both field and armature. Field winding consists of a few turns of thick wire on each pole, the windings on all poles being connected in series. Field current depends upon the load; large with heavy load and small with light. Resistance of field winding is made low, so that loss of voltage and power in that circuit will be small. Characteristics of a series motor are: a speed varying with every change in load, high speed at light load, and low speed at heavy load. Efficiency is high throughout a wide range of speed. Speed will be dangerously high at no load; thus a series motor must always be connected rigidly to its load. Since torque is high at low speeds, this motor is especially adapted to work requiring frequent starting.

Compound motor. Usual form is the cumulative motor, each pole of which has both series and shunt winding, wound and connected for mutual assistance in producing the magnetic field. It is a combination of shunt and series motor, designed to give the good starting qualities of the series motor and to avoid danger of excessive speed at light loads.

Differential motor has opposed shunt and series winding; not much used and not recommended.

Inclosed vs open type referring to the mechanical housing of the motor. Open type has all parts freely exposed to the air and is therefore well ventilated. Intended to be used indoors or in protected places. Inclosed type is for use in exposed locations, where there is liability of dampness and dirt. Special means must be provided to circulate air inside the machine, but even then an inclosed motor is larger and more expensive than an open motor of same capacity. Relative capacities in output of open, semi-inclosed and totally inclosed motors, are shown by Table 6. Totally inclosed motor weighs about 15% more than an open motor of same capacity, notwithstanding that it is allowed by commercial convention to operate at 15° C higher temp.

Table 6. Data of Typical Commercial Motors

Type	Output, h p	Temp rise, deg C	Weight, lb	Speed, r p m
Open............	10.0	40	970	700
Semi-inclosed....	8.0	40	970	700
Totally inclosed.	5.75	55	970	775

Rating. Motors are rated on basis of their continuous or their intermittent capacity. Continuous rating is the output in h p (or kw) which a motor will give continuously with a maximum temp rise (measured by thermometer above the surrounding air) not exceeding 50 or 70° C in field or armature, depending upon character of insulating material (Art 1). Intermittent rating is the output which the motor will give for 1 hr (starting at room temp), with a maximum rise in temp above surrounding air not exceeding the above values (Standardization Rules of ASA C-50).

Voltage and current. Usual values of voltage for d-c motors are: 110–125 for small units on lighting circuits; 220–250 for motors in factories, shops, and mines, on power mains or on outside mains of a 3-wire system; 500–600 for general railway work; 1 200–2 400 for heavy railway work. Current in amperes required for any motor is: $I =$ (output in h p $\times$ 746) $\div$ (effic $\times$ voltage). Usual efficiencies of motors of different sizes are given in Table 7.

Applications of motors. Chief applications of d-c motors: shunt motor, driving shafting, machine tools, blowers, reciprocating pumps, motor-generators; series motor, R R, and all transportation work, hoists, cranes; compound motor, elevators, hoists, or machinery that is stopped and started frequently.

Speed characteristics. Shunt motor is always used when constant speed is desired. It may be obtained with characteristics such that the drop in speed from no load to full load is 5 to 10%. At full load the speed of any well-designed shunt motor may be increased to equal the no-load speed, by putting resistance into the field circuit. Variable-speed motors are of the series type; they decrease in speed as load increases, every change in load causing change in speed. Multispeed motors are of shunt type, and usually have commutating poles so that they may operate with different strengths of field without suffering from bad commutation. They may be controlled by varying the field resistance, or the voltage impressed upon the armature. By increasing resistance in series with the field of a shunt motor speed is increased, due to weakening of the field. If the motor has commutating poles, to assure good commutation, speed may be varied in ratio of 1 to 2, or even 1 to 4 in small sizes. Motor speed is stable with this mode of control and efficiency is good.

Potential control. By means of several generators and several wires, various definite voltages are available. Thus, with one main generator giving 240 volts and 3 smaller ones giving 40, 80, and 120 volts, combinations may be made giving 40, 80, 120, 160, 200, and 240 volts. By connecting the armature terminals to these voltages, the motor will run at speeds proportional to the voltages. The shunt field is left continuously connected to one circuit, usually the maximum voltage circuit. A shunt motor with normal excitation will be stable at each speed; that is, will operate at fairly constant speed irrespective of load. Efficiency will be good at all speeds. A number of wires are needed to make the different voltages available at the places where the motors are located.

Variable-speed motors. By connecting a rheostat in series with a shunt motor armature, the voltage impressed upon the armature will be reduced by an amount proportional to the current, and speed will thereby be reduced. The speed is unstable, changing with every change of load, and efficiency is poor.

Starting box (rheostat) is always employed in starting d-c motors, to reduce the voltage impressed on the armature when not running at a speed high enough to generate the

proper counter e m f. Fig 10 shows usual connections of a starting box to the line and motor.

Starting box contains: (*a*) means of opening and closing the circuit supplying current to the motor, including the field current; (*b*) set of resistance steps in series with motor armature, and a means of short-circuiting this resistance step by step; (*c*) a magnet coil connected across the motor terminals to open the circuit if impressed voltage fails (low-voltage release); (*d*) a magnet coil carrying main current to actuate a spring and open main circuit, if current exceeds a specified value (overload release).

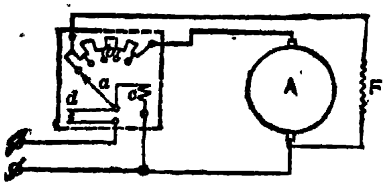

Fig 10. Starting Box Connections for Shunt Motor

Specifications. In calling for bids for d-c motors it is customary to specify: kind of service and load, method of drive, voltage, horse-power, speed, and whether open, semi-inclosed or inclosed, series, shunt, or compound-wound; if shunt-wound, whether shunt field rheostat is to be supplied; if compound-wound, whether cumulative or differential; dimensions of pulley and shaft extension, whether rails or base are required; whether starting box is to be supplied and if so, the style; temp rise for continuous full load; temp rise for 25% overload; efficiency at 25, 50, 75, 100, 125, and 150% load; starting torque required; necessity for withstanding moisture; regulation; percentage of variation in speed between no load and full load, with field resistance constant; variation in speed at full load obtainable by variation of field rheostat.

Installation. (See Art 5.)

Costs. (See Art 19.)

Operation. All motors should be frequently inspected and following points noted: (*a*) Bearings filled with proper amount of oil; (*b*) brushes securely held in proper position; (*c*) brushes fit properly; (*d*) commutator smooth: look for "high mica," or projection of the insulation above the bars; (*e*) air gap true; (*f*) commutator not worn in grooves.

Troubles. Following troubles that may occur in operating d-c motors, and their causes, are stated by Crocker and Wheeler: (*a*) Sparking at commutator. Causes: armature carries too much load, brushes improperly spaced or not in proper position, rough commutator, poor brush contact, internal short or open circuit, field too weak, unequal strength of poles, vibration. (*b*) Heating of commutator and brushes. Causes: sparking, bearing trouble, bad connections, brush friction too great. (*c*) Heating of armature. Causes: overload, internal short circuit, moisture or ground, reversed coil. (*d*) Heating of field. Cause: internal short circuit. (*e*) Heating of bearings. Causes: bearings dry or dirty, shaft out of true, bearings out of line, thrust due to belt, unbalanced magnetic pull. (*f*) Noise. Causes: armature not balanced, brushes dry or not set at proper angle, armature strikes. (*g*) Speed too low. Causes: wrong voltage, overload, armature strikes, bearing too tight. (*h*) Speed too high. Causes: wrong voltage, field too weak. (*i*) Motor stops, or fails to start. Causes: overload, open circuit, wrong connection.

Tests. A motor is usually tested for resistance of insulation and of windings, heat run, stray power, regulation and commutation. Regulation test consists in measuring speed at no load and at full load. Other tests are the same as made on d-c generators (Art 5).

Constants. Efficiency of any particular size of electrical machine may vary widely according to its design. For weight and cost, see Art 19.

Table 7. Average or Usual Constants for D-C Machines

Kw rating	1	5	10	20	50	100	200	500
Efficiency at full load	0.80	0.84	0.86	0.88	0.90	0.91	0.92	0.93
Rev per min	2 000	1 100	850	680	650	600	450	350

Motor-generator set is a combination of motor and generator having separate fields and armatures, but mounted on same shaft with common base and bearings. The two machines may both be for d c, both for a c, or one for each, in accordance with the use to which the plant is to be put. Principal applications are:

Balancers. Two similar d-c machines mounted on the shaft, and connected in series across the mains of a 250-volt circuit. From the common connection a third wire is brought out, thus giving a 3-wire system for 125-volt lamps on each leg, and for 250-volt motors on the outside main. With compound machines the regulation on the 125-volt circuits is good.

Boosters. To raise the voltage on a particular feeder a series booster is used, consisting of a shunt motor driving a series generator, the latter being connected in series with supply and feeder. The set runs at constant speed, and the voltage increases with the current to the load. Voltage at

full load is from 10 to 20% of the rated voltage of the circuit. The combination may be designed to neutralize loss in voltage due to drop in the feeder.

Multiple-voltage systems. Motor-generator sets are used to give the fractional voltages required for these systems. Each set consists of 2 or 3 machines operating as a balancer; that is, each may be a motor at one moment and a generator at the next, depending upon which circuit is supplying the load.

Ward-Leonard system. For regulating the speed of a motor a special generator may be provided, which, being driven by its own motor, forms a motor-generator set. By varying the field strength of the generator any voltage may be generated, from 0 to full rated voltage. If this generator supplies only the armature of the motor, the speed of which is to be regulated, its speed may be controlled from 0 to full speed by merely varying the small current flowing in the field of the special generator. Main supply circuit furnishes current for the motor of the set, and fields of the generator and the controlled motor.

Ilgner sets. Where a motor must start and accelerate a heavy load frequently, as in mine hoists and rolling mills, the motor is advantageously supplied from a special set, consisting of a motor (shunt or induction) driving a special generator, with a heavy flywheel forming part of the set. For such service the set motor must have poor speed regulation. As the accelerating motor starts, it draws a heavy current from the generator, causing speed of set to drop and the flywheel to give up considerable stored energy. This energy supplies the peak demands, and when the peak load period has passed the set speeds up gradually and stores more energy in the flywheel. This combination is expensive, but is used where conditions limit the maximum demand which may be made on the electrical supply system. (See Sec 16.)

7. ALTERNATING-CURRENT CIRCUITS

Sine wave. Every generator for d c as well as for a c has induced in its own windings an alternating voltage. The commutator of the d-c machine rectifies this, giving direct or continuous voltage. Since an a-c machine has no commutator, this voltage is brought to the load in its alternating form by slip-rings.

In designing machines every endeavor is made to obtain an e m f which follows a true sine law: $e = E_m \sin \theta$, in which e is the instantaneous value, E_m the maximum value, and θ gives the phase time, or abscissa at which the instantaneous value is specified. All calculations of a-c circuits are based on assumption that voltage and current do follow a sine law.

Frequency. The series of values from a to c (Fig 11) constitute a cycle or period. Time in seconds required for one cycle is the periodic time T, and $1 \div T$ (number of cycles per sec) is the frequency f. In commercial practice frequencies of 25, 50, and 60 cycles per sec are used, the first for general power, the latter for lighting purposes. If θ is expressed in radians, then $\theta \div t = 2\pi f$, and $\theta = 2\pi f \times t$. Thus phase θ is a conventional means of expressing a given instant of time t. A cycle may be divided into 360°, and θ may be the abscissa expressed in degrees.

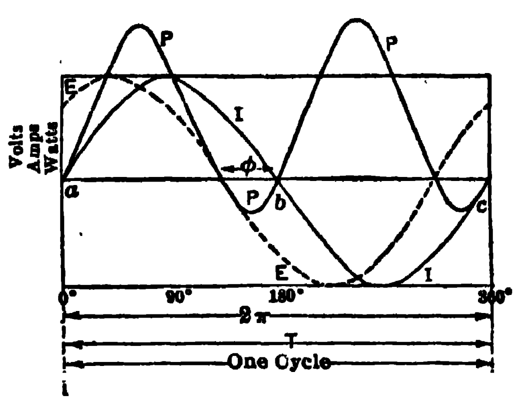

Fig 11. Alternating-current Voltage and Power, Rectangular Coordinates

Effective, virtual, or root mean square value of an a c is equal to that value of a d c which would produce the same heating effect or average power loss in a resistance RI^2. If current follows a sine law, the effective value is equal to maximum value divided by $\sqrt{2}$. Effective value of e m f is that which, when multiplied by the effective value of current in a simple resistance, will give the true power in watts. It is also equal to maximum value divided by $\sqrt{2}$. Effective values of current and voltage are the values shown by all instruments, and are the only ones used in practical engineering. (See Sec 16.)

Inductive reactance, inductive circuit. Any circuit in which the presence of a current produces a magnetic flux is an inductive circuit, the quantity of inductance depending upon the number of turns and the quantity of flux produced by one ampere. When an a c flows in an inductive circuit the current lags behind the impressed e m f, and the relation between voltage and current in such a circuit is $E = 2\pi fLI$, where E = effective value of e m f, f = frequency in cycles per sec, L = inductance in henries, I = effective value of current. $X_L = 2\pi fL$ is the inductive reactance in ohms. $E = X_L I$ in a circuit having inductance only, and the current will lag behind the voltage by 0.25 of a period.

Capacity reactance, anti-inductive circuit. If an alternating e m f is impressed upon a circuit having capacity only, the current which flows precedes or leads the e m f by 90°, and its value is $I = 2\pi fCE$, where C is the capacity in farads and the other quantities are as in preceding paragraph. $X_c = 1 \div 2\pi fC$, called capacity reactance, is expressed in ohms and $E = IX_c$.

Power and power factor. In an a-c circuit containing inductance or capacity, as well as resistance, the product of effective volts and effective amperes (EI) does not give true power, because the current will be out of phase with the voltage; that is, the maximum value of current will occur either later than or before the maximum value of voltage. Therefore EI is the volt-amperes or "apparent power." Ratio of true power P to apparent power is the power factor. It may be proved that the power factor is equal to the cosine of the angle of phase difference between the voltage and current, as shown by equation: Power factor $= \cos\phi = P \div EI$, where ϕ is the time difference in phase between voltage and current, expressed in angular measure.

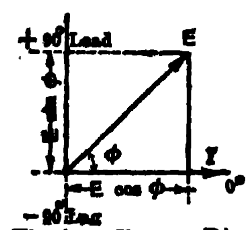

Fig 12. Vector Diagram of Alternating-current Voltage

Fig 11 shows an alternating voltage E and an a c I differing in phase by an angle ϕ, which means that their maximum or their zero values occur at a difference in time of $(\phi \div 360)\ T$ sec, where T is the periodic time of one cycle. Fig 12 is a vector representation of these quantities, and conventionally I is said to lag behind E by an angle ϕ. $E \cos\phi$ is the component of the voltage in phase with the current, and is called the "active component." The useful or heat power in watts is $P = EI\cos\phi$. $E \sin\phi$ is the component of the voltage out of phase with the current, and is called the "reactive component." $Q = EI\sin\phi$ is the reactive power, as it reacts on the impressed forces without producing useful work or heat. Total volt-amperes or apparent power is $EI = \sqrt{P^2 + Q^2}$.

Kilovolt-ampere (*kva*) equals 1 000 volt-amperes.

Calculations. A corollary of the law of conservation of energy is that the sum of all the true (heat) power consumed in a circuit is equal to the input of true power, $P_0 = P_1 + P_2 + P_3$. The sum of all the reactive power consumed in a circuit is equal to the input of reactive power, $Q_0 = Q_1 + Q_2 + \text{etc}$, and $E_0 I_0 = \sqrt{P_0^2 + Q_0^2}$.

Kirchhoff's laws for a-c circuits. First law (for series circuits) (Fig 13 and 14): The sum of all active components of voltage ($E\cos\phi = IR$) in a closed circuit is equal to zero, and the sum of all reactive components ($E\sin\phi = IX$) is equal to zero. Hence,

$$E_0 \cos\phi_0 = E_1 \cos\phi_1 + E_2 \cos\phi_2 + \text{etc}$$

$$E_0 \sin\phi_0 = E_1 \sin\phi_1 \pm E_2 \sin\phi_2 + \text{etc}$$

$$E_0^2 = (E_0 \cos\phi_0)^2 + (E_0 \sin\phi_0)^2$$

Reactive component of voltage in an inductance is positive; that in a capacity is negative. Second law (for multiple circuits) (Fig 15 and 16): The sum of all active components of current ($I\cos\phi = ER \div Z^2$) meeting at a point is equal to zero, and the sum of all the reactive components ($I\sin\phi = EX \div Z^2$) is equal to zero.

$$I_0 \cos\phi_0 = I_1 \cos\phi_1 + I_2 \cos\phi_2$$

$$I_0 \sin\phi_0 = I_1 \sin\phi_1 + I_2 \sin\phi_2 - I_3 \sin\phi_3$$

$$I_0^2 = (I_0 \cos\phi_0)^2 + (I_0 \sin\phi_0)^2$$

Reactive component of current in an inductance is negative; in a capacity, positive.

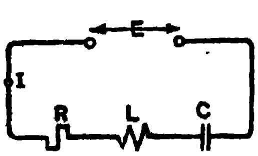

Fig 13. Series A-c Circuit, with Resistance Inductance and Capacity

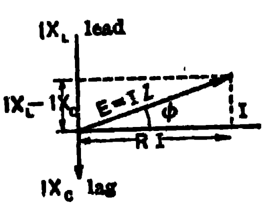

Fig 14. Vector Diagram of Series Circuit

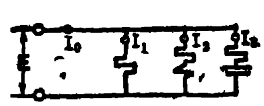

Fig 15. Multiple A-c Circuit with Resistance Inductance and Capacity

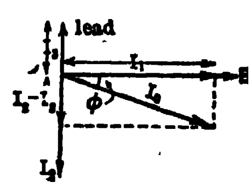

Fig 16. Vector Diagram of Multiple Circuit

Ohm's law for series a-c circuits (Fig 13). In a circuit having resistance R, inductive reactance X_L, and capacity reactance X_c in series, the impedance in ohms is: $Z = \sqrt{R^2 + (X_L - X_c)^2}$, the current $I = E \div Z$, and the power factor $\cos\phi = R \div Z$. Voltage across the resistance RI (Fig 14) is in phase with the current. Voltage across the inductance IX_L is 90° ahead of the current, and the voltage across the capacity IX_c is 90° behind the current. These combine geometrically to give $E = IZ = \sqrt{(RI)^2 + (X_L I - X_c I)^2}$, which differs in phase from I by the angle ϕ, the $\cos$ of which $= R \div Z$, and $\sin = (X_L - X_c) \div Z$.

Multiple circuits (Fig 15, 16). In multiple circuits having resistance and reactance in various branches:

Conductance $G_0 = R_1 \div Z_1^2 + R_2 \div Z_2^2 + R_3 \div Z_3^2$
Susceptance $B_0 = X_L \div Z_2^2 + X_c \div Z_3^2$
Admittance $Y_0 = 1 \div Z_0 = \sqrt{G_0^2 + B_0^2}$
Current $I_0 = E_0 Y_0$ and $\cos\phi_0 = G_0 \div Y_0$

The negative sign is used to denote a lagging current in an inductance in multiple circuits.

Resonance. If an inductance and capacity are connected in series, the voltages across them are opposite in sign; if equal in magnitude their resultant or difference is zero. This is resonance in series circuits. If an inductance and capacity are connected in parallel, the two currents will oppose each other; if the currents are equal a large current may flow in each, but the resultant current in the supply circuit is zero or very small. This is resonance in multiple circuits. The phenomenon is utilized to regulate long transmission lines. The line has inductance, while near the load a synchronous motor is installed, which can act like a large condenser. By adjusting the excitation of the latter its capacity effect is varied until it neutralizes the line inductance, and it is possible to obtain a higher voltage at the load than is given by the generating station.

Polyphase circuits. The single-phase a-c system, while simpler to calculate and best for lighting purposes, is not satisfactory for general transmission and power purposes. This is because: (*a*) a polyphase machine, whether generator or motor, weighs and costs less than a single-phase machine: (*b*) single-phase motors will not start from rest without complicated auxiliary devices; (*c*) in transmission work the 3-phase system requires only 75% as much copper for given power and voltage as the single or 2-phase systems. Therefore some commercial installations use 2-phase, while the great majority use 3-phase.

Two-phase system (sometimes called quarter-phase) consists of 2 circuits, which are usually independent and come from independent circuits in the generator. Voltage of each circuit is the same, and it is endeavored to maintain same current in each. This is called balanced conditions. Generally 4 wires are required, though sometimes 3 wires are used, but the latter arrangement is undesirable as it causes poor regulation. The wiring connections of 2-phase circuit are simple, as each phase is treated as an independent single-phase circuit.

Three-phase system saves 25% of the copper required for transmission line, as compared with any other commercial system, and is in general use. Theoretically, it consists of 3 independent circuits, in which the 3 e m f's differ in phase by 1/3 of a period, or 120 electrical degrees. Since the currents in the 3 circuits combine to neutralize each other, the 3 return wires are not necessary, and the outgoing current in each wire returns by the other two without interference with regulation. It is, therefore, common in 3-phase machinery to connect the 3 windings inside the machine so that only 3 conductors are brought out from the machine. There are two methods of making this connection. Fig 17 shows a Y-connected generator feeding a 3-phase line, at the other end of which is a delta (Δ) connected motor. The different voltages in this system have definite ratios as follows: Let E be the voltage between any 2 wires of the transmission line, and I the current in each line: Generator voltage per phase $= E \div \sqrt{3}$. Line voltage (neutral) $= E \div \sqrt{3}$. Motor voltage per phase $= E$. Generator current per phase $= I$. Motor current per phase $= I \div \sqrt{3}$.

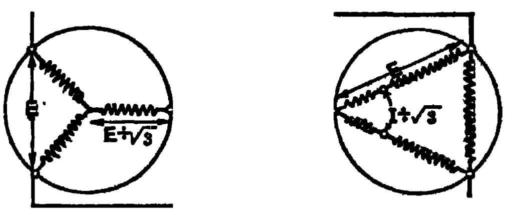

Fig 17. Three-phase Y and Δ (delta) Connections

Choice of Y or delta-connections is a matter of convenience, except for some exceptional pieces of apparatus. To the operator it makes no difference which connection is used, and in fact it is impossible to tell without having the design drawings.

Polyphase transformations. There may be systems of 5, 6, or any number of phases, but the 1, 2, and 3-phase systems are the only ones used for transmission. Some machines have 6-phase windings, but these are always supplied by 3-phase transmission lines. For methods of converting from one polyphase system to another see Art 13.

8. ALTERNATING-CURRENT GENERATORS

Synchronous generators. Field structure consists of a number of poles, excited by coils carrying a d c. The relative motion of armature conductors and field structure generates the voltage. Frequency of the voltage depends directly upon number of field poles and rev per min of revolving part. Revolving-field generators make more effective use of material than those with revolving armatures, and are more easily insulated for high voltages. Most generators of greater capacity than 300 kw are of the revolving-field

type. Advantages: good regulation, high efficiency, and satisfactory operation in parallel. Most alternators built at present are separately excited, because voltage regulators are now available which are simpler and more reliable than the self-excited machines formerly in use. INDUCTION GENERATORS are a special form of synchronous machine, having a revolving-field structure consisting of a spider with bare projecting poles, and one coil of d c which excites all poles.

Induction generators are constructed like induction motors. The magnetic field is of the rotating polyphase type, produced by a c in same windings as the load current. An induction generator must always be connected to a synchronous generator, from which it must receive its excitation. Only a minority of the units of a station may be of the induction type. Advantage: less violent effects in case of short circuits.

Connections (single, two, and three phase). Single-phase generator is usually about 30% heavier and more costly than a polyphase of same rating. Two and three-phase generators of same capacity and voltage are practically of same dimensions, weight, and cost. By changing the internal armature connections any polyphase machine may be reconnected as a 3, 2 or single-phase machine. As transmission by 3-phase currents is more economical of copper than by 2-phase or single-phase currents, all transmission lines are 3-phase; hence, the 3-phase generator is preferable.

Voltage. Alternators are now built for voltages up to 16 000 and 22 000 between lines, either single or polyphase. For higher voltage, owing to extra cost of insulation and danger of damage, it is cheaper to install transformers with a lower voltage alternator.

Frequency depends upon speed of rotation and number of poles. If the rotative speed of revolving part is given in rev per min, the frequency is $f =$ (r p m $\times$ poles) $\div$ 120. Formerly it was found more economical to run alternators at high speeds. Hence frequencies as high as 133 and 125 cycles per sec were customary; but, as systems increased in size and complexity, high frequencies caused electrical difficulties. Usual frequencies are now 60, 50, 40, and 25 cycles per sec, of which 60 is standard in U S. In Europe 50 cycles are used instead of 60.

Single phase. Voltage per phase is the same as between lines, and current per phase same as current per line. The product of voltage and current = volt-ampere rating.

Two-phase or quarter-phase. Each phase supplies half the rating; thus the voltage and current per phase in the machine are the same as the voltage and current per phase of the line. The current is

$$I = \text{Power output in watts} \div 2\,Ep$$

where I = amperes in each line; E = volts between lines; p = load power-factor.

Three-phase machines may be either Y or delta-connected. In both cases the relation between output, current in each line, and voltage between lines is the same:

$$I = \text{Power output in watts} \div \sqrt{3}\,Ep$$

Tests. Principal commercial tests on a-c generators are: resistance, cold and hot; friction; saturation and core loss; synchronous impedance and load loss; heat run and insulation. Friction, core loss, and saturation tests are made during one run; synchronous impedance and load loss during another. For testing, the generator is driven by a small motor of about 1/10 the capacity of the generator. Synchronous impedance is used to calculate regulation of the generator; results of the other tests give the efficiency. Losses are friction, core loss, excitation, armature I^2R or copper loss, and load loss. Efficiency is the output divided by the output plus all losses at that output. Armature I^2R and load loss vary as the square of the load; other losses are approximately constant. Heat runs may be made by operating the generator under normal load conditions, or by a compromise method in which the generator supplies current to a synchronous motor, which runs free and is under-excited, the current being wattless or reactive. Temp of windings after the heat run is determined by comparing their resistance at that time with their resistance when machine was at a known (room) temp.

Usual efficiencies at full load for different sizes of generator are given in Table 8. These values are merely indications and vary with frequency, voltage, speed, power-factor, etc. A 60-cycle low-voltage machine will probably have a better efficiency than a machine of same rating for 25 cycles or high voltage.

Table 8. Usual Efficiencies

Rating, *kva*	Efficiency, %
100	91
500	94
1 000	95
2 000	96
3 000	96.5
5 000	97
10 000	97.2

Regulation of a generator is defined as the ratio of the difference in terminal voltage at no load and at full load to the voltage at full load, the field excitation being kept constant at full load value and the speed being constant. Expressed as a percentage, the regulation is 100 $(V_0 - V) \div V$, where V is terminal voltage at full load and V_0 is terminal voltage at no load, with excitation for full load. Usual value, 5 to 25%.

Operation. In the operation of an a-c generator several factors are considered: EXCITATION. A-c generators of the synchronous type (that in most general use), require d c to excite their field windings; usually obtained from an exciter, which is driven by a separate engine, or by an electric motor, or from the generator itself by belt or other mechanical connection. Usual potential for field circuit is 125 volts, though some machines are designed for excitation at 250 volts. Since most machines have revolving fields, the d c is led into the field coils by collector rings on the main shaft. In series with exciter and field circuit a rheostat is connected, to vary the current in field coils, and thereby the excitation and voltage of the generator. Usual power for excitation is from 0.5 to 2.5% of rating. Before STARTING A GENERATOR its bearings are inspected, cleaned, and oiled. Machine is then brought up to speed, and bearings again inspected to see that oil rings are running properly. Exciter or excitation circuit is then put in readiness, and the rheostat in alternator-field circuit adjusted for maximum resistance. Before exciting the field the armature insulation must be thoroughly dry; otherwise, the armature is short-circuited through an ammeter, and run for several hours at a partial excitation to give about rated current in the short-circuited armature. When insulation is thoroughly dry the short circuit is removed and the excitation adjusted to give rated voltage at armature terminals at correct speed. To stop the machine, load is first removed by opening the circuit breaker; then the field rheostat is turned to maximum resistance, as is also the rheostat in the exciter field if there is an individual exciter. Field circuit is then opened.

Paralleling of generators. Before connecting a generator to the bus bars (to which one or more other generators are connected), following conditions must be satisfied; (*a*) frequency of generator must be the same as that of bus bars; (*b*) frequency of generator, and therefore its speed, must be constant for an appreciable interval of time; (*c*) voltage of generator must be the same as that of bus bars; (*d*) generator and bus-bar voltage must be in phase.

If two machines have not the same frequency, or if frequency is not constant, a condition will occur intermittently in which the voltages are 180° apart, or the machines are in series on a short circuit, and a dangerous current will flow. If voltages are not equal, a large wattless current may flow, and if they are not in phase, a large power current will flow, causing a mechanical shock. Two methods are used for determining when these conditions are favorable for connecting the machines together without disturbance; that is, for indicating when the machines are in SYNCHRONISM. For synchronising with lamps, the connections as in Fig 18a are such that the lamps remain dark when above conditions are satisfied; with connections as in Fig 18b, they will remain bright. If the frequencies are wrong, the lamps will flicker (the slower the flicker the nearer the frequencies). If voltages are wrong, lamps will glow slightly but steadily. SYNCHRONOSCOPE is an instrument which indicates the relative frequencies and phases of 2 alternators; usually installed on switchboard of a station, if a number of generators are used.

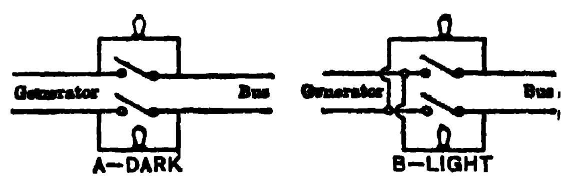

Fig 18. Connection of Lamps for Synchronising

Cost and weight. Generators vary widely in their specific weights and costs, that is, weight and cost per *kva* rating; but they may be divided into classes in which these characteristics are fairly definite. Conditions affecting specific weight are: method of rating, speed, frequency, voltage, and size. Method of rating is fundamental. For comparison, rating is taken as the output in *kva* which each machine will give continuously with a temp rise not exceeding 50° C. On this basis, specific weight decreases as the speed, frequency or capacity increases, and it increases with increase of voltage. A-c generators are divided into 3 classes according to their speeds and purposes: high speed, as turbine-driven generators; medium speed, as belt-driven and water-wheel driven; slow speed, or engine-driven. See Table 17, Art 19.

9. SYNCHRONOUS MOTORS

Operation. Any alternator will operate as a motor. If two synchronous alternators are connected in parallel to bus bars supplying a load, and the driving power is removed from one prime mover, the alternator connected to this prime mover will continue to run at same speed, taking power from the other alternator and driving its own prime mover or other apparatus coupled to it; this alternator thus acts as a motor. Speed of such a motor depends solely upon the speed of the generator or generators supplying electric energy to it; it is therefore said to run in "synchronism" with source of supply and is called a synchronous motor. The speed of a synchronous motor having p poles, and supplied with current of a frequency of f cycles per sec, is: r p m $= 120f \div p$. If load on the motor increases, speed will not decrease, unless load reaches a value so excessive that

the maximum output or "pull-out torque" is reached; then the motor will drop out of step and come to rest, while the current taken will increase to short-circuit value and torque will decrease to a negligible value. Difference in construction between an alternator and a synchronous motor is that the latter has, in the face of the field poles, a squirrel-cage winding, intended to give good starting torque and prevent "hunting" while running. HUNTING defines the occasional undesirable action of synchronous machines, of varying in speed, current, and voltage, at a frequency observable in meters. If excessive, a short circuit results (see Specifications below). A standard 2 300-volt generator will operate satisfactorily as a motor at 2 080 volts, and as these are the natural values of the generated and delivered voltages, this characteristic of the synchronous motor accords well with customary distribution practice. A standard generator may have a squirrel-cage winding added to its poles and become a good synchronous motor.

Number of phases. Synchronous motors may be single, 2, or 3-phase. The single-phase motor is not self-starting, and has a considerably lower efficiency than the polyphase. It is also more liable to hunt and be unstable, and is therefore far less desirable than a polyphase motor. The 2 and 3-phase motors are very similar in all their characteristics.

Terminal voltage. Since synchronous motors are usually built with a revolving field and a stationary armature, the armature winding can be insulated for voltages as high as 13 000, thus often obviating need of transformers.

Relations of voltage and current. Relations between line voltage and phase voltage are the same as in a-c generators (Art 8). Current in each line of a 3-phase motor is: $I = \dfrac{746\,P}{\sqrt{3}\,eE\cos\phi}$, where P = output, h p; E = voltage between lines; e = efficiency at assumed load; $\cos\phi$ = power factor (may be unity). Usual values for efficiency are about the same as for a-c generators.

Advantages of synchronous as contrasted with induction motors: higher efficiency, higher power factor, controllability of power factor with constant speed, high voltage, lower cost. DISADVANTAGES: need of an exciter, will not start as great a load.

Applications. To transform from a c to d c, or from one kind of a c to another differing in frequency, potential, or phase relation, motor-generator sets, consisting of a synchronous motor direct connected to one or more generators, are often employed (Art 6). The potential of the secondary or distribution circuit is thus made independent of the variation in potential of the primary circuit supplying power to the motor. In certain cases it is desired to take power from a 25-cycle circuit and supply power at 60 cycles for lighting purposes. Here a synchronous motor-generator set would be used; often called a "frequency changer." In some applications of electric drive by induction motor one synchronous motor is installed to make it take leading current, in order to neutralize the lagging current taken by the induction motor. This effect is produced by over-exciting the fields of the synchronous motor. The motor may be used to drive any machinery not requiring much starting torque. Such a motor is a "rotary phase modifier" or "rotary condenser" (see below).

Tests of synchronous motors. The first four tests of an a-c generator (Art 8) apply also to synchronous motors.

Phase characteristics, or V-curves at no load, full load, and any other specified load. Machine is operated as motor with specified load kept constant throughout the run. Voltage and frequency impressed upon the motor are also kept constant. Current in the field is varied from minimum at which motor will operate to the maximum (from 0.25 to 1.5 normal), and the variation in current input to armature noted. Readings are taken of load, volts armature, amperes armature, and amperes field. A curve is plotted with amperes armature as ordinates, and amperes field as abscissas. This gives the characteristic V-curves. At point of minimum current input for each load the power factor is unity. At lesser values of field current the armature current lags and power factor is poorer; at greater values the armature current leads.

Starting. All synchronous motors have a squirrel-cage winding in the faces of the poles, which enables them to start as induction motors with a torque of 40% to 80% of rated torque. The induction motor action brings the speed up to about 95% of synchronous speed. Then the field switch is closed and a strong field supplied. This causes the rotor to pull suddenly into exact synchronism. Frequently there is a "Field Breakup Switch," which is kept open during starting and closed just before pulling into synchronism. This protects the field windings from breaking down, due to the high voltage induced in them at low speeds. If there is considerable flywheel mass in the load it is difficult for the motor to pull into synchronism. Special synchronous motors are available for unusual starting requirements. After the motor has reached synchronous speed, the full load may be applied and the field rheostat adjusted to give minimum armature current, or a leading power factor if the motor is designed for that particular operation.

Installation and operation. Precautions to be taken in installation are the same as for a-c generators (Art 8). Direct current must be provided for excitation. If a synchronous motor is operated on a polyphase system having unbalanced voltages, it will take unequal currents in the different lines and tend to balance the voltages. But these unequal currents increase the heating for a given load.

Specifications. Synchronous motors are rated in same manner as synchronous generators, and same heating limits and specifications apply (Art 8). It is customary to specify the value of current taken by the motor in starting with no load other than the friction of its own bearings; or its own friction plus that of the machine to which it is connected, in case it is part of a motor-generator set. It is sometimes stated in specifications that the motor will not hunt, provided the total resistance drop between generator and motor is less than some specified value (10 or 15%).

Dimensions, weight, and costs are given in Table 19, Art 19.

10. INDUCTION MOTORS

Principles. Induction motor is a machine having distributed windings, like those of the armature of a d-c machine, on both stationary and revolving members. One winding, the primary, receives polyphase currents from the supply circuit and thereby sets up a rotating magnetic field. This field cuts the conductors of the secondary winding, induces currents in it, and thereby drags it along with the field. The action is reversible; either member may be the primary, provided it is connected to the line. That member which remains stationary, whether it be primary or secondary, is called the stator; the other, the rotor. In U S the stator is usually primary.

Synchronous speed. Speed of rotation of the magnetic flux is called the synchronous speed. At light loads the rotor speed is nearly equal to the synchronous speed. If f is the frequency of the current, and p the number of poles of motor windings, the synchronous l is: rev per min = $120 f \div p$.

Slip. At any appreciable load the rotor speed is less than the synchronous speed. Difference between the actual rotor speed N_1, and synchronous speed N is "slip." It may be expressed as a percentage or a fraction: $S = (N - N_1) \div N$.

Methods of rating. Amer Inst of Elec Engs recommends that the rating of an induction motor shall be the h p which it will deliver continuously at the shaft with a maximum rise in temp not injurious to its insulation (Art 1).

Starting and break-down torque. In addition to the ability to carry its rated load without excessive heating and with reasonable values for efficiency, power factor, and slip, the motor should be able to start such loads as must be brought up to speed, because good starting ability in an induction motor involves certain complications and expense. It is important also that the motor be able to carry momentary overloads without "breaking down," that is, gradually coming to a standstill. To prevent this the max motor output must be known and should be at least 50% greater than rated output.

Frequency and speed. Induction motors can be built for any frequency. The higher frequencies are satisfactory where the load never exceeds the normal. Frequencies as low as 25 are preferable where overloads are common, or large starting torques are required. Rotor speed of an induction motor at normal loads approaches within 5 to 10% of the synchronous speed, which is fixed by the frequency of the system and its number of poles (see above). Hence, for a given frequency of supply circuit, only certain speeds are available. Thus, for 60 cycles, the rev per min are: 3 600 for 2 poles; 1 800 for 4 poles; 1 200 for 6 poles, etc.

Phase connections. Two-phase or quarter-phase motors are usually wound with independent phase windings. Three-phase motors are connected in Y or delta, depending upon convenience of designing engineer. In single-phase and 2-phase motors the voltage and current per phase are the same as voltage between lines and current in line; in a Y-connected 3-phase motor, the current per phase is equal to line current, and voltage per phase is equal to line voltage divided by $\sqrt{3}$; in a delta-connected 3-phase motor the current per phase is equal to line current divided by $\sqrt{3}$, and voltage per phase is equal to line voltage.

Table 9. Power Factors and Efficiencies at Full Rated Load for Polyphase Motors

H p	25 cycles		60 cycles	
	Effic	Power factor	Effic	Power factor
1	0.79	0.78	0.78	0.78
5	0.85	0.88	0.82	0.88
20	0.88	0.91	0.84	0.91
50	0.90	0.92	0.87	0.92
100	0.905	0.925	0.89	0.92
200	0.91	0.925	0.905	0.92

Currents taken by motors. Let: P_0 = output, h p; I = current in each line; e = efficiency as a decimal fraction; $p = \cos\phi$ =

power factor as a decimal fraction; E = voltage between lines (between one outside wire and the middle wire for 3-wire, 2-phase line). Then, for 2-phase: $I = 373\,P_0 + peE$; for 3-phase: $I = 431\,P_0 + peE$.

Testing. Induction motors may be given an "input-output" test (Art 5) at working load, from which efficiency, power-factor, slip, and maximum output may be determined; or, a no-load excitation and a no-load short-circuit test, from which all characteristics may be calculated. The former is similar to a stray-power test (Art 5) on a d-c motor, the latter to a resistance measurement. No-load tests require very little power, and are preferable for large motors, where it would be expensive to supply power and inconvenient to dissipate the energy. They are equally accurate.

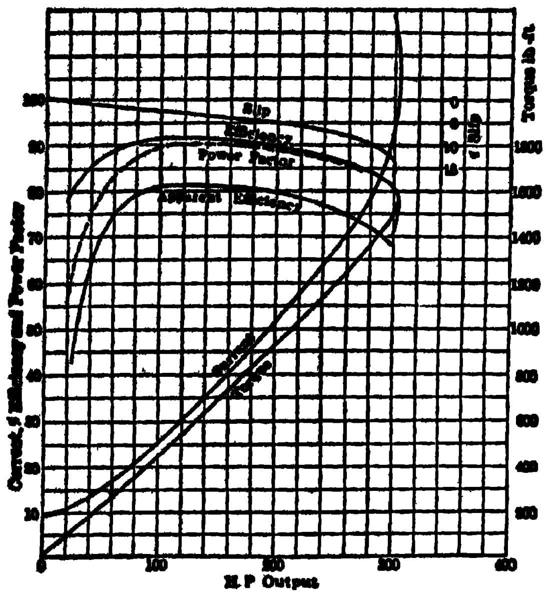

Fig 19. Characteristic Curves of a Three-phase Induction Motor

Characteristic curves. Fig 19 shows examples of the usual characteristic curves of an induction motor. Typical break down of all the curves at maximum output is shown at 300 h p. Power-factor curve shows relation between the true power input and the apparent power, or volt-amperes. Low power factor involves no greater registration of the watt-hour meter, or cost of energy to operate the motor, but does involve poor voltage regulation of the system as a whole and a larger capacity of wiring, transformers, etc. Apparent efficiency is the product of the power factor and true efficiency, and is equal to output in watts divided by input in volt-amperes. Its value determines the actual capacity of the line and transformer supplying the motor.

Starting. To start an induction motor without injurious heating, a resistance must be connected in the secondary circuit, or the voltage impressed upon the primary must be reduced. These methods are known as RHEOSTATIC CONTROL and POTENTIAL CONTROL. They are also available to control the motor speed.

Potential control consists in reducing and regulating the voltage impressed on the primary, usually by a starting compensator or auto-transformer, which provides 1 or 2 fractional voltages. For this the secondary must be of higher resistance than with other methods of starting, but no changes of connection of the secondary are necessary. Hence, a squirrel-cage rotor winding is used, made of one bar per slot, all bars being connected at both ends to solid copper rings. To start the motor the primary is connected to taps on the compensator, which give a voltage of from $^1/_2$ to $^2/_3$ the rated voltage if it is a small motor, and $^1/_3$ to $^1/_2$ if it is large. A small motor may be brought up to speed with this voltage, but a larger one may require an intermediate step. When motor is up to speed (indicated by the low, steady value of the current) it is connected to full line potential.

Rheostatic control. Better apparent torque efficiency, that is, more torque for a given current, is obtained by inserting in the secondary circuit a much greater resistance than can be permanently used. To do this a special starting resistance is connected in series with each of the 3 armature windings, and a switch provided for short-circuiting the resistance, either step by step or as a whole, as the motor speeds up. There are two commercial methods. The first is for use only when the torque required at starting is not great, in which case the starting resistance may be small and placed within the armature spider. The switch lever is so arranged that the resistance can be short-circuited in steps while armature is revolving, thus obviating the need of collector rings and external connections. Second method, for large starting torque, consists of bringing the 3 terminals of the secondary winding to collector rings. From brushes on these rings conductors lead to external resistances, with steps or taps, so that the resistance can be short-circuited gradually by a controller.

Speed control. Speed of an induction motor may be controlled in 5 ways: (*a*) By varying the potential applied to the primary of a motor having suitable permanent resistance in the secondary. (*b*) By varying the resistance in external circuit of the secondary. (*c*) By so changing the internal connections of primary winding as to change the number of poles. (*d*) By connecting two motors in "concatenation" (similar to series connection). That is, the stator of first motor is connected to the supply, rotor of first motor is connected directly to rotor of the second, and stator of second motor is treated as its secondary. (*e*) By changing frequency of the applied voltage. Method (*b*) (rheostatic) is the most general and practical where more than 2 speeds are required; any speed may be obtained. Method (*c*) is best where only 1 motor is available and only 2 speeds are required. Method (*d*) requires 2 motors and gives 2 speeds; not as desirable as (*c*). Method (*e*) is of theoretical interest only.

Installation. Induction motors, even in large sizes, are usually self-contained, the bearings being a part of the end frame of the motor. They are either direct-connected or

belted. Belt drive is the commoner, since an induction motor can be built only for a definite speed, corresponding to a certain number of poles. Small motors need no foundation, and are often attached to the wall or ceiling, the bearings and end shield being so made that they may be turned through 90° or 180°, for proper operation of the oil rings. Most motors must have reasonable ventilation, free from dust and dirt. For severe service, as in cement mills or mines, motors are built totally inclosed (" iron-clad ") and may then be even submerged in water. This increases both size and cost.

Operation. Small motors are designed to start merely by closing the main switch. With larger motors, if starting switch is in proper position, potential may be applied to the motor, and the starting resistance gradually cut out by the switch. Induction motors are very sensitive to variations in the impressed voltage. A decrease from 100 to 80 volts will cause the maximum output and starting torque to decrease from 100 to 64, with a roughly proportional increase in heating for a given load. UNEQUAL VOLTAGES in the different phases cause decrease in maximum output, and increase in heating for a given output. An unbalancing of 25% in voltage doubles the heating effect at full load; giving the same heating as 50% overload. CARE IN STARTING. Before starting for the first time, see that the starting device is in operating condition and in proper position, to avoid injurious heating. Wiring must be proportioned to carry the starting current without an excessive drop in voltage (see above).

Faults. Some of the common faults in induction motors, with their indications and remedies, are: SECONDARY OPEN-CIRCUITED. Motor will not start, and will not take a current greater than exciting current; probably due to the starting resistance not being connected in. ONE PHASE OF SECONDARY OPEN-CIRCUITED. Motor tends to remain at half synchronous speed, although the current is apparently normal. If the armature is blocked, the currents in primary will be unbalanced. ONE PHASE OF PRIMARY OPEN. Motor will not start, and current will be unbalanced. ONE PHASE OF PRIMARY REVERSED. Currents in primary will be very much unbalanced when motor is running, and starting torque will be very slight. SHORT-CIRCUITED COIL IN PRIMARY. There will be humming when potential is applied to the motor and excessive local heating around the short-circuited coil. VIBRATION due to mechanical unbalancing is chiefly noticeable at high speeds, particularly in high-speed machines. If vibration is due to magnetic unbalancing, it is probably caused by inequality in the air gap at different portions of circumference, and at different positions of armature. It may be detected by measuring the air gap with taper wedges at different points around the circumference, with the armature in several positions.

Specifications. Following memoranda (from Amer Handbook for Elec Engs) will assist in framing specifications: PRINCIPAL CHARACTERISTICS AND CONDITIONS OF SERVICE. Use to which motor is to be put; kind of load and method of drive; voltage and number of phases; rating, horse-power; frequency and speed. STYLE AND DESCRIPTION, CONSTRUCTION DETAILS. Whether to be open, semi-inclosed or inclosed; requirements regarding pulley and length of shaft; whether rails are required; method of starting; compensator, external resistance or internal resistance; whether motor is to be run at speeds other than full speed; whether starting devices are to be supplied. PERFORMANCE AND TESTS. Final temp rise at full-rated load; temp rise in 2 hr at 25% overload applied immediately after full-load run; efficiency at 25, 50, 75, 100, 125, and 150% load; starting torque with full-load current, ft-lb; high-potential tests of insulation; requirements as to effect of moisture upon insulation.

Weight and cost of induction motors vary with type of armature winding and character of mechanical frame and housing; also with speed, frequency, and voltage. Table 18, Art 19, gives weights and costs for standard 60-cycle motors.

Single-phase motors may be of either induction or commutator type. INDUCTION TYPE is the commoner, as its constant-speed characteristic is more generally appropriate than the variable speed of the usual commutator a-c motor. A 2- or 3-phase induction motor may be operated as a single-phase machine after it is once up to speed; but it has lower efficiency and power factor, and smaller maximum output than it would have as a polyphase motor. Slip, for a given output, is less in a single than in a polyphase motor. Because of the poorer operating characteristics, and especially the smaller maximum output or maximum torque, the motor must be rated at lower capacity when run single phase. A single-phase motor having same frame and wt of iron and copper as a polyphase motor will rate at from 60 to 70% of the capacity. Single-phase induction motors usually consist of standard 3-phase motors with their rating changed; thus a 10-h p, 90-volt 3-phase motor would make a typical 7.5-h p, 120-volt single-phase motor. STARTING. A single-phase induction motor has no torque at standstill, and must be started by some such means as a phase-splitting device. A common method is to connect a Capacitor in series with one phase winding of a special wound polyphase motor. This gives a good starting torque and improves the power factor under running conditions. Or, a commutator on the rotor may be used, making it possible to operate as a repulsion motor (see

below) having good starting qualities. After reaching considerable speed the brushes are removed and the secondary windings are short-circuited.

Commutator type. The several types of a-c commutator motors designed to operate on single-phase circuits differ chiefly in their electrical connections. They may be divided into series motors and repulsion motors. Both have an armature wound like that of a d-c motor and a commutator. SERIES A-C MOTOR is connected like a d-c series motor, and has the same general characteristics. Principal difference is that the a-c motor has an extra winding placed in the face of the poles and connected in series with armature and field. This winding improves the power factor. Limiting feature of most a-c commutator motors is sparking at the brushes, which is much worse than in d-c motors. REPULSION motor has a stationary structure or field (primary) with a completely distributed winding like that of an induction motor. The winding may be for any voltage. The armature or secondary is like that of a d-c commutator motor. The commutator brushes are short-circuited upon themselves, and are placed at a small angle away from the neutral. This motor acts like a combination of transformer and series motor, having the variable speed, high torque, and runaway characteristics of the series motor. It is started by applying a reduced potential to the primary, and is reversed by moving the brushes or by reversing the current in one particular portion of the primary winding known as the exciting turns. REPULSION-INDUCTION TYPE of motor is made in small sizes to drive machinery requiring good starting torque. It is a repulsion motor with extra brushes on the commutator, the brushes being connected across a portion of the primary. This gives a constant speed characteristic like a shunt motor, and a good power factor.

11. SYNCHRONOUS CONVERTERS AND RECTIFIERS

Since it is more economical to transmit electrical energy in the form of a c and more convenient to utilize it in the form of d c, some means of converting it from one form to the other is desirable. For this purpose synchronous converters, motor-generator sets (Art 6) and rectifiers are available.

Synchronous converter, also called "rotary converter," is similar to a d-c generator, in which certain commutator segments, or the conductors leading from them, are connected to 2, 3, 4, or 6 collector rings. When the movable member rotates, the voltage between any 2 rings is alternating. Such a machine may be operated as an a-c generator, or as a "double-current" generator giving a c from its collector rings and d c from its commutator. If the rings are connected to an a-c source, the machine will run as a synchronous motor, and d c may be obtained from the commutator brushes; that is, the machine with but one set of windings acts simultaneously as an a-c motor and a d-c generator. It therefore has the friction, core loss, and excitation loss of one machine instead of two: and since the motor and generator currents flow in the same winding, and opposite directions, they more or less balance each other, and the armature RI^2 loss is much less than in either a motor or generator alone.

Converter *versus* motor-generator. A converter is much more efficient, weighs and costs less than a motor-generator set of same capacity, and occupies less space. But, since only one winding is used, there is a definite relation between the voltages of the a-c and d-c terminals. Maximum value of the alternating wave bears a definite relation to the direct e m f (see below). The converter must therefore be supplied with a voltage of the same order as the direct voltage, which requires transformers if a high-voltage transmission line is used to supply the converter. EFFICIENCY of a converter approximates 93%, and of the transformers, 97%; the efficiency of the combination is therefore about 90%. Efficiency of a synchronous motor is about 93% and of a d-c generator, 92%; hence the combination motor-generator set has an efficiency of 85.5%. If the supply voltage is greater than 13 000 volts, transformers will also be needed for the motor-generator set, the net efficiency being then 83%.

Application of converters is commonest in electric railway work. Nearly all motors for electric traction are of d-c series type, operating at 500 to 600 volts. For this service the energy is transmitted over long distances, requiring a high-voltage a-c transmission line and converters to link the d-c distribution with the a-c transmission.

Phases and rings. SINGLE-PHASE CONVERTER has 2 collector rings, each connected to the windings by as many equally spaced taps as there are pairs of poles. The taps for the 2 rings alternate

at equal spaces. A single-phase converter is therefore a 2-ring converter. THREE-PHASE CONVERTER has 3 rings and 3 equally spaced taps (one for each ring) for every pair of poles. A 4-phase or quarter-phase converter has 4 rings and 4 taps, and a SIX-PHASE CONVERTER has 6 rings and 6 taps, per pair of poles.

Shunt and compound-wound converters. A converter may be shunt or compound wound, depending upon the service. Series winding is intended to make the converter take leading current when the load increases, and thus increases the voltage at the a-c terminals, but the ratio of the a-c terminal voltage to the d-c voltage remains unaltered.

Inverted converter converts from d c to a c. It works satisfactorily, but its speed depends upon nature of the a-c load. An inductive load in the a-c circuit causes the armature to demagnetize the fields, with a resultant increase in speed. It is therefore dangerous to operate an inverted converter on an inductive load, unless it is provided with a speed-limit device. This does not occur when the machine operates as an a-c motor, since its speed is fixed by the frequency of the supply circuit.

Connections and voltage ratios. The ratio of voltage on the a-c side to that on the d-c side depends upon the number of rings and type of connection (Table 10). In practice the current on input side must be greater than that given in the table, in order to supply the converter losses, and the a c will also vary inversely as the power factor, which is taken as unity in the table. There are other losses besides RI^2; hence practical figures for output differ slightly from those in the table.

Table 10. Voltage, Current, and Capacity Relations of Converters

	D-C generator	Converters					
		2 ring	3 ring	4 ring	6 ring diametrical	6 ring double delta	12 ring
D C, volts	100	100	100	100	100	100	100
A C, volts between lines	...	71	61.2	71	71	61.2	71
A C, volts between rings	...	71	61.2	50	35	35	18
D C, amperes	100	100	100	100	100	100	100
A C, amperes in line	...	141	94	71	47	47	24
A C, amperes in winding	...	71	55	50	47	47	45
Relative RI^2 loss	100	137	55	37	26	26	20
Relative output, unity power factor	100	85	134	165	197	197	224
Relative output, 87% power factor	...	. .	99	115	129	129	135

Testing. Converter tests are practically the same as those on a synchronous motor (Art 9), with the addition of a test on ratio of a-c to d-c voltage, taken at no load and at full load.

Regulation. A converter, like a synchronous motor, may be used to cause a rise in voltage in the transmission line supplying it. It is done by over-exciting the fields. The voltage on the d-c side will rise correspondingly, and thus the machine may be compounded. For this to take place there must be considerable inductance between generating station and converter.

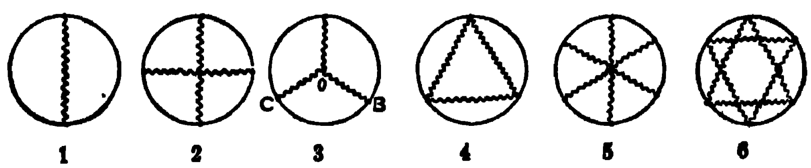

Fig 20. Transformer Connections and Vector Relations of Synchronous Converters

Operation. As a converter exerts no appreciable mechanical torque, its structure and foundations are light. Fig 20 shows usual modes of connecting transformers to supply converters. The transformer secondaries must give a voltage which is a definite fraction of the direct voltage desired (Table 10).

Starting. A converter may be started by either of the methods described for synchronous motors, or it may be speeded up as a shunt motor, and then synchronized with the a-c supply circuit like an alternator (Art 8). All converters are supplied with a "field break-up switch," which opens the field circuit in several places to avoid the strain of the high potential induced in field windings during starting, and to reverse direction of field current after the machine is up to speed, in order to reverse the polarity if necessary. This is usually a double-throw switch with several poles. For normal operation it is thrown down to "running" position. To change the polarity it is thrown up to "reverse" position and left closed only for a moment; then it is returned to "running" position. SPEED-LIMITING DEVICE. If a converter be disconnected from the main a-c supply circuit, and still remain connected to the d-c circuit, it will tend to operate as a

d-c motor, and its speed might become dangerously high. To avoid this a centrifugal governor placed on the shaft opens the main d-c switches of the converter.

Rectifiers. The operation of a mercury-arc rectifier depends on the facts that: (1) a tube containing mercury and mercury vapor under low pressure (less than 0.01 mm), having one electrode in the mercury (the cathode) and the other of some conductor, usually graphite (the anode), offers very high resistance to a current tending to flow from the mercury to the anode, but (2) offers very little resistance to a current flowing from anode to cathode, provided the current is once started by forming an arc inside the tube. An alternating e m f impressed on this tube will cause a unidirectional current to flow in separate pulses. With two anodes and one cathode, with suitable connections, the pulses are largely smoothed out, and with some inductance in the circuit a unidirectional current with but little variation is obtainable. In practice a 3-phase alternating current is usual, with 3, 6 or 12 anodes in the tube, producing a direct current of almost no pulsation.

Losses. In such a rectifier there is a loss in voltage of 20 to 30 volts, no matter what the working voltage or current, and the product of this voltage and the current used gives the rectifier loss in watts. There is practically no other loss in the rectifier, but there are other losses in the auxiliary apparatus, transformers, vacuum pumps and cooling water circulator. An auxiliary "starting anode" is necessary. This draws an arc giving the initial ionisation to the mercury vapor; after which the working current maintains the ionised conditions.

The anode tank is of steel, insulated from the ground, with elec connections to the several electrodes carried through the tank walls by special "insulating seals," of porcelain or a special glass, in which the different materials have the same heat expansion coefficient. This tank is surrounded by another tank and between them circulates water for cooling. The inner tank is maintained at a vacuum of 1 to 5 microns (the upper limit of successful operation being 10 microns, or 0.010 mm) by two pumps in series, a mercury condensation pump operating continuously for fine adjustment and a rotary pump for coarse work. The latter operates only occasionally.

Applications. Mercury-arc rectifiers are chiefly used to supply direct current to railways at voltages of 600 and greater. They are at their best at high voltages, because their efficiency is higher, but operate satisfactorily at 200 volts with a lower efficiency and greater bulk and cost per kw.

Hot-cathode mercury rectifier, known to the trade as "phanotron," has a hot cathode of a suitable metal which emits electrons, and contains a small amount of mercury in form of vapor. This operates as a rectifier with much smaller values of current than the pool type, but with about half as much loss in voltage and therefore with a higher efficiency at low voltages, and is suitable for circuits of 125–250 volts, though not yet in very general commercial use.

Tungar rectifier is similar to the preceding, except that it uses argon gas in a glass tube and is suitable for lower voltages, 60 volts or less, and small currents, 15 amp or less. It is useful for charging storage batteries and is cheaper.

Copper-oxide rectifier is a very simple device, consisting of a pile of copper plates whose surfaces have been treated in a particular manner. It can rectify alternating voltages of the order of a few volts, but has current capacity up to hundreds of amperes.

12. ELECTRIC POWER PLANTS (See also Sec 16)

Location of an electrical power plant is governed by: form of power; distribution of load; cost of ground; possibility of good foundations; room for extension; convenience of coal, and of water supply for evaporation and condensing; limitation of voltage used.

Form of power, whether steam or water, is usually definitely determined by local conditions. Choice between steam, gas, or oil depends chiefly on relative cost of fuel and of maintenance of an oil or gas engine. If steam is to be used, the choice between turbines and reciprocating engines is governed largely by size of units; in large sizes the steam turbine costs less per h p and is cheaper to operate, while in small sizes the reciprocating engine is more economical. In designing a power plant and selecting the number and size of units, it is important that the total capacity be sufficient to carry the maximum load with margin, and that it be divided into units of a size to carry average load economically. Each unit is usually capable of carrying 25 or 50% overload for 2 hr. There should be at least 4 units in a large plant, and nothing is gained by having more than 8 units. A sufficient number of exciters are necessary to carry the peak load, with one exciter to spare. Transformers are commonly arranged in groups, one group for each generator. In hydro-electric plants it is often advisable to install 1 or 2 steam-driven units and boilers, to serve if water supply should fail (see also Sec 16).

Alternating vs direct current. Choice depends upon length of transmission line and value of energy. For utilising all the energy within a short distance of the generating

station d c is preferable, because d-c motors (particularly in small sizes) are more convenient, easier to control, and are available in greater variety of form and characteristics than a-c motors. But the voltage obtainable from a d-c generator is limited by the commutator to about 600; and, for transmission to a considerable distance by d c, the quantity of copper becomes prohibitive; hence a c is used, and with the a-c transformer the transmission line potential is independent of the voltage at either generators or motors. The dividing line between the best fields for d-c and for a-c plant is not clear cut, and can be determined only by careful calculation and comparison of costs. Some installations use a-c generators and a c for transmission, but these are converted into d c in sub-stations near the point of utilization, and at a distance from the generating station. When the sub-station cost is less than the difference between the cost of the copper requisite for d c and for a c, the a-c system with sub-station is preferable. If the a-c system be chosen, 3-phase generators are advisable, as 3-phase transmission requires 25% less copper than 2 phase or single phase, and there is no advantage in the 2 phase over the 3 phase. If the power plant is for a varied service, including lights as well as motors, the frequency should be 60 cycles, because incandescent lights operated at 60 cycles are satisfactory, while at 25 cycles the flickering is harmful to the eyes. Transformers for 60 cycles are considerably cheaper than those for 25 cycles.

Voltage. The most convenient and widely used voltage for a local power plant is the 220–240 volt 3-wire system, in which two 110-volt generators are connected in series, or a 220-volt generator and a balancer set provide the 3 voltages. In this case the electric lights and small motors are connected to the 110 volts from the neutral to either of the outside wires, while all the large motors receive 220 volts from the 2 outside wires, thereby saving in copper. If 110 volts were used, either an excessive amount of copper would be required, or the voltage on the lamps would vary enough to cause dissatisfaction. For a number of large motors, 500 volts is generally used, but the lighting problem then becomes difficult, as the lamps must be connected in groups of 4 in series, and if any one of the 4 burns out, all in that group go dark. 500 volts is also undesirable in damp places, as in a mine, because there is danger of an unpleasant shock, particularly to horses or mules. The 220-volt, 3-wire system is therefore best, if d c be used.

For the 3-phase a-c system the distribution circuits are best run with 4 wires, with 208 volts between the outside wires and 125 volts between each phase and the neutral. Lights are connected between each phase and the neutral, balancing the load on the 3 phases as nearly as possible, and 3-phase 208-volt motors used on the 3 phases.

Lowest standard voltage for transmission is 2 200, which will take care of reasonable loads within a radius of 1 or 2 miles from the power station, stepdown transformers being used to supply the different sections of the area.

Arrangement. It is common practice to divide the power station, if steam or gas driven, into two parts, separated by a fireproof, dustproof wall. On one side are the boilers or gas producers; on the other, the prime movers, generators, and all electrical apparatus. In the simplest form the boilers are set in a single row along one side of this wall, and the generating units along the other side, the piping being so arranged that any engine may be supplied from any boiler. If transformers are used, they are generally placed in the room with the generators, but on opposite side and on the lowest level, the switchboard being in a gallery above. Cables from generators to switchboard are laid underneath the floor and running up the side of the wall.

Switchboards are of 2 kinds: DIRECT CONTROL, in which case the current is carried by bus bars immediately behind the switchboard panel, the opening and closing of switches in this circuit being effected directly by the operator; and REMOTE CONTROL, in which the current is carried by conductors placed in brick compartments in the basement, and the connections are made by electrically operated switches controlled by a small relay circuit coming from control switches on a benchboard above. If potential is 2 200 or less, and power is less than 5 000 kw, direct control is satisfactory and feasible, but for greater voltage or power the remote control system is preferable.

Switchboard is divided into a number of units, each known as a panel. There are generator panels, exciter panels, and feeder panels, and at one end of the switchboard is a voltmeter; also, in an a-c station, a synchroscope is placed on a swinging bracket, which may be distinctly seen from any part of the switchboard. A circuit-breaker is a switch which opens the circuit when current is excessive; operated by hand or automatically by the current itself. While the make-up and arrangement of the different panels may vary greatly according to individual ideas, the essentials are common to all, as follows. D-C GENERATOR PANEL, 2-wire system: 1 circuit-breaker at top of board, 1 ammeter, 1 hand-wheel for rheostat, 1 field rheostat back of board, 1 single-pole field switch, 1 triple-pole main switch (or 1 double and 1 single-pole) for the equalizer, 1 4-point voltmeter receptacle. D-C FEEDER PANEL 2-wire system: 1 single-pole circuit breaker, 1 ammeter, 1 double or 2 single-pole main switches, 1 4-point voltmeter receptacle, 1 watt-hr meter. A-C GENERATOR PANEL, 3 phase: 3 ammeters, 1 3-phase wattmeter, 1 field ammeter, 1 double-pole

field switch, 1 handwheel for rheostat, 1 synchronizing receptacle, 1 potential receptacle, 1 3-phase oil switch, 3 disconnecting switches, 2 current transformers, 1 potential transformer, 1 voltmeter for group, 1 synchronizer for group. A-c FEEDER OR OUTGOING LINE PANEL, 3-phase: 3 ammeters, 1 3-phase oil switch, 3 disconnecting switches, 1 polyphase watt-hr meter, 3 current transformers. A VOLTAGE REGULATOR may be used, requiring an independent panel.

Costs. See Art 19.

13. ELECTRIC TRANSMISSION

Types. Transmission may be in form of single-phase, 2-phase or 3-phase a c, or as d c. Single-phase and d-c systems require 2 wires; 3-phase, 3 wires; 2-phase, 4 wires. For given voltage between wires the relative weights of copper are: single-phase and 2-phase, 100; 3-phase, 75; d c, 50. Because of the limited voltage at which d c is obtainable, it is not applicable to long distances. Single-phase system is used where the object is lighting only, on account of its simple connections. For important transmission problems the 3-phase system would be chosen (Sec 16).

Line drop is the difference between voltage at generating station and at the load. It is usually expressed as a percentage of the delivered voltage, and most transmission lines are designed for 10% drop when transmitting full or rated load power. In general, the weight of copper required varies inversely as the line drop allowed. This is not strictly true in a-c systems, but is exact in d-c systems, and the relation may be written: $W = 125\ PD^2 + KE^2$, where W = wt of copper, lb; P = power delivered, watts; D = distance one way, in thousands of ft; K = ratio of power lost in line to power delivered; E = voltage delivered.

In an a-c system the inductive reactance must be considered, as well as the resistance. Resistance for a certain length of given size of wire is obtained from a wire table, and is prorated for the given distance. Inductance in henries per mile for one wire of a transmission system is given by: $L = 74 \times 10^{-5} \times \log_{10} (2\ D + d)$, where D = distance between wires, and d = diam of wire, both in inches. Reactance in ohms is $x = 2\ \pi fL$, where f is the frequency. In a single-phase transmission the total resistance and reactance are twice the above values. In a 2-phase circuit, the resistance and reactance per phase are twice the above values. In a 3-phase circuit, the resistance and reactance per line or per Y-phase are used, and these are the values given by the above formulas.

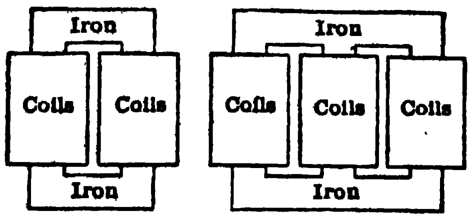
Line regulation depends upon: line resistance and reactance, the current, and power factor of the load. It may be calculated by: $E_0^2 = (pE_1 + IR)^2 + (IX \pm qE_1)^2$, where E_0 = voltage at generating end; I = load current per line; $p = \cos\phi$ and $q = \sin\phi$ at the load; qE_1 is negative for anti-inductive load; E_1 = voltage at receiving end; X = reactance of line; R = resistance of line. For single-phase, E_1 is the voltage at the load, and R and X are taken as the sum of outgoing and return circuits. For 2-phase, E_1 is the voltage per phase at the load, and I is the current per phase in a 2-phase system (Art 7); R and X being taken for the complete circuit of one phase, outgoing and return. For 3-phase, E_1 is the voltage to neutral at the load = 0.58 × voltage between lines; I is the current per line, or Y current; R and X are taken for one line, one way. This gives E_0, the voltage to neutral at generating station. Voltage between lines is then 1.73 E_0.

Size of wire for an a-c transmission. Select first a wire which gives an allowable resistance drop (IR = 5 to 10%), and then find loss in voltage [E_0 (generator) − E_1 (load)] due to combined effect of R and X. If loss be too great, select a larger wire and try again. To obtain a solution in one calculation is too complicated a problem except for experts. Remember that the impedance drop in the line (IZ) is usually much greater than the difference between generator and load voltage due to vector relations. Usual voltages for transmission work are: 2 200, 6 600, 13 000, 19 000, and 33 000 volts between lines, whether single, 2 or 3-phase. A rough rule for choice of voltage is to allow 1 000 volts for each mile of distance between generating station and load. Usual sizes of wire are from No 4 to No 0000 B & S gage in solid conductors and larger sizes in stranded conductors (Table 4). Smaller wire than No 4 has insufficient mechanical strength. Wires larger than No 0000, if solid, would be too stiff, and would break from the repeated bending to which they are subjected.

Stranded conductor. Gage number or rating of a stranded conductor is that of a solid conductor having same cross-section of metal. Resistance and weight of a stranded conductor are greater for a given length than of a equivalent solid conductor, due to the twisted path (and hence greater length) of the individual wires. Actual length of path of the current is increased by about 7%. In spacing the 2 wires of a line, it is usual to allow about 1 ft for every 10 000 volts.

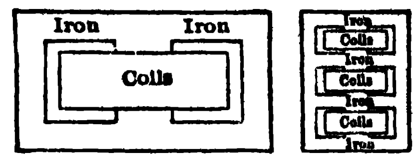
Transformer, commonly called static transformer, is used to transform a c of a given voltage to a higher or lower voltage. Single-phase transformer consists of 2 electrical circuits, usually of a large number of turns, interlinked with a common magnetic circuit of iron. Since the power is approx the same in both windings, the currents are inversely value

proportional to the voltages. Polyphase transformer is essentially two or more single-phase transformers, made into a single piece of apparatus, and so designed that at least part of the magnetic circuit is common to all the phases. A 3-phase transformer has 3 high-tension and 3 low-tension windings, arranged on an iron core (Fig 21). The winding by which energy enters the transformer is the PRIMARY; that by which it leaves, the SECONDARY. Since either winding may be connected to the source of energy, these terms are not definite unless the manner of connection is also stated. HIGH-TENSION WINDING and LOW-TENSION WINDING are used to distinguish the two windings, the high-tension being the one with the greater number of turns. When the high-tension winding is connected to the source of supply, it is a STEP-DOWN TRANSFORMER; when the low-tension winding is so connected, it is a STEP-UP TRANSFORMER.



Single Phase   Three Phase

Fig 21. Core-type Transformers



Single Phase   Three Phase

Fig 22. Shell-type Transformers

Classification of transformers. (A) according to operating characteristics. CONSTANT-POTENTIAL transformers are intended to give an approx constant potential on the secondary side; CONSTANT CURRENT, to give an approx constant current on the secondary, for arc lamps. Both are designed to operate on a constant-potential supply circuit. SERIES TRANSFORMERS are connected in series with the main circuit and receive the line current in the primary. The secondary circuit includes only a meter and the secondary current will be inversely proportional to the transformer ratio. They are used to step down very heavy currents for purposes of measurement by low-reading ammeters and wattmeters. AUTO-TRANSFORMERS or COMPENSATORS, sometimes called single-circuit transformers, consist of one electric circuit interlinked with a magnetic circuit and a tap brought off from some part of the winding. As the voltage between this tap and either terminal of the circuit is a fraction of the total, a fractional voltage may be secured. Windings on each side of the tap are usually proportioned to the current to be carried. Auto-transformers are desirable where the ratio of voltages approximates unity, as they then require much less copper than regular transformers. POTENTIAL REGULATORS are transformers in which the voltage of one member may be varied from zero to a fixed maximum, either by changing the direction of the magnetic flux or by changing the phase of the e m f of the secondary with respect to that of the primary.

(B) according to construction. There are two methods of arranging the electric and magnetic circuits of transformers, the corresponding construction being called "core-type" and "shell-type." CORE-TYPE transformer (Fig 21) has a single magnetic circuit interlinked with 2 electric circuits, each electric circuit containing primary and secondary coils. It is best adapted to small sizes or high voltages and to oil cooling, and is the commoner. The 3-phase core-type is a combination of 3 single-phase transformers into one, to save material and space. SHELL-TYPE (Fig 22) has 2 magnetic circuits in parallel, interlinked with 1 electric circuit containing primary and secondary. Best for air cooling and large currents. Three-phase shell-type is a consolidation of 3 transformers into one.

(C) according to method of cooling. As a transformer is a very compact piece of apparatus, the problem of carrying away the heat is important. NATURALLY-COOLED type has no special means of cooling, but relies upon ordinary circulation of air. Only used in very small sizes, as for meters. In the OIL-COOLED, the core and windings are submerged completely in a tank of oil, and are subdivided by ducts so that oil may circulate and abstract heat from internal parts. The heat is carried to surface of tank containing the transformer, and then dissipates into the surrounding air. Tank must be specially designed, with deep corrugations or projecting vanes or tubes, to provide large air-cooling surfaces. In the AIR-BLAST type there are passages through which air is forced by a blower. WATER-COOLED transformer resembles the oil-cooled type, but a coil of pipe carrying running water is submerged in the oil. Transformers artificially cooled by oil are used when the size is too great for the self-cooling oil type and no water is available. Oil circulates through external coils or tanks, to afford greater cooling surface.

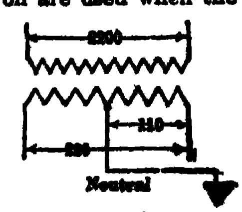


Fig 23. Single-phase, Three-wire

Transformer connections commonly used in lighting and power service are: SINGLE-PHASE SYSTEM with 3-wire secondary (Fig 23), standard in household lighting with a-c system, the neutral wire being grounded on the low-tension side, the primary side not being grounded. Lamps or motors operating at 110 volts are connected between the neutral and either side. Maximum potential between any secondary and ground is 110 volts, but if either outside wire becomes grounded a short-circuit occurs on that half of the transformer. TWO-PHASE, or quarter-phase 4-wire system. The standard is essentially 2 independent single-phase systems, which are

usually electrically independent throughout. TWO-PHASE 3-wire system is occasionally used for distribution of power in small systems. Return wire is common to both circuits. There may be a slight saving in copper, but the chances of unbalanced voltage and bad regulation, especially with an inductive load, render it objectionable. THREE-PHASE Y AND DELTA CONNECTIONS (Fig 24, 25). Transformation in a 3-phase system, with 3 single-phase transformers or one 3-phase transformer, having 3 primary coils and 3 secondary coils, is accomplished by connecting the primary either in Y or in delta, and the secondary either in Y or in delta. Following relations exist between voltage per transformer winding and voltage between lines, current in transformer windings, and current in lines. Power in the 3 transformers in any case is $3 \times 0.58 \times EI = 1.73\,EI$. THREE-PHASE OPEN DELTA, or V-connection, saves expense by omitting one transformer from the delta connection. Is recommended only for low voltages, as 2 300. Regulation and

Connection	Volts between lines	Volts per winding	Current per line	Current per winding
Y	E	$0.58\,E$	I	I
Delta (Δ)	E	E	I	$0.58\,I$

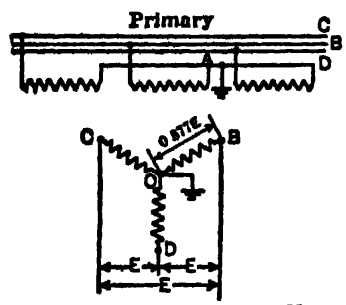

Fig 24. Three-phase Y

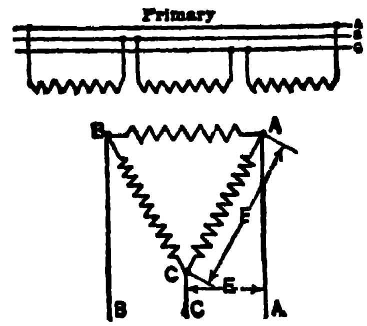

Fig 25. Three-phase Delta

efficiency are poor, as one phase of the load receives power from 2 transformers in series. Aggregate capacity of the transformers should be 15% greater than the load. TWO-PHASE TO 3-PHASE (Fig 26). Scott, or T-connection, consists of 2 transformers which, on the 2-phase side, are connected in normal 2-phase manner. On the 3-phase side one transformer has a tap at the middle point, the other a tap giving 87% of full-transformer voltage. Fig 26 shows method of connecting, and the currents in primary and secondary with balanced loads. Total transformer capacity must be 15% greater than the load.

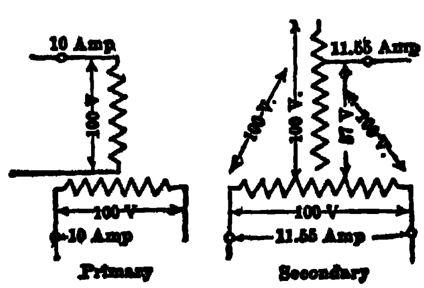

Fig 26. Two-phase to Three-phase

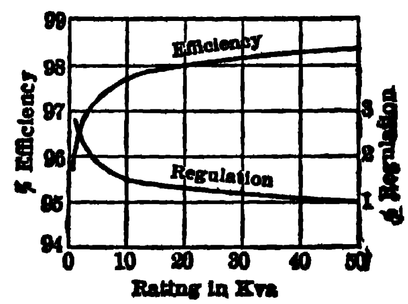

Fig 27. Efficiency and Regulation of a Line of Transformers

Efficiency is equal to the power output divided by output plus core loss plus total copper loss, and is very high. "All-day efficiency" is equal to the energy output for a day divided by the input; with short periods of load it is low, because core loss goes on when there is no load. If P is the load in watts for h hr per day, A the core loss, and B the copper loss, the all-day efficiency is $100\,hP \div (hP + 24A + hB)$ in percentage.

Regulation is $(E_0 - E) \div E$, where E_0 = secondary voltage at no load and E = secondary voltage at full load. It should be from 1 to 4% for load of 100% power factor, and is poorer for inductive loads. Fig 27 shows efficiency and regulation at full load of a line of 60-cycle lighting transformers for 2 300 volts.

Installation. Transformers require no special foundations, but merely provision to carry their dead weight. They must be in a dry place, unless of the totally enclosed "subway" type. They are often placed on poles. They must be thoroughly cooled.

Cost and weight. (See Art 19.)

Substation is a building containing an equipment for transforming or converting the energy of transmission line into a convenient form for use in small units. Since the energy may be used as a c or d c, there are 2 general types of substations: a c to a c and a c to d c. In either case the energy must be distributed to the various consuming devices at a much lower voltage than that of transmission, sometimes at a different frequency, and sometimes in an entirely different form. The substation is therefore the dividing point between the transmission and distribution systems. A-c SUBSTATION in simplest form comprises step-down transformers for lowering the voltage, and incidental regulating and protective devices. There may be a group of 3 single-phase transformers, or one 3-phase. Single-phase transformers are preferable for moderate sizes, as they require a smaller reserve. Since the transmission system is always 3-phase, these groups provide low-voltage 3-phase currents for different groups of motors, or the individual phases may be wired separately for lighting purposes. If transmission system is 25 cycles it may be necessary to install motor-generator sets (Art 6) (frequency changers) to give 60-cycle current for lighting. These usually consist of a synchronous motor driving an alternator. If the distribution system voltage must be kept constant, some form of voltage regulator is installed, which will keep the voltage constant on each individual circuit, or on the 3-phase circuit as a whole. A switchboard with the necessary switches and measuring instruments is requisite. D-c SUBSTATION consists of stepdown transformers, converters, motor-generator sets, or rectifiers with incidental regulating and protective devices. The converter (Art 11) is cheaper and more efficient than the motor-generator set, and is advisable in absence of any local reason for using motor-generators. Converters may be arranged to give constant voltage irrespective of load, or may be over-compounded. The substation then resembles a d-c generating station.

Lightning arresters are to protect the apparatus of a station from natural lightning discharges, and from "internal lightning" caused by sudden changes in current or voltage conditions in the system itself. A lightning arrester permits a current to flow from conductor to ground, whenever the potential exceeds the normal, and stops this current when the excess voltage ceases to exist. This is usually done by letting the excess voltage break down a spark gap, by means of an arc which stops as soon as the voltage drops below a critical value depending upon the width of gap.

Types of arresters. HORN-GAP ARRESTER is simplest and is commonly used for high voltages, but is not sensitive enough for moderate and low-voltage systems. It consists of 2 copper rods, bent like horns, separated by a fraction of an inch at the nearest point and diverging from there. The arc starts at the small end of gap, lengthens as it rises, and finally breaks. The "Autovalve" and the "Thynite" lightning arresters are two new commercial forms of the valve type; that is, they can discharge a very large current for a short time with a very small increase in line potential and can shut off this current as soon as the line potential returns approximately to normal. Each arrester consists of three functional parts, all in series in the circuit from line to ground: (*a*) an air gap, so set as to spacing of terminals that it will break down and discharge a very large current when the line potential rises to a point 20–50% above normal. This initiates the discharge; (*b*) a set of porous blocks or disks, made up of finely divided porcelain and carborundum, stacked and electrically in series. These blocks contain an almost infinite number of very small gaps and resistances in series and multiple, and regulate the flow of current during discharge. Each block is good for about 3 000 volts and enough are put in series to take care of line potential; (*c*) a quench-gap, whose duty is to open the circuit and shut off all current as soon as the discharge has diminished to a reasonable value and the dangerous voltage has been eliminated.

Functional part (*b*) is always used, but in medium-voltage applications (*c*) may not be used and for 600 volts neither (*a*) nor (*c*) is necessary.

14. ELECTRIC DISTRIBUTION

Principles. Three fundamental considerations determine the cross-section and weight of copper conductors for a particular purpose (see also *Art 13*): (*a*) Voltage lost in the line, or IR drop. This depends upon the line current and the resistance of outgoing and returning lines. It is important in affecting the saleability of the energy and desirability of the apparatus served. It causes considerable variation in the light given by lamps, and a variation in speed of motors. (*b*) Energy lost in the line due to I^2R, which represents an actual money loss. (*c*) Current density in conductors. This determines their temp rise, which, if excessive, causes danger of fire.

Usual loss in voltage allowed in distribution systems is less than in transmission; it varies from 2 to 5% of the delivered voltage. In a d-c system the proper cross-section of conductor in circular mils (Table 4) is given by: cm = $(21.6\,DI) \div e$, where D = distance one way, ft; I = current, amperes; e = specified loss, volts. In an a-c system the drop due to resistance of wire is usually the determining factor; reactance drop is probably negligible, as the wires are strung close to each other. Choice between a c and d c for distribution work depends upon character of the load apparatus and the available current. D-c motors are generally preferable, and therefore d-c distribution systems are used, unless the cost of the converting substation is too great.

Examples

Series-arc system (Fig 28). Problem: 80 arc lights, requiring 10 amperes at 50 volts each in a 5-mile series circuit. Allow 3% loss. Voltage consumed = $50 \times 80 = 4\,000$. Let R = resistance per 1 000 ft of wire. Length of wire in thousands of feet = $5 \times 5.28 = 26.4$. Voltage loss $= 4\,000 \times 0.03 = 120 = 10 \times 26.4 \times R$; hence $R = 0.455$. From Table 4, the nearest size of wire is No 7 B & S.

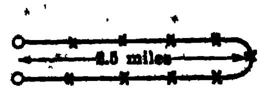

Fig 28. Series-arc Distribution

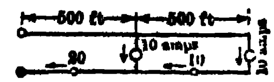

Fig 29. Multiple Distribution

Multiple system (Fig 29). Problem: two loads at 500 and 1 000 feet respectively from distribution center. Each load, 10 amperes. Allowable maximum drop, 5 volts. Find size of wire. Let R = resistance per 1 000 ft of wire. Then, $5 = 20 \times 2 \times 0.5\, R + 10 \times 2 \times 0.5\, R$; hence $R = 0.166$. Choose No 2 B & S wire, of which $R = 0.156$.

Anti-parallel system. Problem: find size of wire to give a maximum drop (on middle group) of 5 volts on loads shown in Fig 30. Let R = resistance per 1 000 ft of wire. Then, $5 = 30 \times 0.2\, R + 20 \times 0.2\, R + 20 \times 0.2\, R + 30 \times 0.6\, R$; hence $R = 0.156$. Choose No 2 B & S wire.

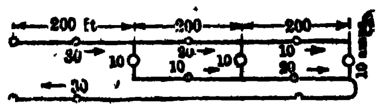

Fig 30. Anti-parallel Distribution

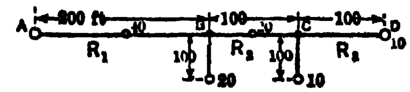

Fig 31. Tapered-conductor Distribution

Tapered conductor. Problem: given 3 loads as in Fig 31, and maximum drop of 5 volts, to find sizes of wires. Assume drop proportional to distance: $AB = 2.5$, $BC = 1.25$, $CD = 1.25$. Then,

$2.5 = 40 \times 2 \times 0.2\, R_1$; hence $R_1 = 0.156$ per 1 000 ft; choose No 2 wire.
$1.25 = 20 \times 2 \times 0.1\, R_2$; " $R_2 = 0.312$ " 1 000 " " " 5 "
$1.25 = 10 \times 2 \times 0.1\, R_3$; " $R_3 = 0.625$ " 1 000 " " " 8 "

Feeder and main. Problem: given loads as in Fig 32, and max drop of 10 volts. Find size of wire. Assume drop to junction point = 8 volts (0.75 of total).

Feeder, $8 = 15 \times 2\, R_1$; hence $R_1 = 0.266$; choose No 4 wire.
Main, $2 = 5 \times 2 \times 0.2\, R_2$; " $R_2 = 1.0$ " " 10 "

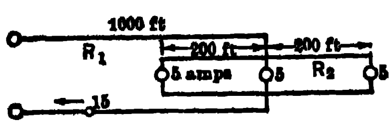

Fig 32. Feeder and Main Distribution

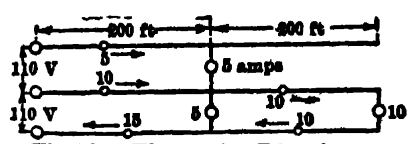

Fig 33. Three-wire Distribution

Three-wire system. Principle: at any given distance from generator the sum of outgoing currents equals sum of returning currents (Fig 33). Problem: Given 3 loads, 200 and 400 ft from generator, as shown. Neutral or middle wire to be same size as outside wires. Max drop, 5 volts. Let R be resistance per 1 000 ft. $5 = 10 \times 0.4\, R + 10 \times 0.2\, R + 15 \times 0.2\, R$; hence $R = 0.555$. Choose No 7 wire.

Construction. Distribution systems may be overhead or underground. Underground system costs about 5 times as much to install as the overhead, but less to maintain. Steel poles are used for high voltage or regular transmission systems, but wooden poles are satisfactory for ordinary distribution. Cedar, chestnut, pine, and cypress are good, costing \$10 to \$20 per pole, according to location. They are usually 35 to 40 ft long, have a taper of 1 in in 5 to 8 ft, are 7 to 8 in diam at top and set 5 to 8 ft in ground. Spans, from 75 to 125 ft. Poles are guyed to anchors on curves, at ends, and at every 20th pole, to take care of breaking of wires. Glass insulators on cross arms are used for moderate voltages, porcelain insulators for higher. In stringing wires, sag must be adjusted with reference to the temp; a large sag in summer, small in winter.

In cities most of the distribution is laid underground in elaborate conduits, which are expensive and unnecessary for mining work. Good results are obtained by laying a lead-covered double conductor cable in a shallow trench and covering it with earth.

Interior wiring of buildings. Definite methods, practices, and regulations covering installation of distributing circuits are based on following considerations: (*a*) avoidance of danger from fire or risk of shock; (*b*) limitation of loss of power and energy; (*c*) maintenance of reasonably constant voltage at the load; (*d*) assurance of reasonable mechanical strength; (*e*) compliance with local specific regulations. STANDARD VOLTAGES: for lighting and incidental power, 100 to 125 volts; for power and lighting on 3-wire system, 220 to 250 volts; for power alone, 550 volts. Usual allowance for drop in building wiring, 2%. LOCAL REGULATIONS to be observed: National Electric Code, for

obtaining insurance on buildings; Municipal Inspection in cities; regulations of local Light and Power Co, if energy is purchased. These regulations are so elaborate that any one expecting to be responsible for an installation of wiring must be acquainted with the National Electric Code, on which most of the other regulations are based. ALLOWABLE CURRENT-CARRYING CAPACITY OF WIRE. Values given in Art 3 are for rubber-covered wire installed indoors. For other insulation, and for exterior work, somewhat greater current is allowed. In laying out a distribution system, a CUT-OUT OR FUSE must be inserted at every junction where size of wire changes, and there must not be more than 660 watts in lamps on any one fuse. Larger motor loads are cared for by a CIRCUIT-BREAKER.

Methods of indoor wiring. OPEN WIRING ON CLEATS. Wire must be insulated with material resisting fire, and dampness and corrosive vapors, if present. Wires must be separated from each other and from any nearby surface by specified distances and the cleats may be spaced not more than 4.5 ft apart (local regulations). No 14 is the smallest allowable wire. MOLDING, either wood or metal, may be used to hold and protect wires, if difference in potential does not exceed 300 volts and the power transmitted is within specified limits. KNOBS AND TUBES. If not prohibited by special regulations, wires may be attached to knobs and run through walls in porcelain tubes; a cheap form of wiring.

Conduit. Best but most expensive method is to run the wires in conduits, built into the walls, floors, or framework of building. Conduit may be lined or not, which has a bearing on amount of insulation required on the wires. Conduit may be rigid or flexible; the former is better and more expensive, and is often required in large cities. ARMORED CABLE, commonly known as "BX," may be used in buildings not provided with conduits, and where very reliable installation is required. Lead-armored cable is used where dampness is expected.

Metering. Charges for electric energy are based upon the kw-hr, which is the total integrated amount of energy delivered in 1 hr to a circuit in which the average power is 1 kw. Cost per kw-hr varies from 1¢ in large quantities, to 10 and 15¢ for small quantities. The ampere-hr is not an accurate measure of energy, unless the circuit voltage remains absolutely constant. See also Sec 16.

Instrument used for measuring electric energy is the watt-hr meter, sometimes called integrating wattmeter. Electric connections are similar to those for wattmeters used in measuring power. MEASUREMENT OF TOTAL POWER OR ENERGY: (*a*) in d-c or single phase a-c circuit, by one meter having its current coil in series with the load and its potential coil in parallel with the load; (*b*) in a 3-wire d-c or in a 2-phase circuit, balanced or unbalanced, by 2 meters connected as if in 2 independent single-phase circuits (total power being the sum of the 2 readings); (*c*) in a balanced 3-phase system, by 1 meter connected in 1 of the 3 receiving circuits (its reading being multiplied by 3) or by 1 meter connected with its current coil in 1 of the line wires and its potential coil connected from 1 line wire to the neutral (total power being obtained by multiplying the reading by 3); (*d*) in a 3-phase system, balanced or unbalanced, by 2 meters, connected as in Fig. 34. Total power is the sum of the 2 readings, if the power factor be greater than 0.5, or the difference of the readings if it be less than 0.5, in which case the potential leads of 1 meter must be reversed, to bring the pointer on the scale.

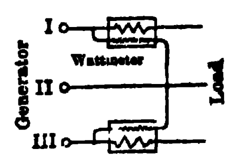

Fig 34. Power and Energy in Three-wire Distribution

Watt-hour meter comprises 3 parts: (*a*) a small electric motor, of commutator, mercury and disk, or induction type, which runs at a speed proportional to the power; (*b*) a brake or generator system, usually consisting of an aluminum disk revolving in the field of permanent magnets to give a drag by eddy currents proportional to the speed; (*c*) a train of gears driving pointers for recording number of revolutions. While the type of motor varies with the make and purpose of the meter, the brake and recording devices are common to all. COMMUTATOR TYPE consists of a small d-c motor, the field being excited by the load current in current coil and the armature connected in potential coil carrying a current proportional to potential. It is operative on both d-c and a-c circuits, but is used only on d-c, the induction type being cheaper and better for a-c. MERCURY-MOTOR watt-hr meter contains a motor consisting of a disk of copper or aluminum floating in a well of liquid mercury. Main current is led to the mercury, but passes through the disk because of its lower resistance. This forms an elementary armature. Potential coils are on an iron core; they form the motor field and produce a torque in the armature which revolves it. Operative on both a-c and d-c circuits, but the induction type is preferable for a c. INDUCTION TYPE watt-hr meter is similar to a 2-phase induction motor, the current coils forming 1 phase, the potential coils the other. This gives a rotating magnetic field which drives a metal disk rotor. Operates only on a c. Cheaper than either of the other types, and more reliable and accurate. POLYPHASE WATT-HR meter contains 2 current coils and 2 potential coils, connected as 2 wattmeters would be connected; but both elements act on same shaft and drive same set of gears, thus mechanically taking care of any positive and negative readings in either element, and giving correct total energy in one reading. Sometimes a single-phase watt-hr meter is used on a balanced 3-phase circuit (such as one containing motors only). Its current coil is connected in one line, and its potential coil is connected between one line and a neutral obtained by connecting 3 equal high resistances in Y. Total energy is 3 times the reading.

Meter capacity. In dwellings it should be 50% of the total capacity of the connected load; in offices, 75%; for elevators, hoists, etc, 150% of the load.

Installation. Watt-hr meters must be installed on a rigid support free from vibration, and must be level. They should be at least 15 in between centers, and must not be near iron girders nor steam pipes, nor conductors carrying large currents. They must be protected from mechanical shock, weather, heat, dirt, vermin, and dampness.

Sources of error. Adjustments are provided to take care of normal friction loss. Variation in friction of brushes or bearings causes error. Mechanical shock, dirt, or dampness may alter the friction. External magnetic fields cause variation in adjustment. In induction meters variations in frequency, voltage, or load power factor may cause a slight error. Meters should be inspected and calibrated at least once a year. To CALIBRATE a watt-hr meter, connect it to a constant known load and count revolutions of the disk per min. Note the constant K painted on the disk, and substitute in formula: watts = 60 r p m × K.

15. ELECTRIC LIGHTING

Light distribution follows the law that the intensity is inversely as the square of the distance, providing the greatest dimension of the light source is less than 0.1 of the distance between source and object.

Definitions. INTENSITY of light is the relative amount of luminous energy given by any source and is measured in candles or candle power. CANDLE POWER (c p) is a measure of light intensity, determined by comparison with a well-seasoned incandescent electric lamp, that has been accurately checked with a standard lamp at the National Bureau of Standards, Washington. ILLUMINATION is measured in ft-candles. One ft-candle is intensity of illumination on a surface 1 ft distant from a source of one c p. At 2 ft distance the illumination would be 0.25 ft-candle. Light is the means; illumination, the end. INTRINSIC BRILLIANCY of a source is measured in c p per sq in. When excessive it is harmful to the eye. Intrinsic brilliancy of tungsten lamp is 1 000 c p per sq in. A light source generally gives different intensities in different directions. Hence, c p means nothing unless direction is specified. MEAN HORIZONTAL CANDLE POWER (m h c p) is the average c p of a lamp in all directions in a horizontal plane passing through center of the source, and is usually obtained by rotating the lamp about a vertical axis. MEAN SPHERICAL CANDLE POWER (m s c p) is the average c p of a lamp in all directions, or the c p of a uniform source giving the same total flux of light. It is directly proportional to the total light given by the lamp, and is measured by taking intensity readings in all directions, or by placing the lamp in a hollow dull white sphere and measuring average intensity. Flux of light is measured in LUMENS and is the quantity emanating from a source of unit intensity (one c p) and contained in a unit-soled angle. There are 4π or 12.56 lumens emanating from a source of unit intensity and 12.56 N lumens from a source of N spherical c p. Luminous effic is expressed in lumens per watt consumed and is from 10 to 20 in modern incandescent lamps, the higher values for the larger lamps (see mfrs guarantees).

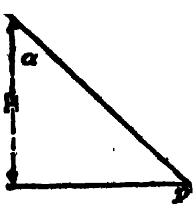

Fig 35. Law for Intensity of Illumination

In applying the laws of photometry to the calculation of a problem in illumination certain qualifications are necessary: source of light must be small compared to the distance of the object illuminated; luminous surface must be at right angles to the line of direction from the object to be illuminated; reflection and refraction must be negligible. The most useful and general application of the law is expressed by: $I_h = (\text{c p} \div H^2) \cos^3 \alpha$; where I_h = intensity of illumination in ft-candles at a given point p (Fig 35) on any horiz plane; c p = intensity of light source in given direction, expressed in candles; H = height in ft of lamp above horiz plane containing point p; α = angle from vertical.

General illumination of reasonable intensity (0.5 to 1.0 ft-candles) facilitates a general view and perspective of the surroundings, while a greater intensity (1 to 5 ft-c) facilitates reading or work. In DIFFUSED ILLUMINATION light comes from all directions, casting no deep shadows; extreme diffusion gives flat lighting and may be monotonous. To protect the eye some diffusion is usually desirable, for it tends to remove glaring reflection from objects in view; thus, when reading from glazed paper or working on polished metals light must not be strongly directional. In DIRECT ILLUMINATION, shadows are dark, contrasts great, and forms are clearly outlined. Details are best brought out by a light rich in the color corresponding to that of the object viewed. DIRECT LIGHTING unit sends most of its light at once to the object to be lighted. SEMI-INDIRECT unit consists of a diffusing medium between the lamp and the object, which directs most of the light to the walls and ceiling, from which it is reflected. TOTALLY INDIRECT unit directs all light from the lamp to the walls or ceiling, from which it is reflected. While more light is lost with the indirect system it is easier on the eyes, glare is avoided, the eyes are more sensitive, and vision is improved.

Arc lights are generally in large units (1 000 c p), are among the most efficient sources, have high first cost and high maintenance cost, compared to incandescent lamps.

They operate on either d-c or a-c circuits (but are not interchangeable), and may be of series or multiple type. The d-c lamp is usually a little more efficient and more reliable than the a-c. SERIES-TYPE ARCS are in series on one circuit, supplied by a generator or transformer designed to give a constant current irrespective of the lamps in operation. MULTIPLE-TYPE ARCS operate either singly or in pairs in series, on the usual constant-potential circuits with motors and incandescent lamps. Arc lamps other than the mercury and sodium-vapor type are becoming obsolete.

Mercury-vapor lamp is used on d c multiple circuits; 110 volts with individual auxiliary starting and regulating device gives a blue green light, an effic of 15 to 20 lumens per watt and comes in units of 300 to 500 watts. Sodium-vapor lamp is a new development, particularly adapted to highway lighting. It requires considerable auxiliary apparatus, gives a yellow light and has very high effic. Operates in multiple on 125-volt a c circuits.

Incandescent lamps are made in many forms and sizes and for many voltages and currents, for operation in multiple or series. The multiple type for 115, 120 or 125 volts, either a c or d c, is the most common. They consist of a coiled filament of fine tungsten wire, enclosed in an inside frosted bulb containing an inert gas, nitrogen or argon.

Rating of incandescent lamps. All multiple lamps are now rated in watts input, and in lumens rather than candle power; thus the 25-watt lamp gives 250 lumens; the 40-watt 420; 60-watt, 750; 100-watt, 1 500. The useful life is from 1 000 to 1 200 hr; that is, at end of this time the output of light is reduced to 80% of the original value. All incandescent lamps are very sensitive to variations in impressed voltage, respecting life, as well as effic and candle power. The smaller sizes give 10–15 lumens per watt when new.

Fluorescent lamp consists of a mercury-vapor arc in a tube with fluorescent or phosphorescent coating, which gives the light a wide range of agreeable colors; it operates on a c or d c, more efficiently on a c. It is more efficient than the incandescent lamp.

Fixtures, known as luminaires, are very important. The direct type sends all the light downward, the indirect type sends the light upward and depends upon a good, reflecting ceiling. There are many intermediate types. Utilization factor of a fixture for a room is the ratio of the useful lumens of light delivered to the working plane to the total lumens output of the lamps. It varies from 0.15 to 0.72; mean value, 0.5. The reflecting qualities of the surroundings have an important bearing. To determine the number and rating of lamps required: $F = AE \div u$, where F = total lumens required; A = horiz area to be illuminated, sq ft; E = desired illumination in ft-c (Table 11); u = utilization factor for the particular surroundings. Choosing the number of units desired, based upon the uniformity of illumination required, gives the lumens per lamp.

Cost per hr of supplying a given illumination comprises cost of lamp and of energy: $C = \frac{Pn}{L} + \frac{n\,w\,K}{1000}$; where C = total cost of light required, cts per hr; P = price of lamps, cts per lamp; n = number of lamps required obtained as above; L = aver life of lamps, hr; w = watts per lamp; K = price of energy, cts per kw-hr.

Interior Illumination. Interiors are generally illuminated by incandescent lamps on multiple circuits, and to supply general illumination of even intensity a number of medium size units (60 to 250 watts) are usually preferable to one large unit. Units should be placed or shaded so as to be out of line of sight of eye. Best method of distribution is to divide the room into equal squares, having sides of 10 to 20 ft, depending upon degree of illumination desired and height of ceiling, and placing a source of light at ceiling in center of each square (not at corners). The side of each square should not exceed twice the height of the lamp above the working plane. Any local concentrated illumination may be provided by special local fixtures. Diffusing globes should be used on all lamps in line of vision, and frosted lamps in all fixtures unless completely shaded. Customary criterion for good interior lighting of factories by Masda lamps is to supply 1 to 2 watts per sq ft of floor space; the higher value when work is exacting or walls are of dark color. This is based on an illumination of from 3.5 to 7.0-ft candles on a plane 30 in above floor, using tungsten lamps.

Table 11. Usual Intensities of Illumination (Ft-candles) in Plants, as Mine Plant

Service	Ft-candles	Service	Ft-candles
Desk work	8–30	Steel works: Unloading yards	2–5
Factory, general	3–5	Open-hearth floors	4–10
Local bench, for fine work	25–100	Blast furnace	2–5
Local bench, for coarse work	6–20	Rolling mills	4–10
Machine tools	10–20	Wire drawing	3–5
Pattern shops	10–20	Threading, pipe mills	2–5
Power house	3–5	Warehouse, Wharf	2–5

Mine lighting. Tunnels, shaft stations, and all places of traffic, are usually lighted by 40- or 60-watt Masda lamps, with weatherproof sockets and steel porcelain enamel reflectors. In gaseous

mines lamps are enclosed in heavy vapor-tight glass globes protected by iron guards. 200 to 300-volt circuits are used in mines, for which voltage lamps are available. Working places may be lighted by portable storage battery lamps, carried on the cap with separate battery or in the hand with battery combined (Sec 23, Art 10). To be approved by the Bureau of Mines these lamps must be free from possibility of igniting gas, must be of light weight (not over 5 lb) and must not spill or leak electrolyte. They must illuminate a 7-ft circle, give about 0.7 c p, and are usually for 2 volts (Bureau of Mines Schedule 6).

Reflectors should be used with all lamps. Reflector for arc lamps for general lighting is an integral part of lamp, and designed to throw the light downward and outward. Reflectors for incandescent lamps may be extensive, intensive, or focussing; extensive throws the light downward, within a solid angle of about 90°, intensive in an angle of 60°, and focussing in an angle of 60 to 40°. Industrial reflectors may be made of white enameled steel, aluminum, or painted metal; for interior use, plain glass or prismatic glass. Latter uses the principle of refraction to send downward the rays that would normally pass through the glass. Reflectors and lamps must be cleaned regularly, to prevent loss of efficiency. Tungsten lamp should be cleaned while the current is on, as there is less liability of breaking the filament.

16. APPLICATIONS OF ELECTRIC TRANSMISSION TO MINE SERVICE (See Sec 16 for details)

17. ELECTROCHEMISTRY

Equivalent weight or chemical equivalent of any substance is its molecular weight divided by its highest valency: thus, equivalent weight of copper in $CuSO_4$ is 31.78, being the atomic weight of copper 63.57 divided by its valency 2. Equivalent weight of the SO_4 radical is $[32.07 + (4 \times 16)] \div 2 = 48.03$. Equivalent weight gives the relative weights of various substances deposited in electrolytic work by a given current.

Gram molecule or mol is the number of grams of a substance which are equal to its molecular weight; thus, 1 gram molecule of $CuSO_4$ is 159.64 gm. GRAM EQUIVALENT is the number of grams of a substance which are equal to its equivalent weight; or to its mol divided by its valency. The gram equivalent of $CuSO_4$ is $159.64 \div 2 = 79.82$.

Electrolyte. When an electric current passes through certain substances, chemical action takes place at the points where the current enters and leaves the substance. Such substances are called electrolytes and the chemical action produced is electrolysis.

Electrodes are the conductors by which the current enters and leaves the electrolyte. ANODE is the electrode by which the current enters; CATHODE, that by which it leaves. The anode is connected to the positive terminal of the generator. Hydrogen and metal atoms of salts flow to cathode and are called CATHIONS; oxygen, and acid and basic radicals flow towards anode and are called ANIONS. All anions and cathions are called "ions."

Electrochemical equivalent OF AN ION is the mass in gm of the ion which would be deposited by one coulomb (Art 1) of electricity. ELECTROCHEMICAL CONSTANT OR FARADAY (F) is the number of coulombs required to liberate one gram equivalent of any ion; value is 96 450 coulombs for all ions.

Faraday's Laws. Quantity of an electrolyte decomposed by an electric current is directly proportional to total quantity of electricity which passes. Rate of decomposition is directly proportional to current. Quantity decomposed is theoretically independent of voltage, current density, size of electrodes, and concentration of electrolyte. In practice local reactions cause deviation from this law. A given quantity of electricity always decomposes equivalent weights of different electrolytes in definite proportions for different elements. Total weights of different substances deposited by a given current in a given time are proportional to the equivalent weights of those substances. Some elements, as copper, may have different valencies in different combinations. Weight of such substances deposited is inversely proportional to the valency.

Electrochemical equivalent OF A SUBSTANCE is the number of gm of the substance deposited by 1 ampere flowing for 1 sec. The ampere is the unit of electric current, which will deposit 0.001118 gm silver in 1 sec. For calculating weights deposited by different currents in commercial practice it is more convenient to use the value of grams deposited by 1 ampere in 1 hr (Table 12).

The electrochemical equivalent of any ion may be calculated by dividing the gram equivalent of the ion by the Faraday. Thus, grams deposited in 1 sec by 1 ampere equals the gram equivalent of the ion $\div$ 96 450. Weight of any substance in gm deposited in 1 hr is obtained by multiplying the values given in Table 12 by the current in amperes.

Decomposition or critical voltage is the minimum potential which must be impressed to cause decomposition of a substance. With lesser potential no action takes place; with greater potentials action is proportional to current. This value depends upon chemical composition of the electrolyte, and is a function of the chemical energy of the process

Table 12. Electrochemical Equivalents of Common Elements Deposited per Ampere-hr

	Grams		Grams
Aluminum	0.337	Lead	3.865
Bromine	2.981	Magnesium	0.454
Calcium	0.7476	Nickel (val = 2)	1.093
Chlorine	1.322	Oxygen	0.2984
Copper (val = 1)	2.371	Platinum (val = 2)	3.640
" (val = 2)	1.186	Silver	4.024
Gold (val = 1)	7.36	Sodium	0.8576
" (val = 3)	2.453	Tin	1.107
Hydrogen	0.0375	Zinc	1.219
Iron (val = 2)	1.042		
" (val = 3)	0.6944		

Table 13. Decomposition Voltages of Solutions used in Metallurgical Industries

	Volts		Volts
Acid, hydrochloric	1.31	Hydrate, potassium	1.67
" nitric	1.69	" sodium	1.69
" oxalic	0.95	Nitrate, lead	1.52
" perchloric	1.65	" potassium	2.17
" phosphoric	1.70	" silver	0.70
" sulphuric	1.67	" sodium	2.15
Chloride, nickel	1.85	Sulphate, cadmium	2.03
Chloride, sodium	1.98	" nickel	2.09
		" zinc	2.35

Values given in Tables 12 and 13 are useful in checking efficiency of any electrolytic action; for, with these constants, the theoretical value of grams separated per kw-hr may be calculated and compared with the results obtained in practice. Thus, if A is the value of grams deposited per ampere-hr (Table 12), and B is the critical voltage for that substance (Table 13), then the theoretical grams per kw-hr = $(A \div B) \times 1\,000$. Example. Copper is deposited from a cupric solution at the rate of 1.186 gm per ampere-hr (A), and requires 1.59 volts to maintain the action (B). Therefore the maximum possible recovery is $(1.186 \times 1\,000) \div 1.59 = 748$ gm per kw-hr. Similarly, zinc is decomposed at rate of 1.219 gm per ampere-hr (A), and requires a critical voltage of 2.35 (B). Hence, a primary battery consumes a minimum of $(1.219 \times 1\,000) \div 235 = 520$ gm per kw-hr. The kw-hrs required to deposit 1 kg of material are given by the formula: kw-hr = $B \div A$

18. BATTERIES, STORAGE AND PRIMARY

Lead storage battery consists of 2 lead electrodes in dilute H_2SO_4. The positive plate has lead peroxide supported by a grid of pure lead; the negative is lead sponge similarly supported. The chemical reaction is:

$$\underbrace{\underset{+\text{ plate}}{PbO_2} + 2\,H_2SO_4 + \underset{-\text{ plate}}{Pb}}_{\text{(charged)}} = \underbrace{\underset{+\text{ plate}}{PbSO_4} + 2\,H_2O + \underset{-\text{ plate}}{PbSO_4}}_{\text{(discharged)}}$$

Reading from left to right gives the action of discharging; from right to left gives charging. There are 2 types, the Planté and the Faure. PLANTÉ TYPE consists of plates of pure lead with surface area increased by roughening by webs, ribs or grooves, and formed by charging electrolytically. There are 3 forms of construction of Planté plates: central web, cast lead, and pellet. In general, Planté cells are heavier and more bulky than Faure cells, but last longer. FAURE TYPE (paste type) has active material consisting of a paste containing litharge (PbO) or red lead (Pb_3O_4) applied to all grids and dried. Plates are then formed by being charged and discharged. Faure cells are lighter and therefore preferable for vehicles. Positive plates are those from which the current flows to the load during discharge. They have a dark chocolate color when charged, with hard smooth surface. Negative plates are gray, with softer surface. The ELECTROLYTE H_2SO_4, diluted with distilled or pure water, should have sp gr of about 1.15 when new, but different values are used for different services. It must be free from chlorine, nitrates, copper, iron, mercury, arsenic, acetic acid, and platinum, and should be made for the particular purpose. When cell is fully charged, the sp gr is 1.21 to 1.3; when discharged, about 1.15. Open-circuit voltage is 2.

Capacity of a lead battery is stated in ampere-hr. Normal discharge current is that which the cell will give for 8 hr. Ampere-hr rating is this current multiplied by 8.

Special ratings may be stated for a 1-hr or 4-hr discharge. Rate of charge and discharge varies from 6 to 10 amperes per sq ft of plate area, not including area obtained by corrugating. Any current may be obtained from a cell by putting enough plates in multiple. Watt-hr efficiency is the ratio of output to the input necessary to bring the battery back to its original condition. It is 90 to 92% for a battery floating on the line, and 75 to 90% for a battery completely discharged before recharging. A cell is discharged until its terminal voltage while discharging has decreased to 1.8 volts, and is charged until it requires 2.5 volts to force rated current through it. If a cell is discharged so that its voltage at normal current is less than 1.75, $PbSO_4$ may form, making it difficult to charge again.

Care of lead storage batteries. All terminals and electric connections of a lead cell must be of lead; joints are formed by burning, or are lead covered. Instructions for care of batteries are given by makers, and should be followed carefully according to conditions and service. Electrolyte must be free from the injurious substances mentioned above, must be of definite sp gr for each condition, and must cover all plates. Cells must be cleaned before any deposit of sediment on bottom is high enough to touch the plates. Exterior of the cells must be cleaned and kept dry to prevent grounding and deterioration of terminals. Any leak must be repaired at once. Charge as soon as possible after cell has been discharged, at a current slightly in excess of the 8-hr discharge current, continuing until the negative plates give off gas steadily; then stop. In discharging, stop when terminal voltage drops to 1.8 for normal 8-hr current and 1.6 volts for the 1-hr rate. Keep temp of the battery below 105° F. Cells to be put out of commission for some time should first be fully charged, electrolyte removed and replaced by pure water. Then discharge through a very low resistance, until practically discharged (avoiding heating of cells). Electrolyte is then removed, plates washed, dried, and put away.

Edison storage battery contains positive plates consisting of perforated steel tubes heavily nickeled and filled with alternate layers of nickel hydroxide and thin flakes of pure metallic nickel. Tubes are supported by a grid of cold-rolled nickel steel. Negative plates consist of a nickel-steel grid, holding rectangular pockets filled with powdered iron oxide. All plates are insulated from each other and from steel container. Electrolyte consists of a 20% solution of potash in distilled water. Chemical reaction is:

$$\underset{+\text{ plate}}{2\,NiO_2} + 2\,KOH + \underset{-\text{ plate}}{Fe} = \underset{+\text{ plate}}{Ni_2O_3} + 2\,KOH + \underset{-\text{ plate}}{FeO}$$

Read from left to right for discharge; from right to left for charge.

Rating. Batteries are rated at the current which they will give for 5 consecutive hr. Ampere-hr rating is this current × 5 hr. Charging current is same as discharging, but time is about 7 hr instead of 5. Ampere-hr capacity is practically independent of rate of discharge, as battery is not injured by reasonable overload and may be discharged to 0 volts. Watt-hr efficiency is 60 to 65%. Average voltage per cell at normal rate of discharge (5 hr) is 1.2, varying from 1.45 to 1.0 volt. During charging at normal rate voltage is 1.55 to 1.85.

Operation. Steel containers must be insulated from each other, kept clean and dry, and plates kept covered with electrolyte. Charge at 75 to 85° F; discharge at 120 to 125° F. Sp gr of electrolyte should be constant at 1.2. Batteries are shipped with plates discharged, and after setting up should be charged at their normal rate for 12 hr. This overcharge should be repeated after the first 30 and 60 days, and thereafter whenever electrolyte is renewed. Battery may stand idle indefinitely if level of electrolyte is above the plates. It should be ventilated, as the hydrogen gas given off is explosive. As in case of all storage batteries the maker's instructions must be carefully followed.

Weight and cost. Lead storage batteries rated on 8-hr basis cost about $50 per kw-hr of capacity, or the cost may be $500 to $600 per kw capacity on 8-hr basis. Weight: 120 lb per kw-hr for portable style, 260 lb in glass jars, 370 lb in lead-lined tanks. Nickel storage batteries rated on 5-hr basis cost about $75, and weigh about 90 lb per kw-hr capacity. On this basis the cost per kw rating is about $400. The nickel-iron storage cell gives about 12 watt-hr per lb of gross weight per charge; portable type of lead cell, about 8 watt-hr per lb.

Primary batteries consume zinc or other metal by H_2SO_4, KOH, or similar electrolyte, and produce electrical energy. Zinc is usual for negative pole, and carbon or copper for positive. Inside a primary battery current flows from zinc to carbon. Polarisation results from new chemical substances (usually hydrogen) at the poles, causing a back e m f. Depolarisers are chemical reagents used to combine with these substances and prevent or reduce back e m f. There are 3 general types: wet, dry, and standard. Wet cells are being superseded by dry cells on account of their greater convenience. Typical wet cells are: Daniell, giving 1.07 to 1.14 volt; Gravity, 1 volt;

Bunsen, 1.9 volt; Edison-Lalande, 0.75 volt; LeClanche, 1.5 volt. The Daniell and Gravity are similar, and are good for continuous small currents. LeClanche cell is good for intermittent service, as its depolarizer takes time to operate. It is the commonest wet battery. DRY CELLS are of LeClanche type, consisting of a zinc container which is also the negative pole. A carbon rod forms the positive pole, the electrolyte being sal-ammoniac and zinc chloride held in blotting paper, saw dust, or the like. Manganese peroxide is used as a depolarizer. Voltage is 1.5 to 1.6. Internal resistance is 0.05 ohm new and 0.5 ohm after 10 months. The short-circuit current through an ammeter of 0.01-ohm resistance should be from 18 to 30 amperes. High temp increases the current. Potential decreases with age, due to drying out. Cells are not good after 10 to 12 months, even if not used. Their ampere-hr capacity is 24 to 30; higher on intermittent service, but capacity and life are very poor on continuous service. Life of cell depends greatly upon relative external and internal resistance, a matter requiring careful consideration. By putting 2 cells in parallel their combined life may be much more than twice the life of one alone on the circuit. Usual size of cell is 6 in high by 2.5 in diam. Cost is 10 to 40¢ each, depending upon quantity and quality purchased. (Standard Cell, see Art 1.)

19. COSTS (as of 1938)

The war has altered all price schedules, but the 1938 data indicate relative costs and show weights of various sizes.

D-c generators are usually of the compound-wound type, and comprise 3 classes: high speed, to be belted to prime mover; moderate speed and low speed, to be direct-driven by an engine. The last class is least important. Table 14 gives costs and weights of the first 2 classes, for 125 or 250 volts. Machines to operate at lower speeds cost more. Add about 10% for installation.

Table 14. Weight, Cost and Speed of D-C Generators

Kw	High speed			Moderate speed		
	Speed, r p m	Wt, lb	Cost	Speed, r p m	Wt, lb	Cost
25	1 450	1 090	$ 790	850	1 825	$ 930
50	1 150	2 035	1 250	700	3 550	1 800
75	850	3 550	1 750	575	4 900	2 550
100	700	4 900	2 250	575	6 160	3 000
150	575	7 500	3 100	500	7 620	4 300

D-c motors. Shunt motors, usually rated at the output they will give continuously without injury to themselves, are divided into classes according to speed (small high- and moderate-speed units, Table 15). For installation, excluding freight, add 5 to 10%.

Table 15. Weight, Cost, and Usual Speed of Shunt Motors for 115 or 230 Volts

H p	High speed			Moderate speed		
	Speed, r p m	Wt, lb	Cost	Speed, r p m	Wt, lb	Cost
0.5	1 750	55	$ 60	1 150	70	$ 74
1	1 750	105	92	1 150	130	115
2	1 750	160	115	1 150	200	141
5	1 750	285	225	1 150	350	280
10	1 150	485	370	850	570	430
25	1 150	1 000	600	700	1 300	770
50	850	1 500	1 100	690	1 800	1 300
100	850	2 450	1 600	690	3 200	1 950

Table 16. Weight, Cost and Usual Speed of Series Motors for 230 Volts

H p, 1 hr	Speed, r p m	Wt, lb	Cost
10	725	790	$ 696
25	575	1 670	1 042
50	500	2 970	1 531
75	475	3 900	2 052
100	460	5 000	2 600

Table 17. Cost, Weight and Usual Speed of A-C Generators

Kva	R p m	Wt, lb	Cost
100	450	4 400	$2 300
200	450	6 500	3 400
400	400	10 000	5 000
800	400	13 000	7 000

Series motors are usually of the "Mill Motor," totally enclosed type, rated at the output they will give for 1 hr without injury.

Table 17 gives data on a line of slow-speed, 60-cycle, three-phase generators, for 440 to 2 200 volts. For installation and cost of exciter add about 15%.

Three-phase induction motors for 60 cycles are standard. In Table 18 costs and weights are given for a standard line having the good starting characteristics obtained by a definite wound secondary. Squirrel-cage motors are slightly less expensive. Single-phase motors cost 30% more for given output and speed. Installation is simple for most a c motors and its cost can be taken at 4% to 8% of first cost.

Table 18. Weight, Cost and Usual Speed of 60-cycle, Wound Rotor, Induction Motors

H p	Speed, r p m	Wt, lb	Cost
1	1 800	137	$ 95
2	1 800	175	135
5	1 800	280	210
10	1 800	410	300
25	1 200	825	580
50	1 200	1 400	800
100	1 200	2 100	1 150

Table 19. Weight, Cost and Usual Speed of Synchronous Motors for 60 Cycles

H p	Speed, r p m	Wt, lb	Cost
20	450	1 465	$ 750
50	450	1 625	900
100	360	2 200	1 200
200	300	3 000	1 700

Costs of synchronous motors for 60 cycles, three-phase, are given in Table 19. Cost of installation and an exciter must be added, aggregating 10%.

Motor-generator sets, with 2 d-c machines, or 1 a-c and 1 d-c, cost about $23 per kw rated output for a 200-kw set running at 750 r p m; more for smaller sets. Flywheel sets and specially controlled sets cost more because of special features.

Table 20. Cost of Oil-cooled Transformers for 60 Cycles

Kva	Voltage	Wt, lb	Cost
3	2 400	170	$116
5	2 400	225	144
10	2 400	330	205
25	2 400	535	360
50	2 400	1 080	580
100	2 400	1 550	800

Transformers. Weights and costs of oil-cooled transformers for 60 cycles are given in Table 20; 25-cycle transformers cost 20 to 30% more. Cost of installation is very small, as there are no moving parts.

Transmission lines for 3-phase, 33 000 volts, with No 2 B & S wire, wooden poles and porcelain pin insulators, may be erected for $3 600 to $4 000 per mile, if topography of district is not difficult.

Power plants. Costs of building and equipping are: STEAM PLANTS, with reciprocating engines, vary according to size and character of plant from $90 to $140 per rated kw. STEAM-TURBINE PLANTS, from $60 to $150 per kw. HYDROELECTRIC PLANTS, from $100 to $300 per kw, including dam and other equipment. GAS ENGINE PLANTS, with gas producers, from $90 to $125 per kw. In each case the lower figure applies to very large installations.

Cost of operation of power plants varies so widely with local conditions that great detail is necessary for accurate estimates. A value of 0.5¢ per kw-hr (excluding fixed charges) is low, and is attainable only in large plants. 1¢ per kw-hr delivered to bus bars is common where load factor is reasonable, say 0.3 to 0.4, and is a figure commonly used for preliminary estimates. LOAD FACTOR is the ratio of average load for some period (as 24 hr) to maximum load during that time. Duration of PEAK LOAD must be specified (as 1 min or 15 min); it is usually a short period during which the machinery may carry the overload without injury. Total cost of a kw-hr, including fixed charges, is high when the load factor is low and vice versa.

SECTION 43

ELEMENTS OF STRUCTURAL DESIGN

BY

J. K. FINCH

RENWICK PROFESSOR OF CIVIL ENGINEERING, COLUMBIA UNIVERSITY

Note.—Numbers in parentheses, except numbers of formulas, refer to Bibliography at end of this section.

ELEMENTS OF STRUCTURAL DESIGN

1. GENERAL PRINCIPLES (1)

In structural design, one or all of 3 conditions may govern: safety, economy, and esthetic effect. Safety involves knowledge of the stresses produced by the external forces acting, mechanical properties of materials of construction, and details of design best suited to the purpose.

To compare two designs from standpoint of economy, the elements of cost are reduced to a common basis, using either capitalized or annual cost:

$$P = C + \frac{M}{r} + \frac{E}{(1+r)^m - 1} + \frac{R}{(1+r)^n - 1}$$

where P = capitalized cost, or sum which would build and perpetually maintain the structure; C = first cost; M = annual maintenance and operation; E = cost of extraordinary repairs every mth year; R = cost of renewal of structure in nth year; r = rate of interest. Annual cost = Pr.

Mine structures have a useful life not greater than life of the mine, and a sinking fund should be included = $S \div [(1+r)^x - 1]$, where x = useful life of structure in years. Esthetic principles are seldom considered except in important structures like bridges or architectural work. Following case is also common. An addition to a plant will be required n years hence and will cost A dollars. The expenditure that can be afforded now to avoid this future outlay equals the present worth of A dollars due in n years, or $p = A \div (1+r)^n$. See Tables on these subjects in Sec 45.

MECHANICS OF MATERIALS

2. STRESS, STRAIN, AND ELASTICITY (2, 3)

Strain or deformation is the change in dimension produced on any material by an external force; usually expressed as a ratio, inches per inch. Poisson's ratio of lateral to direct strain is about 0.25–0.3 for metals. STRESS is the resistance offered to deformation. For equilibrium it must equal the external force which it resists. It is expressed in units of force per unit area, lb per sq in or per sq ft. There are 3 kinds of strain and stress: TENSION, COMPRESSION, and SHEAR. Bending and torsion are combinations of these, though sometimes classed separately.

Modulus of elasticity or Young's Modulus = E = unit stress $\div$ unit strain = a constant (within elastic limit); or " stress is proportional to strain " (Hooke's law).

The modulus is generally the same in tension and compression for all materials in common use; a fundamental assumption in the theory of beams and columns. In shear or torsion, modulus = G = about 0.45 E. Hooke's law holds only for "elastic" materials (not plastic), and imperfectly for C I, concrete, and some other materials. Thus, a steel bar 1 in diam by 12 in long, under tensile load of 23 000 lb (= 29 300 lb per sq in), taking E = 30 000 000, will stretch 29 300 $\div$ 30 000 000 = 0.001 in per in, total 0.012 in. If this law held until strain = unity, the length of bar would be doubled; hence E is sometimes defined as force which would stretch a rod of unit cross-sec to double its length.

Elastic limit is the limiting stress, usually in lb per sq in, up to which Hooke's law holds. Most easily determined in testing by "drop of the beam" of the testing machine, which occurs at the YIELD POINT, or commercial elastic limit; higher than true elastic limit (see Fig 1). Yield point is not well defined in some materials; for C I, average is about 0.5 of ultimate strength.

Ultimate strength is the greatest stress, lb per sq in, which a material develops before failure; sometimes greater than BREAKING LOAD. Some materials in compression fail to give a true ultimate, but continue to compress and increase in cross-sec.

Resilience is a measure of DUCTILITY of material, and hence its ability to withstand shock or suddenly applied loads. It is the work required to produce a given stress.

Direct or static stresses are those acting always in one direction. REPEATED STRESSES vary in intensity in one direction, but never pass through zero. ALTERNATING STRESSES pass through zero, as from tension to compression. Rupture may be caused not only by a force exceeding the ultimate resistance of the material, but also by repeated action of forces of these two types, acting between certain limits which are less than the ultimate; known as the FATIGUE.

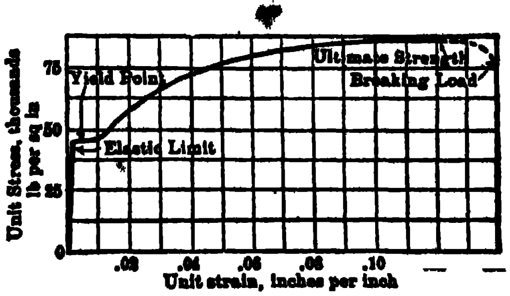

Fig 1. Stress and Strain for High-carbon Steel

Suddenly-applied loads, shock, and impact. A load is considered suddenly applied when its full amount acts instantly upon the material loaded. It produces strains and stresses double those produced by a gradually-applied load. Shock is produced when a load moves freely before acting upon the material. The effect is that of a suddenly-applied load plus the effect of the motion. In practice suddenly-applied loads seldom occur; shock is avoided if possible, but, in structures like RR bridges, an allowance for effect of impact (a combination of sudden application of load and of shock due to irregularities in roadbed, etc) is always made, as in designing hoisting ropes, and links and pins for couplings.

Working stress is the max considered safe by the engineer and used by him in designing. FACTOR OF SAFETY = ult strength divided by working stress; it depends on: (*a*) uniformity, reliability, and durability of material; (*b*) kind of stress and character of loading, and certainty with which amount of load is known; (*c*) character and life of structure. For uniform materials like steel, factor of 4 may be used; for variable materials like wood, 8–10. Factor of safety is greater for alternating than for direct stress; less for temporary structures than for permanent. In many cases (as for steel columns) safety factor should be computed on basis of elastic limit rather than ultimate strength.

3. BENDING MOMENTS AND SHEARS IN BEAMS (2, 3)

Beams: (*a*) simple beams or horiz members, with end supports; (*b*) cantilevers, having but 1 support, or projecting from a support; (*c*) constrained beams, having 2 supports and being rigidly fixed at one or both, or projecting over one or both, so that moments occur at the support; (*d*) continuous beams, with more than 2 points of support. Beams are subject to bending and shear; struts or columns to bending and compression. External bending moments and shears in (*a*) and (*b*) are easily determined as below. The derivation of formula for (*c*) is based on equation of the elastic or deflection curve, while (*d*) involves special treatment, based on Theory of Three Moments. Table 1 gives formulas for (*a*), (*b*), and (*c*); for (*d*) see (2, 3).

End reactions must equal total load, from law $\Sigma V = 0$. Also $\Sigma M = 0$; hence they may be found by taking moments about either support.

Example, Fig 2, M about $A = (2\,000 \times 3) + (4\,000 \times 4) = R_B \times 10$, or $R_B = 2\,200$ lb, and $R_A = 2\,000 + 4\,000 - 2\,200 = 3\,800$ lb.

Bending moment at any section is the algebraic sum of moments of all forces to left of the section, calling forces tending to cause clockwise rotation positive and others negative.

In Fig 2, bending moment at section $xy = (3\,800 \times 7) - (2\,000 \times 4) - (4\,000 \times 3) = +6\,600$ ft lb, and also equals $2\,200 \times 3$, or the moments to the right, if counter-clockwise be called plus.

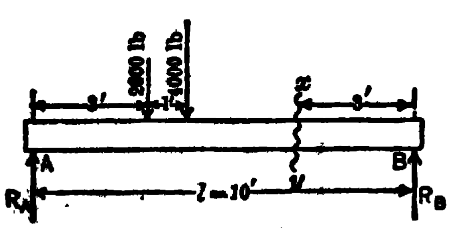

Fig 2. Loaded Beam

Vertical shear. At any section in a beam 2 equal and opposite forces may be acting, one on right and one on left, tending to shear the beam at that point. Vert shear at any section is equal to algebraic sum of forces to the left of the section, upward forces being taken as positive, downward forces, negative. Forces to right of section may also be used, changing the sign.

In Fig 2, vertical shear at $xy = 3\,800 - 2\,000 - 4\,000 = -2\,200$ lb. Fig 3 shows moments and shears at different sections of a beam.

Table 1. Reactions, Bending Moments, and Deflections of Beams

Simple Beams. Reactions, Bending Moments and Max Deflection (For Uniform Cross-sec)				Cantilever and Restrained Beams. Reactions, Bending Moments and Max Deflection (For Uniform Cross-sec)			
Beams and loading	**Reactions**	**Bending moments**	**Max deflection**	**Beams and loading**	**Reactions**	**Bending moments**	**Max deflection**
	$R_A = R_B$ $= 1/2\, wl$	$M = 1/2\, wx(l - x)$ $M_{max} = \frac{wl^2}{8}$	$\frac{5wl^4}{384EI}$		$R_B = wl$	$M = -\frac{wx^2}{2}$ $M_{max} = -\frac{wl^2}{2}$	$\frac{wl^4}{8EI}$
	$R_A = R_B$ $= 1/2\, P$	$x < 1/2\, l$ $M = \frac{P}{2}x$ $M_{max} = 1/4\, Pl$	$\frac{Pl^3}{48EI}$		$R_B = P$	$M = -Px$ $M_{max} = -Pl$	$\frac{Pl^3}{3EI}$
	$R_A = \frac{b}{l}P$ $R_B = \frac{a}{l}P$	$x < a$ $M = \frac{Pb}{l}x$ $M_{max} = \frac{Pba}{l}$	$\frac{Pb(6la - 3a^2)^{3/2}}{81EIl}$		$R_A = R_B$ $= 1/2\, wl$	$M = \frac{w}{12}(6lx - l^2 - 6x^2)$ $M_{max} = -\frac{wl^2}{12}$	$\frac{wl^4}{384EI}$
	$R_A = R_B$ $= P$	$x < a$ $M = Px$ $x > a < (l - a)$ $M = M_{max} = Pa$	$\frac{Pa(3l^2 - 4a^2)}{24EI}$		$R_A = R_B$ $= 1/2\, P$	$x < l \div 2$ $M = \frac{P}{8}(4x - l)$ $M_{max} = \pm\frac{Pl}{8}$	$\frac{Pl^3}{192EI}$
	$R_A = R_B$ $= 1/2\, W$	$x < l \div 2$ $M = Wx\left(\frac{1}{2} - \frac{2x^2}{3l^2}\right)$ $M_{max} = \frac{Wl}{6}$	$\frac{Wl^3}{60EI}$		$R_A = 3/8\, wl$ $R_B = 5/8\, wl$	$M = \frac{wx}{8}(3l - 4x)$ $M_{max} = -\frac{wl^2}{8}$	$\frac{wl^4}{185EI}$
	$R_A = \frac{W}{3}$ $R_B = \frac{2W}{3}$	$M = \frac{Wx}{3l^2}(l^2 - x^2)$ $M_{max} = \frac{2}{9\sqrt{3}}Wl$	$.01304\frac{Wl^3}{EI}$		$R_A = 5/16\, P$ $R_B = 11/16\, P$	$x < l \div 2$ $M = -5/16\, Px$ $x > l \div 2$ $M = P \div 16\,(8l - 11x)$ $M_{max} = -(3Pl \div 16)$	$\frac{1}{\sqrt{5}}\frac{Pl^3}{48EI}$

Maximum moments and shears determine the cross-sec of a beam. It is generally economical to use same cross-sec throughout, hence only max moments and shears need be computed. Point of max moment is found from principle shown in Fig 3; it occurs where shear passes through zero. Max shear occurs at supports. In designing structures for moving loads, a series of concentrated loads is used, similar in spacing and amount to the cars or moving load to be used. These loads may occupy different positions, and the max moment is determined as in Art 19. Table 1 gives formulas for reactions, max bending moments, moments at any section and max deflection (for uniform cross-section), for common forms of beams and loading.

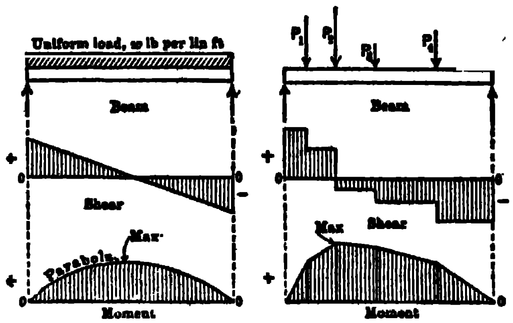

Fig 3. Graphic Representation of Moments and Shears in a Beam

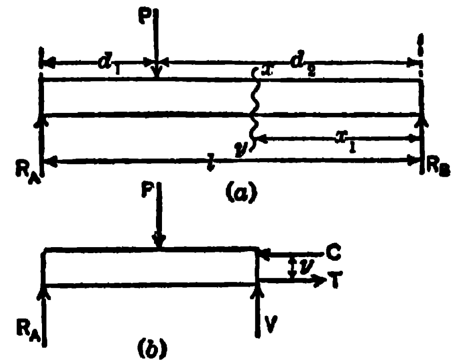

Fig 4. Bending Moment in a Simple Beam

4. FLEXURE OF BEAMS (2, 3)

All beams, when subjected to loading, are stressed in tension, compression and shear. Vert loading produces vert shear, causing equal horiz shearing forces, which give to the horiz fibers of the beam their tension and compression stresses. Investigation of beams is based on the 3 laws of equilibrium (Sec 36, Art 32), the external forces being usually coplanar and at right angles to beam.

Thus, if beam in Fig 4*a* be cut at any section xy, the bending moment at $xy = P\,d_1x_1 \div l$, and shear at $xy = P\,d_1 \div l$ (Art 3). This moment must be resisted by the inner forces of beam acting on the right of section xy, or 2 forces C and T (both equal since ΣH must $= 0$) and acting with lever arm y. Assuming E equal in tension and compression, that Hooke's law holds, and that plane sections of a beam before bending remain plane after bending (Navier's hypothesis), then C and T are resultants of uniformly varying stresses acting over the upper and lower sections of beam, having 0 intensity at a horiz plane passing through the center of gravity of section (known as the NEUTRAL AXIS), and max intensity at the extreme fibers of beam, directly proportional to distance of these fibers from neutral axis. The internal, or RESISTING MOMENT, is then $= M = kI \div d = kS$, where M is in inch-lb, k = extreme fiber stress, lb per sq in, I = moment of inertia of the section, in^4, d = distance from neutral axis to extreme fiber, in, and $S = I \div d$ = SECTION MODULUS.

Example. Assuming a T-section (Fig 5), subjected to external bending moment of 9 000 inch-lb, I is found $= 2.34$, the center of gravity being 2.09 in from bottom, or 0.91 in from top, giving extreme fiber stress in compression, $k = dM \div I = (0.91 \times 9\,000) \div 2.34 = 3\,500$ lb per sq in, while for tension side, $d = 2.09$ and $k = 8\,050$. For a symmetrical section, k is equal in tension and compression. In design, the greatest d should be used. For moments of inertia of various sections see Art 26 and Sec 36, Art 41–45.

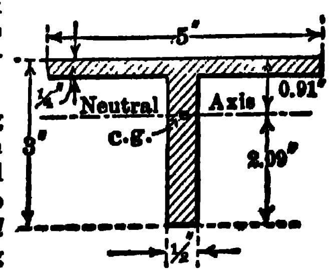

Fig 5. T-Section Beam

Working value of k used in design is found by reducing by a proper factor of safety the k found by testing a beam to failure. Value at failure is the MODULUS OF RUPTURE, and is computed on assumption that above equation holds to failure (actually true only to elastic limit), since M, I and d are known. The work of design is facilitated by tables giving values of S for different beam sections. Instead of S, the COEFF OF STRENGTH is often given. Thus, assuming M in ft-lb, let C = coeff of strength $= 8\,M$ ($= Wl$ for uniform loading or $2\,Wl$ for concentrated, where W = total load, lb, and l = span, ft), then $C = {}^2/_3\,kS$; and, knowing value of C, the safe load is computed, or vice versa. C is in ft-lb.

Shear. In Fig 4*b*, a force V, equal to the vert shear, must be applied at section xy for equilibrium. $V \div$ the area of cross-sec of beam $= v =$ the aver intensity of shearing stress, and for rectangular beams the max intensity $= 3\,v \div 2$ or $3\,V \div 2\,bh$, and occurs

at the neutral axis, where b = breadth and h = depth of beam. Usually, the limiting factors in design are axial tension and compression, it being unnecessary to increase size of member because of shear. In short or deep beams, shear may become the limiting factor, and in short timber beams especially, due to laminated structure, horiz shear often controls. Diagonal stresses are only important in reinforced concrete beams (Art 14).

5. COLUMNS AND STRUTS (2, 3)

Compression members are of 3 classes, depending upon mode of failure, which in turn depends on ratio of length of column to its least RADIUS OF GYRATION (Sec 36, Art 42), or in solid sections to its least diam, expressed as $l \div r$, where l = length, in, and r = least radius of gyration, in (Art 28).

Short columns, in which $l \div r$ is less than 10 or 15, generally fail by compression only, and are sometimes termed short blocks. The safe working stress in compression is used in their design.

Short blocks are tested for determining strength of materials in compression; most concrete and many timber columns fall in this class. They fail by compression or by shearing in a plane making an angle of slightly over 45° with the axis of block. Shear failure occurs when resistance to shear is less than 0.5 resistance to direct stress, as compression induces shearing stress on all oblique planes and max intensity (= 0.5 that of the direct stress) on a 45° plane. Hence length of test specimens should always be stated, and generally will be 3 times breadth; many tests fail to agree, due to use of variable lengths.

Ordinary columns, in which $l \div r$ ranges from 40 to 120, fail by combined compression and bending. There are 2 kinds of formulas used: (*a*) those derived from theory, in which constants are inserted from tests; (*b*) empirical formulas, from tests only. For column design, see Art 14, 21, 28. For eccentric loading, see Art 6. The most widely used of the first kind is Gordon's or Rankine's formula (demonstrated first by Tredgold): $P = cA \div \left(1 + a\frac{l^2}{r^2}\right)$, where P = ult strength, lb; A = area, sq in; l and r as above, and c and a are constants depending upon kind of material, and l and a depending on condition of fixity of ends of column. This formula may be used for design by reducing P by a proper factor of safety.

Theoretically, the strongest column has flat ends, a column with round or pin ends which is free to bend and not restrained at the ends being only 0.25, and a column with one end round and one end free only about 0.5 as strong. Practically, pin-end columns appear to be as strong as flat-end, probably due to difficulty in getting an even distribution of loading and the resulting eccentric stress with the latter. Hence a should be determined by tests of both flat and pin-end columns.

The principal formula of type (*b*) is the STRAIGHT-LINE FORMULA, so called because its graph is a straight line. This line is obtained by plotting, for a series of tests of columns of one type, the ultimate strength and $l \div r$ ratio, and drawing an aver line through these points. The general form is $p = A - B\,(l \div r)$, where $p = P \div A$ = intensity of stress, and A and B come from the tests. This formula is widely used, often displacing the Gordon. As before, p is properly reduced for design. LONG COLUMNS, in which $l \div r$ exceeds say 200, are barred from structural practice and will not be discussed (2).

6. TORSION AND COMBINED STRESS

Torsion, a type of shearing stress, is fundamental in the design of shafts and other members subjected to a twisting moment. For circular section the formula is $d = 1.72 \sqrt[3]{M \div s}$, where d = diam, in, of a shaft capable of resisting a twisting moment M, in-lb, with a max torsive shear in the extreme fibers of s in-lb per sq in.

Example. Assume a working torsive shearing stress of 8 000 lb per sq in, in designing a circular shaft to carry a twisting moment produced by a force of 2 000 lb acting with a lever arm of 48 in. $M = 2\,000 \times 48 = 96\,000$ in-lb, and from the formula $d = 4$ in (about).

Combined stress is the condition of stress occurring when a member is simultaneously subjected to 2 of the 3 elemental forms of stress. A common case, compression and bending, occurs in the eccentric loading of columns and joints, and foundations of masonry structures.

Eccentric loading of columns. Whenever possible in column design the load is applied to coincide with the axis of the column. Through use of brackets, some columns are loaded at a distance e

from the axis, as in Fig 6. This increases compression on left side and decreases it on the right, and must be provided for by increasing the section until the max stress does not exceed the allowable. The unit compression due to direct stress $= p_0 = P \div A$. The unit bending stress caused by the moment $M = Px$ will be $p' = Md \div 2I$, where I = moment of inertia of the section. Max unit stress $= p = p_0 + p'$, and must not exceed the safe value. Minimum stress $= p_0 - p'$. These formulas, though in common use, are only approx, as increase in stress due to deflection is not considered. (See Art 8 for foundations.) Combined stress also occurs in inclined bridge members, as eye bars and chords, which are subjected to bending due to their own wt as well as the direct stress of tension or compression. The common method of procedure is like to that given above. Shafts also frequently act under the combined stress of torsion and bending (as in drum shafts of hoists).

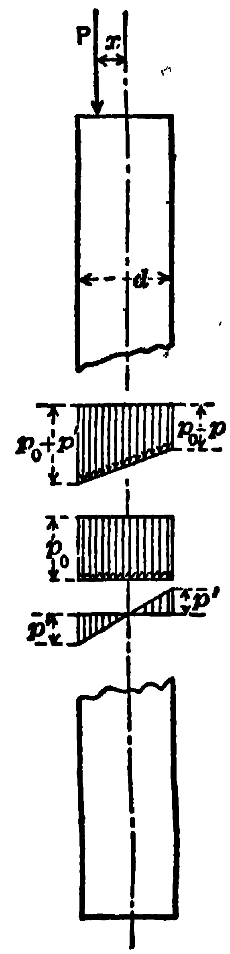

Fig 6. Eccentric Loading of Columns

FOUNDATIONS

7. BEARING POWER OF SOILS (5, 6)

Failure of foundations is generally caused by use of empirical rules, neglect of fundamental principles and poor judgment of designer.

Requisites of foundations: (*a*) They should be leveled off approx at right angles to the direction of loading. This insures that no component of the press will be tangential to the foundation surface, hence no tendency to sliding. Natural inequalities in rock surfaces usually hold the footing in place and make expensive stepping unnecessary. (*b*) When built on earth, design should be such that center of press and center of base coincide. In retaining walls, it is too costly to adhere to this rule; low foundation pressures are required and settlement is common. On rock, little or no settlement can take place. (*c*) Each foundation for separate parts of a structure supported at several points, as walls and interior columns in a building, should be so designed, when on a compressible material, as to be subjected to pressure intensities that will cause uniform settlement.

Safe bearing values of foundation materials depend on character, condition, depth and amount of moisture present, of the foundation material, general sub-surface conditions at the site; also the type of structure and character of loading. Borings, or test pits and soil tests, should be made for important structures. Permanent foundations should be well below the frost level. Some soils become more compact as depth increases and loads may be increased. Also the surcharge effect, or lateral confinement, permits higher loads where foundations are below general level of excavation. Danger of disturbance by adjacent excavations or operations must be considered. A foundation fails when settlement, especially unequal settlement, partially destroys the use of the structure placed upon it.

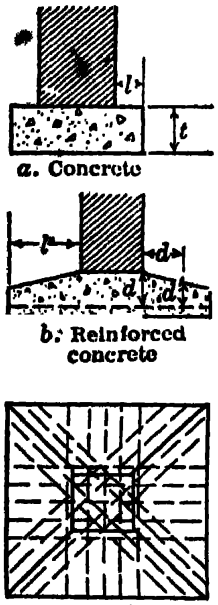
Table 2. Allowable Pressures of Foundation Bearing Materials (Boston Build'g Code)

Class	Material	Allowable bearing value (tons per sq ft)
1.	Massive bedrock, as granitic rock; also gneiss, trap rock, felsite and well cemented conglomerates, in sound condition (sound condition allows some cracks)	100
2.	Laminated, such as slate, schist, in sound condition (some cracks allowed)	35
3.	Shale in sound condition (some cracks allowed)	10
4.	Residual deposits of shattered or broken bed rock of any kind except shale	10
5.	Hardpan	10
6.	Gravel and sand-gravel mixtures, compact	5
7.	Gravel and sand-gravel mixtures, loose; sand, coarse, compact	4
8.	Sand, coarse, loose; sand, fine, compact	3
9.	Sand, fine, loose	1
10.	Hard clay	6
11.	Medium clay	4
12.	Soft clay	1
13.	Silt, shattered shale, or any deposit of unusual character not provided for herein	Value determined by tests

The wide variation in bearing values in tons per sq ft of various materials is illustrated by Table 2 (Boston Bl'd'g Code), which is a guide in design but must be used with judgment and caution. In recent years the science of soil mechanics has been rapidly developed, and design, although still largely a matter of experience, is based more and more on scientific data and knowledge of the physical characters of soils.

8. SPREAD FOUNDATIONS (5)

The commonest foundation for walls and buildings is a spread footing, which distributes load over a larger area at the base to reduce the press per sq ft to that considered safe from a study of site and soil. TOTAL LOAD comprises dead plus live load. The DEAD LOAD, or wt of structure, is computed as in Art 17. The LIVE LOAD is often uncertain in amount, and for buildings on compressible soil, the footings of interior columns should be designed with allowance for the fact that usually only a small part of total live load acts at one time. Otherwise unequal settlement will occur, as the footings carry chiefly fixed dead load.



a. Concrete

b. Reinforced concrete

c. Column footing of type *b* (plan)

Fig 7. Spread Footings

Depth of foundation below lowest level of structure will depend on: (*a*) necessity of going below frost line, to prevent heaving due to freezing; (*b*) depth required to reach suitable foundation material. Frame buildings are quite flexible, loads usually light, and foundation wall is seldom carried deeper than 1.5–2 ft, or much below cellar level. Masonry buildings require deeper and heavier foundations to prevent excessive settlement and cracking. In larger structures design is more involved.

For moderate loads, wall and column footings of concrete may be used, the projection of the footing beyond face of wall or pier not being large enough to demand special reinforcement. In such cases the thickness of the footing t should be proportioned to the offset l (Fig 7*a*) and should generally be in the ratio of about 2 : 1. Where wider spread is required, modern practice uses a reinforced footing or grillage of steel I-beams encased in concrete. For column footings the spread is in 4 directions and reinforcement must be in 2 or more layers with bars as in Fig 7*c*.

The footing in Fig 7*b* may be designed as in Art 14. Experiments indicate that the shear should not exceed the allowable at a distance d from face of wall; hence d is usually greater than required for bending, being fixed by d' which depends on shear. When the required offset l must be large to keep unit press low, large masses of masonry and deep excavations are avoided by using a grillage consisting of 2 or more layers of timber or steel beams (17), or a reinforced footing with rods in both directions. For more complicated designs, see Bib 5.

9. PILE FOUNDATIONS (5)

Pile foundations are intermediate in type between the spread footing and costly caisson foundations carried to great depths. They are used: (*a*) where a soft, compressible soil of poor bearing capac overlies a firm layer of good quality. The pile then becomes, in effect, a column, partly supported by the surrounding material, but transmitting its load largely by point bearing to the good material below; (*b*) where the foundation material is of gradually increasing capac and the pile carries its load both by point bearing and by skin friction; (*c*) in loose or silty soils of low bearing capac, which can be compacted by pile driving to permit increased bearing loads and where skin friction is most important. In case (*a*) the total load carried will be the safe load per pile, x, and the no of piles, provided the point reaches rock or a very resistant soil. In general, clusters of piles act with a "group effect" and may carry far less than this value.

Design of pile footings is not a simple matter and no one rule is always applicable. For piles in sandy material (*b*, *c* above) some indication of safe load P, lb, may be obtained from the empirical equation, $P = 12\ Whe \div (s + c)F$, where W is wt of the driving hammer, lb; h, the fall or drop, ft (or equivalent ht for a steam hammer); e an effic allowance, 75% for drop and about 90% for steam hammers; s, aver penetration of the pile under the last 10 blows; c, a constant, 1.0 for drop and 0.1 for steam hammers; F, factor of safety 3–6. Soft materials may develop some "structure" (interlocking of particles) and excessive pile driving may destroy this natural quality and cause lower bearing capac. Minimum spacing of piles is about 3 diams. Overdriving wood piles causes splitting.

Wood piles are used for both temporary and permanent foundations, and when below water level will last indefinitely. In temporary work, as trestles, the pile serves the purpose of both foundation and column. Oak, pine and spruce are in common use, depending upon difficulty in driving, length required, and purpose, oak being good for hard driving or where pile is subjected to abrasion. For very hard soil, piles are pointed with iron shoes and the butt is chamfered off and banded with iron 0.5–1 in thick and 2–3 in wide. Special driving caps, with a tapered recess, are also effective. Wood piles should generally be at least 6 in diam at point (preferably 8 in) and about 14 in at butt (not over 18 in).

Concrete piles are cast-and-driven or cast-in-place. They are for permanent construction where excavation to water level, required for wood piles, would be too costly. Recently piles of type (a) have been sunk by driving steel pipe with hammer, with or without use of water jet, blowing out interior with compressed air, and filling with concrete. Such piles are essentially small caissons; used to sizes 2 or 3 ft or more in diam.

Capping of piles to provide a foundation footing is usually done by excavating 12 in below tops of piles and encasing with concrete carried to 12 in or more in thickness over top of piles.

MASONRY AND CONCRETE STRUCTURES

10. LIME, CEMENT AND MORTAR (4)

Common lime is calcined limestone, which, when fresh, should be in lumps with little dust. It should be stored in a dry place. When slaked with water, lime paste may be kept indefinitely under water (protected from air). If exposed to air in a thin layer lime may be slaked to a dry powder, sold as HYDRATED LIME.

Cement is of 3 kinds, Natural, Portland, and Pozzuolana. NATURAL CEMENT is calcined cement rock, containing proper proportions of lime and clay, ground to a fine powder. It is not now used for structures requiring great strength, having been superseded by Portland cement, which costs but little more and is stronger. It was early made at Rosendale, N Y, hence sometimes called Rosendale cement. PORTLAND CEMENT is made by grinding to a fine powder the clinker from calcining to incipient fusion a powdered mixture of properly proportioned lime and clay materials. Limestone mixed with clay may be used, also cement rock and clay or limestone, marl and clay, limestone and slag.

Production of Portland cement in U S has increased rapidly, to over 100 million bbl annually. Cement is measured in bbl and usually sold in paper bags or in bulk, the aver price at the mills being \$2–\$3 per bbl. Wt of Portland cement averages 100 lb per cu ft. A bbl weighs 376 lb; a bag, 94 lb. A bbl contains about 3.8 cu ft. Natural cement weighs 265–300 lb per bbl and 90–100 per bag. POZZUOLANA CEMENT proper is made by grinding hydrated lime and pozzuolana, a volcanic material occurring near Naples, and used by the ancient Romans. So-called SLAG CEMENT is of this class, although slag is also used for a true Portland cement which differs in no essential from other Portland.

Testing cement. Portland cement has now become, in name, if not fully in fact, a standardised product and for all except largest works is usually bought without specific testing. It is well to specify A S T M standards (Am Soc for Testing Materials), and it is common to require that specimens of concrete be tested both as a check on the cement and as a measure of the quality of the aggregate and mixing.

Cement grout is a mixture of 1 vol of cement with 1, 2 or more vols of sand. It is used in a semi-liquid form for grouting column bases, bearing plates and wherever space requires a fluid mix.

Cement mortar, usually in proportion of 1 vol cement to 2–3 sand, is used for masonry. Pure cement mortar is "short" and difficult to handle with a trowel. Addition of 5–10% hydrated lime to the cement makes the mortar "slick" and easier to work. A cu yd of 1 : 2 mortar requires about 2.6 bbl cement and 0.9 cu yd sand; a 1 : 3 mortar, about 1.9 and 1.0, for aver sands.

11. STONE MASONRY.

Cut-stone masonry, formerly widely used, has, due to rising costs of labor, been superseded in practically all work except where architectural effect justifies cost. But when labor is cheap and cement costly, rubble masonry of unsquared or roughly squared stone, can sometimes be used to advantage. In such work stones should be laid in irregular courses in natural bedding plane, with joints overlapped so as to interlock; with frequent headers extending into wall, to tie in or bond stretchers (see brickwork for terms) and with all voids filled with small stones and mortar. The hammering or sliding of stones on work under construction should be prohibited and porous stone should be wetted before use. Aver quantity of mortar per cu yd of rubble varies with shape and amount

of dressing of stones, from 0.2 to 0.4 cu yd. Rubble masonry will carry 10–15 ton per sq ft; best quality cut-stone masonry may safely carry 30 or more.

12. BRICK AND BRICKWORK

COMMON BRICK is used for ordinary construction. Best brick, when broken, shows a fine, uniform texture, deep salmon color, contains no fissures, air bubbles, pebbles nor lumps of lime. It should also have plane faces and parallel edges (no warping), and give a clear ringing sound when struck (thorough burning). Usual size is 8.25 × 4 × 2.25 in. Overburned brick is dark in color and liable to be warped and brittle. Light or yellow color indicates soft or underburned brick. PRESSED BRICK is brick molded under heavy press. It is uniform in shape and of greater density, absorbing only 10–20% of its wt of water, while common brick may absorb 30–35%. It is used for exterior faces of walls, or for neat finish. ENAMELED BRICK is made from clay containing a large amount of fire clay, on which a surface finish of enamel is placed before or after burning. GLAZED BRICK is produced by applying a slip to the unburned brick, which adheres to clay and holds a glaze composed of readily fusible materials giving a vitreous surface. FIREBRICK is of fireclay burned at a high temp. Good fireclay is free from pyrites, lime, and other ingredients which would cause swelling or vitrification. Fireclay brick should be of uniform color, white or white speckled with brown throughout; should be laid in thin paste of fireclay, with joints as thin as possible. SAND-LIME BRICK is generally pure white. Made by molding 4 to 6% of finely powdered lime with silica sand. CEMENT BRICK is of sand, with Portland cement as the binding material.

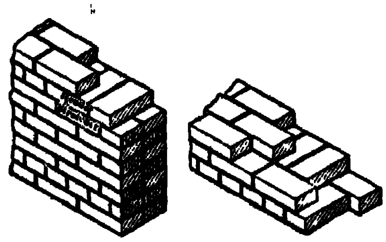


Fig 8. Bonds for Brickwork

Bond results from laying brick so as to tie the wall together longitudinally and transversely. Fig 8 shows the common bond, consisting of 4 to 7 courses of STRETCHERS to 1 course of HEADERS, the latter tying the wall together transversely. In laying brick, vert joints in header courses must be of such thickness that they will not come over a joint in the stretcher course. Brick should be thoroughly wet before laying; joints $^1/_4$–$^3/_8$ in thick, and for best work brick should be placed on a full mortar bed and shoved into place ("shove joints"). All vert joints should be thoroughly "slushed" with semi-liquid mortar, so the brick will be well bedded. Face of the wall may be finished with either flush, struck or weather joints.

Number of brick required depends on size. For common masonry 1 cu ft generally requires 20 brick; 1 cu yd, 500 to 600 brick.

Quantity of mortar. For aver joints ($^1/_4$–$^3/_8$-in) 1 cu yd common brickwork requires $^1/_4$–$^1/_3$ cu yd mortar, or about 0.5 cu yd per 1 000 brick.

Working stresses for compression are: for common brick in Portland cement mortar, 175 lb per sq in. Brick piers may be designed by the formula, $p = P - 6H + D$, where p = allowable unit stress, lb per sq in; P = allowable direct compressive stress, lb per sq in; H = height, in; D = least thickness of pier, in.

Common brick are sold by the thousand (M); aver price, $12–$20 per M. One bricklayer will lay 1 200–1 600 brick per 8 hr, in straight thick walls, but only 250–500 for work involving many corners or angles.

13. CONCRETE (7)

Composition. Concrete is a mixture of broken stone, gravel, cinders, or slag, called the COARSE AGGREGATE, and sand or stone screenings, known as the FINE AGGREGATE, with a cementing material, as cement or asphalt. Portland cement is almost invariably used in general construction and for reinforced concrete.

Proportions of ingredients are usually expressed by vol as, 1 : 2 : 4 (a relatively "rich" mix), or 1 : 3 : 6 (a lean mix), indicating parts by vol of cement, fine and coarse aggregates.

Strength of Portland cement concrete (hereafter referred to as concrete) depends upon quality of the 3 basic ingredients; also (*a*) quantity of cement in proportion to total aggregates, (*b*) ratio between coarse and fine aggregates, (*c*) amount of water used in mixing (cement-water ratio), (*d*) adequacy of mixing, (*e*) method of placing, (*f*) method of curing (setting). All other factors being the same, the more cement used the stronger the mix. Ratio of sand to stone by vol is usually about 1 : 2. Great caution should be exercised in using "run of bank" gravel, on assumption that 1 part cement to 6–9 parts total aggregate will be satisfactory. Sand, present usually far in excess of coarse material, is defined as material passing $^1/_4$-in screen and bank gravel requires that part of sand be

screened out; otherwise, the mortar binding the coarse aggregate may be as weak as 1 : 4 or more and concrete is of poor quality. For high density, strength and impermeability, the minimum of water required for setting should be used. As such a mix can not be successfully placed, amount of water is determined by "workability" and will vary with difficulty of placing. Excess water leaves "water voids" in mix, tends to produce "segregation" (settling of coarse aggregates), and excess water flushing to surface washes out cement and leads to later surface disintegration or "map cracking." Workability is measured by slump test. Fill conical shell 4 in diam at top, 8 at bottom and 12 in high, with proposed mix rodded in place and "struck off" at top. When shell is lifted vertically drop of mass, in = slump. For mass work or highway construction water to give slump of 1 to 3 in is used. For building and similar construction requiring placing around reinforcing bars, 3 to 6 in. This usually requires 5 to 8 gal water per cu yd of mix. Varies with character of aggregate.

Hand mixing is now seldom used, mixing machines being available in sizes from a few cu ft to 10 yd or more. Mixing should start with dry materials, cement added to sand, then coarse aggregate and, finally, water.

Care must be exercised in placing, so as to fill forms and avoid pockets or "honeycombing" (areas of coarse aggregate without enough mortar to fill voids). Spading face with tamping bars, hand tamping and vibrating mechanical or elec tampers are used. Avoid excessive tamping, as it causes segregation, as for excess water noted above. Concrete may be placed under water by means of metal pipes, the concrete being fed in at the upper end as fast as it goes out at the lower end, thus preventing it from falling through the water, which would wash out the cement. In joining old and new surfaces, care should be taken to remove all dirt and laitance (scum which forms on surface) and thoroughly to wet the surface of the old work. In long walls, expansion joints should be provided every 30 to 50 ft. Fig 9 shows common forms of joints. Concrete is not injuriously affected by oils and acids, unless there is enough seriously to affect other materials. Salt or alkali water causes disintegration at the water line, due to unknown action, and sand containing alkali should not be used.

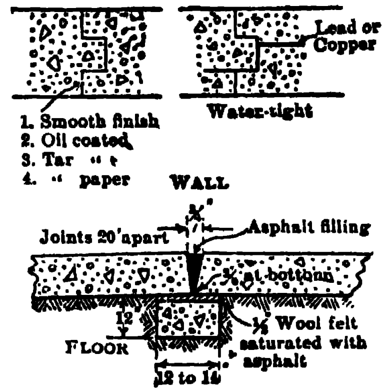

Fig 9. Concrete Floor Joints

Proper "curing" has the object of providing adequate moisture until concrete has set and is vitally important. Fresh concrete should be protected from direct rays of sun by covering with burlap or straw kept constantly damp. An asphalt emulsion coating has recently been used for highway work. In cold weather concrete must be kept from freezing until set, and protected from alternate freezing and thawing until fully hardened.

Coarse aggregate may consist of gravel or broken stone, its quality being at least equal to that of hardened cement mortar, preferably graded in size (although much " single-size " stone is used), clean (broken stone or washed gravel best), durable, and contain no soft, flat, elongated or friable particles. Max size depends on dimensions of construction. For massive work " cobble concrete " or a max size stone of 3 in or more can be used. For thinner walls 1.5 in, for coping and thin walls 1 in, while for reinforced work 0.75-in is usually required. For cinder concrete, hard " steam " cinders should be used, free from soot or excessive fine particles.

Specifications. For small work so-called standard mixes are used as follows: RICH MIXTURE, 1 : 1.5 : 3; for columns or other parts subjected to high stresses or requiring to be completely watertight. STANDARD MIXTURE, 1 : 2 : 4; for reinforced floors, beams and columns, arches, reinforced engine or machine foundations subject to vibrations, tanks, sewers, conduits or other watertight work. MEDIUM MIXTURE, 1 : 3.5 : 5; for ordinary machine foundations, retaining walls, abutments, piers, thin foundation walls, building walls, ordinary floors, sidewalks and sewers with heavy walls. LEAN MIXTURE, 1 : 3 : 6; for unimportant work in masses, for heavy walls, for large foundations supporting a stationary load, and for backing for stone masonry. It is always desirable on important work to experiment and test various mixtures to secure best yield and satisfactory quality. Tendency is to specify required strength for various parts of work rather than set proportions.

Strength of stone concrete in compression, when tested in cylinders (usually 8 in diam by 16 in high) is 1 000 to 4 000 lb per sq in. Strength increases with age, the allowable stresses in design being given in ratios of the ultimate compressive strength at 28 days ($= f'_c$, Art 14). The tensile strength of concrete is even more markedly affected than its compressive strength by factors noted above, hence is usually not counted on in design. For a 1 : 2 : 4 mix, it varies from 200 to 300 lb per sq in; for 1 : 3 : 6, from 100 to 175. Shearing strength is difficult to determine, but it is probably about 0.5 the compressive strength. Modulus of elasticity is also variable, the material not usually showing true

elastic behavior; for working loads, it is 2 500 000–3 500 000 lb per sq in, depending on mixture and age.

Quantities of materials required for 1 cu yd concrete with various aggregates depends so much on character of aggregates, voids, etc., that it is best determined by trial. As a rough approximation for aver broken stone concrete, divide 11 by sum of parts = bbl cement per cu yd. Multiply this by the number of parts of sand and by the cu ft in 1 bbl cement (3.8 aver) and divide by 27. This equals the cu yd of sand required. Similarly for the broken stone.

Example. 1 : 3 : 5 cement concrete. 11 + 9 = 1.22 bbl cement per cu yd. 1.22 × 3.8 × 3 + 27 = 0.51 cu yd sand and 1.22 × 3.8 × 5 + 27 = 0.84 cu yd broken stone.

Rates of work and costs. One man will mix, wheel 50 ft, level and ram, about 1.5 cu yd of concrete per 8-hr day. A gang of 15 men will handle as above an aver of about 20–25 cu yd, and 1 man will level and ram in 6-in layers about 8 cu yd per 8-hr day. Cost varies from $15 to $30 or more per yard, depending on labor and material costs, as well as the kind of work.

Forms for concrete are made of partly seasoned pine or spruce, planed on one side (to give smooth surface and even thickness) and for best work tongued and grooved. The lagging is generally 1 in thick, but for heavy work and where the forms are to be used several times 2 in is better. Studding is commonly of 2 by 4 in to 4 by 6 in, spaced 1.5 to 2 ft centers for 1-in lagging, and 4 to 5 ft for 2-in. Pressure due to concrete is about that of a liquid weighing 80 to 140 lb per cu ft, depending upon the amount of water used in mixing and rate of placing. Since forms cost 0.25 to 0.5 of the entire cost of the work, a concrete structure should be designed with a view to simplicity in the form work, a little extra concrete often being economical. Forms should be carefully designed and constructed, so as to be easily removed without injury to the structure or the forms themselves; this is done by making them in units, joined by cleats, the pressure from the concrete being taken up by transverse tie wires, which are left in the concrete, or by external braces and struts.

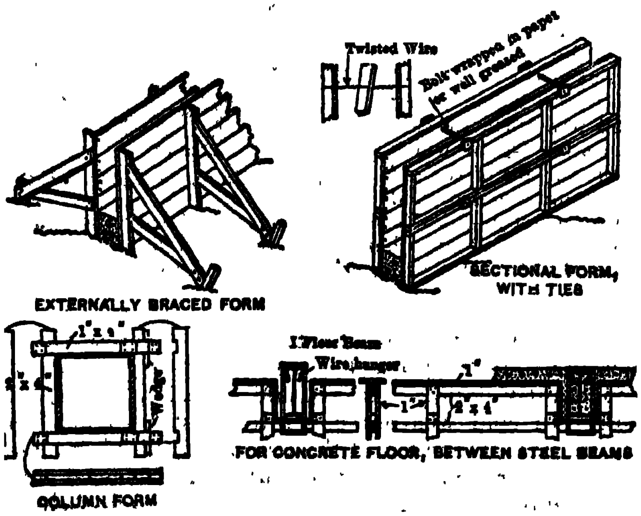

Fig 10. Forms for Concrete

Adhesion of concrete to the forms can be prevented by applying crude oil, soap or grease. Fig 10 shows typical forms. The time which must elapse before forms can safely be removed depends on weather conditions and how soon the structure will receive its load. Time under ordinary conditions: walls in mass work, 1 to 3 days or until concrete will bear press of thumb without indenting; thin walls and columns, summer 2 days, cold weather 5 days, provided they carry no load; slabs, up to 7 ft span, beams and girders, summer 6 days, cold weather 2 weeks; long-span slabs and girders, summer 10 days, cold weather 3 weeks to 1 month; arches, small 1 week, large 1 month.

14. REINFORCED CONCRETE (7, 8)

Concrete, reinforced by steel bars, is one of the most useful and important structural materials, and, for permanent structures, has to some extent replaced older materials. Its economy lies in its greater durability, requiring less maintenance, fire-resistance, and the ease with which it can be molded into shapes. Structures can be built of it economically wherever Portland cement and suitable aggregate are available, and for the most part by unskilled labor. To get the desired results, details of design should be simple, completely worked out and shown on the plans, and construction supervised and inspected by competent engineers. Failures can usually be traced to neglect of these principles.

Reinforcing bars are usually 0.25–1.5 in. The 0.75-in bar is known as BASE, there being no extra charge for this size or larger, but smaller bars cost more. Round bars are used more than squares, especially in sizes less than 1 in. There are 7 standard round

bars and 4 squares (Table 3). Except under unusual circumstances, designs should be limited to these bars. DEFORMED BARS are used to provide a bond between steel and concrete, independent of adhesion. They are obtainable in the 11 standard sizes in Table 3. Wire mesh and various forms of expanded metal are much used in slabs, walls and other thin sections.

Table 3. Data on Standard Bars

Size, in	Shape	Area, sq in	Wt, lb per ft	Perimeter, in
1/4	Round	0.049	0.167	0.785
3/8	Round	0.110	0.376	1.178
1/2	Round	0.196	0.668	1.571
1/2	Square	0.250	0.850	2.000
5/8	Round	0.307	1.043	1.963
3/4	Round	0.442	1.502	2.356
7/8	Round	0.601	2.044	2.749
1	Round	0.785	2.670	3.152
1	Square	1.000	3.400	4.000
1 1/8	Square	1.266	4.303	4.500
1 1/4	Square	1.562	5.313	5.000

Beams. Working formulas, based on Navier's hypothesis and other assumptions listed below, are for design purposes only; that is, within normal working conditions. Since the limit of extensibility of concrete is only about 0.0002 in per in, tension in the concrete is neglected, the steel being supplied to take all the tension. The first time the beam is loaded to its full design load, fine cracks will develop on the tension side of the beam and the above assumption will be very nearly satisfied. In addition, these formulas are predicated on a perfect bond between steel and concrete, and a constant modulus of elasticity in the concrete. The span of a reinforced concrete beam is taken as the clear span plus the depth of the beam, but need not exceed the c-c distance of supports.

Standard notation. For convenience the complete notation is given herewith (lb, in, lb per sq in).

Rectangular Beams and Slabs

- f_s unit fiber stress in steel
- f_c unit fiber stress at its extreme fibers
- f'_c ultimate compression strength at 28 days, when cast in standard 6 by 12-in cyl
- E_s modulus of elasticity of steel
- E_c modulus of elasticity of concrete
- A_s area of cross-sec of steel
- e_s unit strain of steel due to f_s
- e_c unit strain of concrete due to f_c
- n ratio of E_s to E_c
- T total tension in cross-sec of steel
- C total compression in cross-sec of concrete
- M external moment acting on beam due to loads
- M_s resisting moment of steel in tension
- M_c resisting moment of concrete in compression
- b width of beam
- d effective depth of beam = distance from compression face to center of gravity of the steel
- k ratio of depth of neutral axis to effective depth
- j ratio of arm of resisting couple to effective depth
- p ratio of A_s to bd
- r ratio of f_s to f_c
- e thickness of concrete from outside of bottom row of steel to tension face (protective covering)
- i diam of bar
- s side of sq bar

T-Beams

- b width of flange
- b' width of stem
- t thickness of flange

Shear and Bond

- V total external shear
- V_c portion of total shear carried by concrete
- V' portion of total shear carried by web reinforcement
- v, v_c, v' unit shear stresses (see above)
- A_v total area of stirrup, two legs
- f_v unit tensile stress in stirrup
- u bond stress, per unit of surface area of bar
- Σo sum of perimeters of horiz bars

Rectangular beam and slab formulas (Fig 11). From Navier's hypothesis and Hooke's Law (Art 2):

$$r = \frac{f_s}{f_c} = n\,\frac{(1-k)}{k} \tag{1}$$

and the resisting moment of the beam based on working strength of steel is:

$$M_s = Tjd = A_s f_s jd = pf_s jbd^2 = C_s bd^2 \tag{2}$$

where

$$C_s = pf_s j$$

also for the concrete

$$M_c = Cjd = b\cdot\frac{kd}{2}\cdot f_c jd = C_c bd^2 \tag{3}$$

where

$$C_c = \tfrac{1}{2}\,jkf_c$$

If the resisting moment from Eq (2) is greater than that from Eq (3), the beam, if tested to failure, will fail by crushing the concrete and is said to be OVER-REINFORCED. If the reverse condition is true, the beam fails by reaching the yield point of the steel,

and the beam is UNDER-REINFORCED. If a beam has equal strength in each, it is a BALANCED BEAM. For latter with n and r known, from Eq (1) k is fixed and

$$k = \sqrt{np(np+2)} - np \qquad (4)$$

Hence with k fixed, required p is fixed and C_s equals C_c as required. M_s is then equal to M_c and both must equal the external moment, M. Hence, from Eq (2) or (3),

$$d = \sqrt{\frac{M}{Cb}} \qquad (5)$$

where $C = C_s = C_c$

The value of d (Eq 5) is the balanced depth, as it is the only depth that will simultaneously insure full working values of both steel and concrete with n and k fixed. Thus solving Eq (1) for k,

$$k = \frac{n}{n+r} \qquad (6)$$

and Eq (4) may be solved for p and combined with Eq (6):

$$p = \frac{k^2}{2n(1-k)} = \frac{n}{2r(n+r)} \qquad (7)$$

also

$$j = 1 - \frac{k}{3} \qquad (8)$$

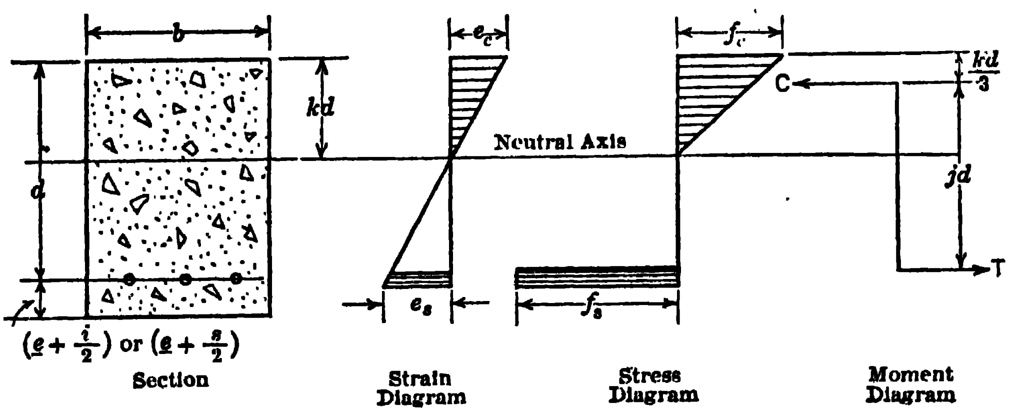

Fig 11. Stresses in Concrete Beams

Thus, with n and r fixed, k is obtained from Eq (6), p from Eq (7), j from Eq (8), and C from Eq (2) or (3). Table 4 gives values of these constants for common values of f_s and f_c, and n. For economy, b should be small, since for equal strength, a deep narrow beam has a smaller area than a wide shallow one. For proper design, this can not be done, as b should be between $0.5d$ and $0.75d$. In fulfilling this specification, most designers proportion all beams for widths of even integral inches, so that a plank of standard width may be used for the bottom form. Using proper proportions for b and d, a balanced depth is readily designed, and closely approximates the most economical. Often the difference from the theoretically most economical design is more than counterbalanced by the saving in form costs.

Table 4. Constants for Balanced Beams

f_s = 18 000 lb per sq in						f_s = 20 000 lb per sq in					
k = 0.400		j = 0.867		S = 1 300 ft-lb C		k = 0.375		j = 0.875		S = 1 458 ft-lb C	
f'_c	f_c	n	p	ft-lb	in-lb	f'_c	f_c	n	p	ft-lb	in-lb
2 000	800	15	0.0089	11.57	138.8	2 000	800	15	0.0075	10.94	131.3
2 500	1 000	12	.0111	14.43	173.2	2 500	1 000	12	.0094	13.70	164.5
3 000	1 200	10	.0133	17.29	207.5	3 000	1 200	10	.0113	16.48	196.8
3 750	1 500	8	.0167	21.71	260.5	3 750	1 500	8	.0141	20.56	246.8

In determining A_s, two formulas are used. By definition

$$A_s = pbd \qquad (9)$$

also from Eq (2)

$$A_s = \frac{M}{f_s jd} = \frac{M}{Sd} \qquad (10)$$

Eq (9) applies only for balanced depth, whereas Eq (10) gives results close enough for other depths, and is used instead of Eq (9). Table 4 gives values of S ($= f_s j$) in ft-lb, which may be used with Eq (10), when M is in ft-lb.

Three general problems may arise: (*a*) to design a balanced beam; (*b*) to design a beam whose depth is fixed by clearance requirements; (*c*) to find the safe load on an existing beam.

Example 1. Using $f'_c = 3\,000$ (working stress $f_c = 1\,200$) and $f_s = 18\,000$; design a balanced beam for a load of 1 000 lb per lin ft on a span of 10 ft (load includes wt of beam itself). Ordinarily a dead wt must be assumed for the beam, and a tentative design made which is modified if the resulting wt does not check the assumed wt. For this loading $M = wl^2 + 8 = 12\,500$ ft-lb. From Table 4, $C = 17.29$ ft-lb units and by Eq (5),

$$d = \sqrt{\frac{12\,500}{17.29b}}$$

A value of b is now assumed, which will give satisfactory proportions. By trial is obtained a 6-in width and a depth of 11 in. From Table 4, p is .0133, and from Eq (9), A_s is 0.88 sq in, or from Eq (10) and using $S = 1\,300$ from Table 4,

$$A_s = \frac{12\,500}{1\,300 \times 11} = 0.88 \text{ sq in}$$

Table 3 shows that several combinations of bars may be used to give this area. Thus two 0.75-in round bars (area = 0.884) or three 0.625-in rounds (0.921) are suitable.

In choosing the number and size of bars, observe the following points. A minimum number is desirable (2 for this beam), and if 2 are used the area is less than for 3, giving a saving in cost; and there is no "size extra" for the 0.75-in size, while there is for the $^5/_8$. But if web reinforcement is necessary (see below), more than 2 bars are advisable. Also, 3 bars will have a greater surface area than 2 bars for the same cross sec area, which will lessen the unit bond stress. Finally, there must be a certain minimum clear distance between bars (1.5 diameters for rounds and 2 × side for squares), and there must be a certain thickness of concrete protection over the steel. Concrete protection for reinforcement shall be at least 1 diam for rounds and 1.5 × side for squares. For surfaces not directly exposed to ground or weather, the protective covering should be 0.75 in for slabs and walls; and 1.5-in for beams, girders and columns. Table 5 gives the least width of beams for different numbers of bars of diam i, or side s.

In Example 1, if 2 bars are used, a beam $5.5 \times 0.75 = 4.12$ in is necessary; or for 3 bars, $8 \times {^5/_8} = 5$ in. Hence from this standpoint either combination is satisfactory. Fig 12 shows detail of beam using 2 bars. Since d is the effective depth to the center of steel, to get the total depth an amount e must be added for protection. Hence $e = 1 \times 0.75 = 0.75$ in; but this is less than the 1.5 in specified as minimum for beams. Hence total depth $= (11.0 + 1.5 + 0.5) \times 0.75$, or 13 in to the nearest 0.5 in.

Table 5. Spacing of Reinforcing Bars

No of rows of bars	Least width, b

8	25	20.5
9	28	23
10	31	25 5

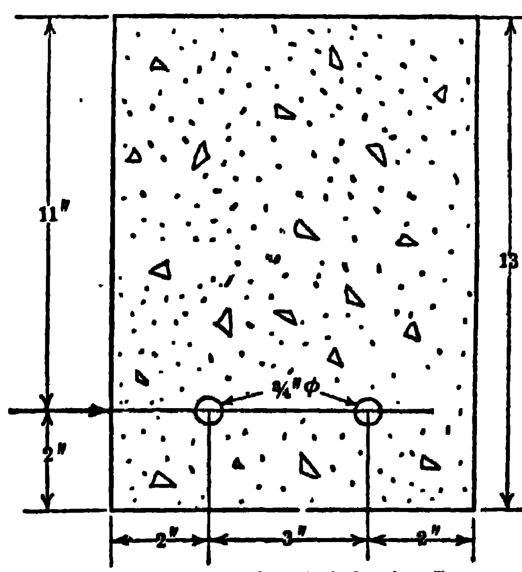

Fig 12. Beam with 2 Reinforcing Bars

Example 2. Suppose on account of clearance, the total depth is limited to 11.5 in, and the effective depth is 9.5 in, or less than the balanced depth of *Example 1.* The concrete will control and be stressed to full working strength, while the steel will be understressed. To keep f_c below 1 200, the beam must be overreinforced. Thus solving Eq (3) and (8) with $d = 9.5$ in; $k = .570$. From Eq (7), $p = .0378$ (against .0133 for balanced depth), and $A_s = .0378 \times 6 \times 9.5 = 2.16$ sq in. Also f_c will be 1 200 and f_s [from Eq (1)] will be only 9 050. A double-reinforced (both tension and compression bars) beam may be more economical in this design.

Example 3. Suppose a total depth of 14.5 in ($d = 12.5$ in) had been used. There will be less steel, stressed to full value, while the concrete will be understressed. The beam will be underreinforced. Using $S = 1\,300$, as for a balanced beam, Eq (10) gives a sufficiently close approx for

A_s, or 0.770 sq in. Hence $p = .0103$ and k, from Eq (4) is .363. From Eq (8), j is .879 and from Eq (10), $f_s = 17\,730$ p s c. From Eq (1), $f_c = 1\,010$ p s i.

Example 4. Slabs may be similarly designed. Required a reinforced concrete floor slab of balanced depth to carry 500 lb per sq ft on a 10-ft span. Assume $f_c = 800$, $f_s = 20\,000$ *psi*; M is 6 250 ft lb, for a strip 12 in wide as a simple beam. From Table 4, C is 10.94, and since b is 12 in, from Eq (5), d is 7 in. Also from Eq (9), A_s is 0.612 sq in per ft width of slab. Necessary spacing in inches of bars of any size to obtain this area = 12 times area of 1 bar divided by required area (A_s) per ft of width. Thus $^5/_8$-in rounds, 6 in c-c, or 0.75-rounds 8 in c-c, could be used. Bar spacings are given in even inches if possible. Minimum protection is 1 diam or 0.75 in. Thus for $^5/_8$-bars, total slab depth would be $7 + .75 + {}^5/_8$ or say 8-in and 8.5-in for the 0.75-in rounds. Most economical slab, $^5/_8$-in bars with 8 in depth.

Example 5. In using these formulas to compute SAFE LOAD for an existing beam, first find p from Eq (9), then k from Eq (4) and M_s and M_c from Eq (2) and (3). Equate the smaller of these to the external moment, and solve for the load. Find the safe load for a rectangular beam simply supported on a 10-ft span. Beam is 8 in wide, and 12 in deep to center of steel, and has 0.96 sq in steel. Take $f_c = 1\,000$ and $f_s = 20\,000$ lb per sq in, hence from Eq (9) p is .01; k from Eq (4) is .383; j from Eq (8) is .872; M_s is 16 750 ft lb and M_c 16 000 ft lb. This beam is over reinforced and would fail by crushing the concrete. It could carry 16 750 ft lb moment, and the steel stress would not exceed 20 000 lb per sq in, but the concrete stress would exceed 1 000. Hence M must not exceed 16 000 ft lb, at which time $f_s = 19\,100$ from Eq (2). Also $M = wl^2 \div 8 = 16\,000$ and $w = 1\,280$ lb per lin ft, including wt of the beam, or about 1 180 lb of live load.

Diagonal tension, shear and bond. Besides failing by crushing of the concrete or yielding of the steel, the beam may fail by diagonal tension or by bond failure. Horiz and vert shear, modified by the fiber stress due to bending, produce max tensile stresses having direction shown by curved lines in Fig 13; hence, best position of reinforcing bars would be curved to follow these lines.

If horiz bars only are used, since concrete has little tensile strength, a beam may fail due to inclined or diagonal tensile stress at ends, causing cracks A, A (Fig 13). As it is impracticable to compute diagonal tension, which is dependent on the shear, shear is used as a measure of the diagonal tension in experiment and design. To prevent failure in this way 3 methods are used:

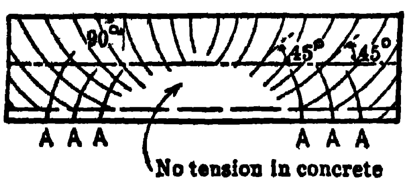

Fig 13. Diagonal Tensile Stress

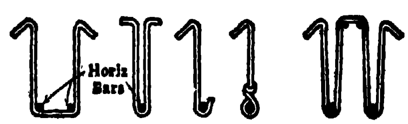

Fig 14. Common Forms of Stirrups

1. Shear is kept below safe value. The max intensity of shear is $v = V \div bjd$ (11)

With no web reinforcement, this should not exceed v_c, which is limited by specification to $v_c = 0.02f'_c$. In slabs where it is impractical to place web reinforcement, depth d is increased over that required for bending, if necessary, to comply with the above condition.

2. Bent-up longit bars, with inclination of 15° or more to axis of reinforcement. If this is done, v may not exceed $.06\,f'_c$; that is v' cannot exceed $.04\,f'_c$ and v_c equal to $.02\,f'_c$. Compute the distance from support to where v equals v_c and beyond which no web reinforcement is necessary. Bend up one or more bars (preferably symmetrically) at angle θ. Compute aver total vert shear V' over a length of beam l', in which a portion of the shear is to be taken by bent-up bars. Stress in bar is

$$f_v = \frac{V'l'}{A_v jd(\sin\theta + \cos\theta)} \tag{12}$$

which should not exceed safe stress for the bar. Suitable adjustment of distance l' will give a solution which meets all conditions. Note that bars can not be bent up until they are no longer required in tension reinforcement for bending. The distance from support x, where bars of area t may be bent up is given by

$$x = l\left(1 - \sqrt{\frac{t}{m}}\right) \tag{13}$$

where l is span and m is total area of bars. This formula is derived on basis of a uniformly distributed load and can only be used for such. Also the bond stress in the remaining horiz bars should not exceed a safe value of $.04\,f_c$ for plain bars, or $.05\,f'_c$ for deformed bars. This stress u will be greatest at support and equals

$$u = \frac{V}{\Sigma_o jd} \tag{15}$$

Bars must extend into the support at least 10 diam and if the above bond stress values are exceeded, special anchorages (hooks) must be provided.

3. Stirrups are used (Fig 14). If these are computed to take the excess v', over what the concrete takes, v_c, the shear stress v should not exceed $.06\,f'_c$, unless the longit steel is specially anchored and in no case should v exceed $.12\,f'_c$.

Procedure for stirrup design (Fig 15): (1) find length to be reinforced, $X = \frac{L}{2}(1 - v_c \div v)$; (2) total area of stirrups, $A_v = \frac{v'bX}{2f_v}$ (required in length X); (3) approx number of stirrups, $N = \frac{3X}{d}$; (4) area of 1 leg of 1 stirrup, $a = 1/2\,\frac{A_v}{N}$; (5) select nearest size to give area a,

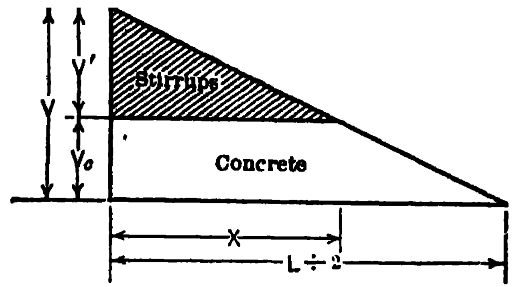

Fig 15.* Shear Diagram

(1/4", 3/8", or 1/2"); (6) adjust number of stirrups for size selected, $N = 1/2\,\frac{A_v}{a}$; (7) space according to Table 6, without exceeding .50d. Adjust spacing to nearest 1/2 in and add stirrups where allowable spacing is exceeded.

Table 6. Coefficients for Spacing Stirrups

Total number of stirrups

										.81	12

n = number of the stirrup from the support.
To find distance from support to any stirrup, multiply the factor from table by X, in.

T-beams. The area of concrete below neutral axis in a rectangular beam is of no value against bending. If part of it is removed the resulting T-beam (Fig 16) will be stronger, as it is relieved of some dead load. Hence, as long as t exceeds kd, the beam is essentially rectangular, and the formulas for rectangular beams are used. If t is less than kd, use Eq 16–20. As shown in Fig 16 for rectangular beam, Eq 1, 6, 10 hold equally well for T-beams. The compression carried by the small portion of the stem above neutral axis is usually neglected. Practically

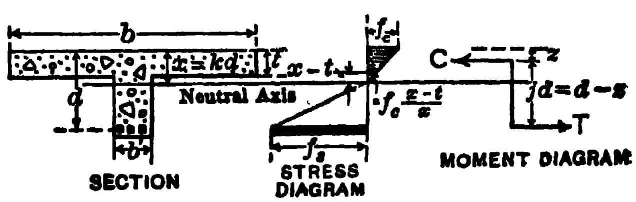

Fig 16. Design of T-beam

$$f = \left(\frac{3kd - 2t}{2kd - t}\right)\frac{t}{3} \qquad (16)$$

and can never exceed $t \div 2$; hence, approx,

$$M_s = f_s A_s\left[d - \frac{t}{2}\right] \qquad (17)$$

Actually

$$M_s = f_s A_s jd \qquad (9)$$

where

$$j = d - f$$

Also

$$M_c = \frac{(2kd - t)btf_c jd}{2kd} \qquad (18)$$

In designing T-beams, a balanced depth is seldom used, but the proper proportions of stem are found from other factors, as area required for shear and headroom. In general, proper proportions for stiffness require that b' shall be between $^1/_3$ and $^1/_2\, d$. Also, where the stem forms part of a floor, the slab of thickness t being the flange, for economy the relation of b' and d should be such that

$$d = \sqrt{rM + f_s b'} + t + 2 \tag{20}$$

where r = ratio of unit cost of steel to concrete, or 50–70. The value of t, where beam forms part of a floor slab, is fixed, and b should not be taken greater than $16t + b'$, the distance c–c of T-beams, or over 0.25 the span. For independent T-beams, b should not exceed $4b'$, and t should not be less than $0.5d$. Three problems may arise.

Example 1. T-beam is part of a floor system; t = 4.5 in. Design stem for moment of 92 700 ft lb. Max reaction = 16 800 lb; span 22 ft. Use f'_c = 2 000 lb per sq in; f_s = 20 000. Max allowable shear = $.06 f'_c$ = 120 lb per sq in. Min area of stem $b'd$ for shear = 16 800 ÷ $^7/_8$ × 120, Eq (1) = 160 sq in, or say 9 by 19, as b' would be between $0.3d$ and $0.5d$ for proper proportions. But from Eq (20) when b' = 9, it is economical to make d = 23.0 in. From Eq (17), A_s = 2.68 sq in, which can be made up by several different combinations, as six .95-in rounds, placed in 2 rows of 3 each. Since d = depth to center of gravity of steel, the total depth is determined as in Fig 17, where e = 1.5 in. Checked by the exact formula, $b = (16t + b')$ = 81 in, or b = 0.25 × 22 × 12 = 66 in. Use 66 in for b, as it is the smaller. From Eq (19), as kd = 4.70 in, this is a true T-beam. From Eq (16), t = 1.56 in; from Eq (10); f = 19 600, lb per sq in, and from Eq (1), f_c = 334, which is satisfactory. Stirrups must be provided.

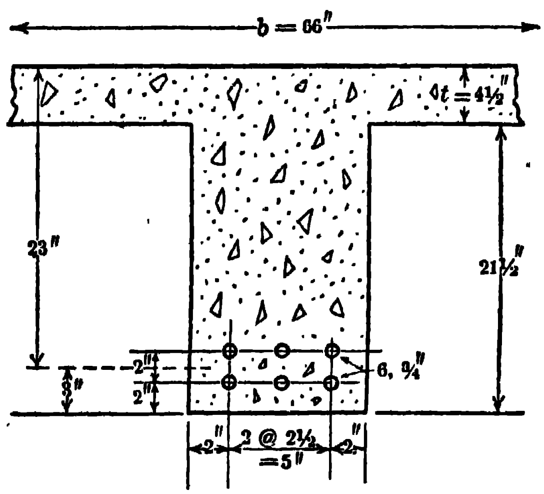

Fig 17. Design of T-beam

Example 2. Design an independent T-beam for 40-ft span, to carry 3 000 lb live load, and assumed dead load of 1 400 lb per lin ft. $M = wl^2 \div 8$ = 10 560 000 in-lb. Max V = 88 000 lb; hence min area for shear is 838 sq in, using f_s and f'_c as in Example 1. Selecting b' = 18, and d = 47 in as good proportions, this may be designed as a balanced T-beam. Thus from Eq (6), k = .375 and kd is 17.6 in. Selecting t as 16 in, since it must be at least $^1/_3 d$, this is a true T-beam. From Eq (16), f = 5.78 in and jd = 41.22 in. From Eq (9), A_s = 12.80 sq in, and solving Eq (18), b = 36.7 in, which is less than $3b'$ as required and gives a good design. To get the steel area required, 9 1 $^1/_8$-in and 1 1.25-in square bars could be used. To place this steel properly in 2 rows, the width of beam might be 20 in, instead of 18 in. End bearing required is at least

$$\frac{88\,000 \times 2}{18 \times 450} = 21.8 \text{ in}$$

This assumes an allowable compression of 450 lb per sq in, and increases the load by 100% to allow for unequal distribution over bearing surface.

Example 3. Given a T-beam forming part of floor; t, b', d and A_s being known, find safe load; b from data above, and kd from Eq 19. If kd is less than t, use rectangular beam formulas; if greater, it is a true T-beam and z is found from Eq 16, giving jd. M_s is computed from Eq 10, and M_c from Eq 18, and the smaller used. Also, test strength in shear and bond.

Reinforced concrete columns. General formulas apply to "short columns," where unsupported length does not exceed 10 × least lateral dimension. Principal columns in buildings shall have a min diam or thickness of 10 in and min gross area of 120 sq in. Noncontinuous posts between stories must have min diam of 6 in. Unsupported length of columns is taken as: (1) clear distance between floor slabs (or to bottom of capital in flat slabs); (2) clear distance between floor and underside of deeper beams framing into column at next higher floor level; (3) clear distance between lateral struts providing adequate lateral support.

Spirally reinforced columns (Fig 18). Permissible axial load P, on columns with closely spaced spirals enclosing a circular concrete core, reinforced with longitudinal bars; $P = A_g(0.22f'_c + f_s p_g)$, where A_g = gross area of column (including protective concrete covering, f'_c = compressive test strength of concrete; f_s = nominal working stress in vert column reinforcement = 40% of yield point (16 000 for intermediate grade, or 20 000 lb per sq in for rail or hard grade steel, max not to exceed 30 000), p_g = ratio of effective cross-sec area of vert reinforcement to gross area, A_g.

Limitations for vertical reinforcement. p_g is not less than 0.01 or more than 0.08. Min number of bars = 6, min diam = $^5/_8$-in round. Also, c-c spacing of longit bars within periphery of core is not

less than 2.5*d* for round bars, or 3 × side for sq bars, or a clear spacing not less than 1.5 in, or 1.5 × max size of aggregate used in the concrete mix. Protective covering, poured monolithically with core, not less than 1.5 in or 1.5 × max size aggregate (not less than special requirements for fire protection or weathering).

Tied columns. Permissible load, when reinforced with longit bars and separate lateral ties, shall be 70% of that given for spirally reinforced columns: p_g not less than .01, or more than .04; longit reinforcement not less than 4 bars, min dia = $^5/_8$ in. Lateral ties at least 0.25 in diam, spaced not over 16 bar diameters, 48 tie diameters, or least dimension of column. Each bar must be held with lateral support equal to that provided by a 90° corner tie.

For composite columns (encased structural steel or C-I and pipe columns and long columns) see Am Concrete Inst Building Code.

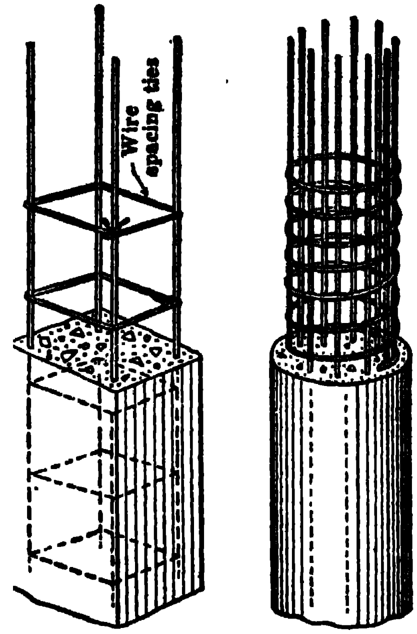

Fig 18. Reinforced-concrete Columns

15. RETAINING WALLS (7)

General. Retaining walls are of masonry, sometimes laid dry for unimportant walls, concrete or rubble concrete, or reinforced concrete. Principal forces acting are lateral earth thrust and wt of the wall itself. In gravity walls these are the only forces to be considered, but in reinforced walls the stability of the various parts must be investigated.

Gravity walls, when small, are built without special computation and of more or less standard section, that is, a top width of 1.5–2 ft, bottom width 0.4–0.6 of total height, front face battered 1 : 12. Foundations are carried below frost line (3–5 ft) and back sloped or preferably stepped as required by these dimensions. Drainage of back fill is most important in reducing press, and is cheaper than to use a heavier wall. Selected back fill of sand, cinders or gravel that drains readily is desirable where natural fill is of bad quality. The design of larger walls involves checking stability against failure by tilting forward due to excessive settlement, or sliding forward on base (Fig 19). Considering 1 linear ft of wall, the earth thrust E may be combined with wt of wall W, producing resultant R, and if R passes outside toe of wall A the wall will overturn. R may be resolved into a vertical component V, which produces a varying base press, greater at the toe of the wall A than at the back of the base (hence usual unequal settlement), and horiz component H, which tends to produce sliding.

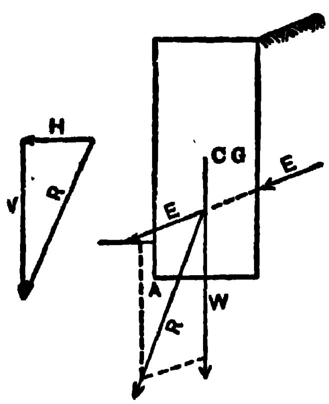

Fig 19. Gravity Retaining Wall

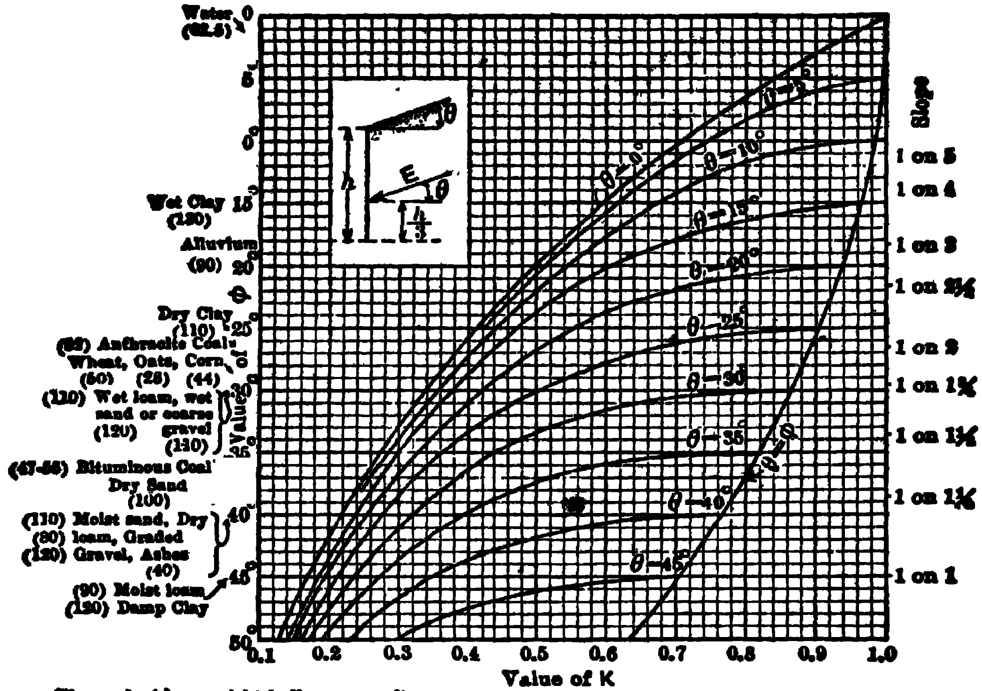
Earth pressure. Modern studies and observations indicate: (1) E (representing about a min value of the equivalent hydrostatic press) = $Kwh^2 \div 2$, where w is wt of earth, lb per cu ft, h is total height in ft, and K is a coeff usually 0.3–0.6; (2) K depends not only upon character of the earth backing, amount of moisture present and time after backing has been placed, but also on settlement of wall which causes its tilting forward; (3) Rankin's formula $K = \cos\theta \dfrac{\cos\theta - \sqrt{\cos^2\theta - \cos^2\phi}}{\cos\theta + \sqrt{\cos^2\theta - \cos^2\phi}}$ gives theoretical value of K for a vert wall with fill sloping upward from top at an angle θ, the fill having a coeff of friction represented by angle ϕ. For dry, granular material and horiz fill ($\theta = 0$), as in design of ore bins, this value can be used. Fig 20 gives aver values of K for a number of materials, but must be used with caution and judgment. For important earth retaining walls certain possible modifications must be considered, namely, that theoretically E acts at $^1/_3$ height above base; actually, depending on amount of wall yield, it may act as high as 0.5 and in design it is best to assume 0.4; theoretically, also, E acts parallel to slope of back fill, thus having, for surcharged walls, a vert component (= E sin θ) which aids stability; actually E may act horiz, depending on presence or lack of friction on back of wall and on its tilting; (4) factors noted in (3) may increase effect of E to values twice those indi-



Figures in ( ) = weight in lbs. per cu. ft

Fig 20. Pressure Factor K for Granular Materials

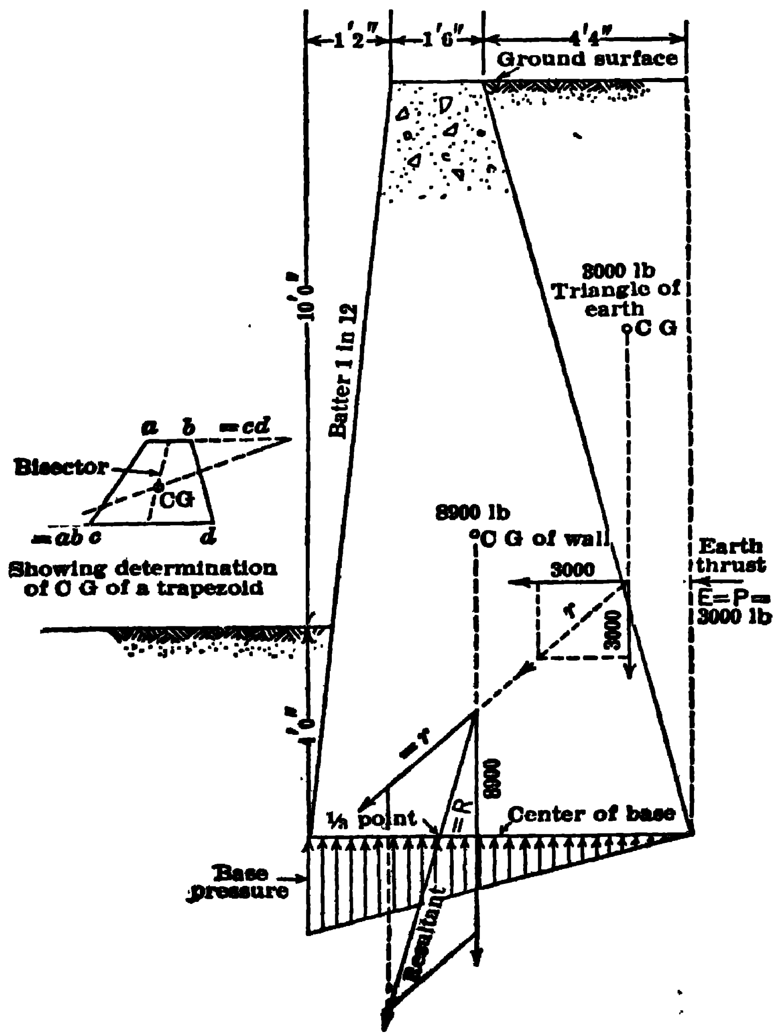


Fig 21. Graphical Design of Retaining Wall

cated by theory, hence conservative design requires ample margin of safety; (5) most failures occur (*a*) directly after heavy rain, due to building up of hydrostatic press back of wall, so that provision for carrying off surface water from back fill and for draining fill by tile drains is most important, or (*b*) by gradual tilting forward of wall due to unequal settlement of base. This is liable to occur on soft, wet foundations and emphasizes importance of drainage.

Example. Check design of a wall for a clear height of 10 ft with horiz fill ($\theta = 0$). Foundation, 4 ft deep. Assume w for fill, 100; wt of wall, 150 lb per cu ft; material, well drained gravel, $\phi = 33°$; suitable top width, 18 in; trial width of base, 0.5 total height, or 7 ft. From Fig 20, $K = 0.3$, E against a vert (Fig 21) = 3 000 lb per ft of wall. Combining this graphically with wt of triangle of earth back of wall, 3 000 lb, gives resultant press on wall, r. This combined in turn with wt of wall, 8 900 lb, gives resultant R which cuts base slightly inside the third point Assuming a uniformly varying distribution of base press, this would vary about 3 400 lb per sq ft at the front (toe) to approx 0 at the rear (heel) of the base. This design is to be regarded as a minimum; E being taken as acting at 1/3 point of height (see under 3 above). For poorly drained soil K would exceed 0.3, so that a wider base would be required. Computed base press is moderate, but, while V would not change (11 900 lb), the distribution of this press depends on moment of E, and thus the max value would be affected by changes in b and E.

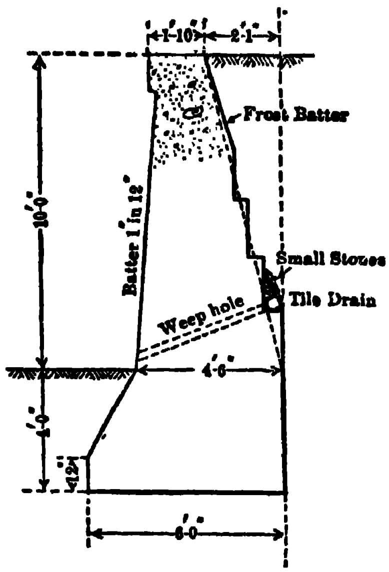

Fig 22. Stepped Retaining Wall

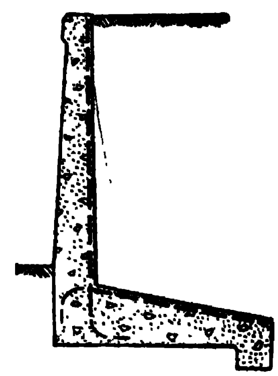

Fig 23. L-type Cantilever Retaining Wall

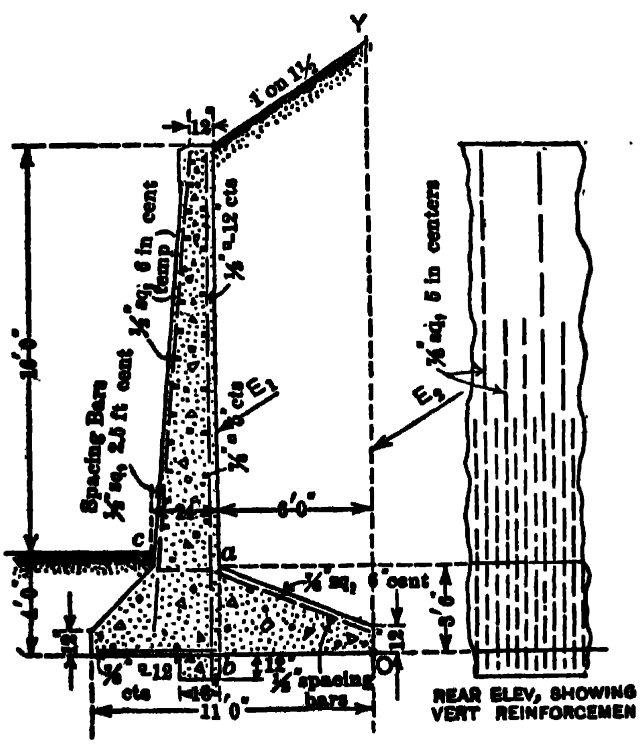

Fig 24. T-type Cantilever Retailing Wall

In the final design, the back of the wall would preferably be stepped, the sloping line in Fig 21 being an aver section. This insures vert action on wall of triangle of earth (3 000 lb), which can act only on the sloping back if friction (uncertain) exists between wall and fill. The upper 3 ft are often left with slope forming a frost batter to relieve possible thrust from freezing (note also drainage). Expansion joints must be provided at intervals of 30–60 ft (Art 13). The variation from the trapezoidal form in Fig 22 results in a slight saving of material and smaller base press.

Reinforced-concrete retaining walls are of 3 types: cantilever, counterfort and cellular. Forms for the counterfort wall cost more than for cantilever, but the counterfort is more economical for heights over 20 ft, while the cantilever is cheaper than the gravity wall, except for very low walls. The cellular type has been used where foundations are poor, and piles can not be used, and where wall must be built close to property line.

Cantilever wall of L-type (Fig 23) is required when the front face is on the property line, and the foundation can not extend beyond it. The base press in such walls is liable to be high, requiring the use of piles. Whenever possible, the T-type (Fig 24) is used, as it not only requires a smaller base and is therefore economical, but it gives smaller base press. The vert stem should be placed at about the third point of the base.

Design of a cantilever wall (Fig 24). (*a*) Estimate is made of thickness of footing *ab*, which determines approx height of the vert wall. Top width is assumed as 12 in, and base *ac* is found by Eq 5 (Art 14), considering the wall as a vertical cantilever slab subject to the earth thrust E_1, and taking moments about *a*. If necessary, this thickness is increased to keep shear below 40 lb per sq in, as web reinforcement is not desirable. This also applies to *ab*. (*b*) Dimensions of base are assumed, earth thrust E_2 on plane *OY* is computed and combined with wt of earth and wall to find position of resultant on base. Front toe is then designed to keep resultant inside third and p_{max} as desired. (*c*) Rear footing. Take moments about *a*. Downward load is wt of earth in front of *OY*, and the vert component of E_2, which is taken as being uniformly distributed over the footing. Foundation press acts upward. Design *ab* for bending and shear as in (*a*), taking steel required from Eq 10, Art 14. (*d*) Design front footing as in (*c*). Only force considered is the upward foundation press. (*e*) Redesign vertical wall, using correct value of *ab* from (*c*). All steel need not go to top. For A_s use Eq 10, as in (*c*).

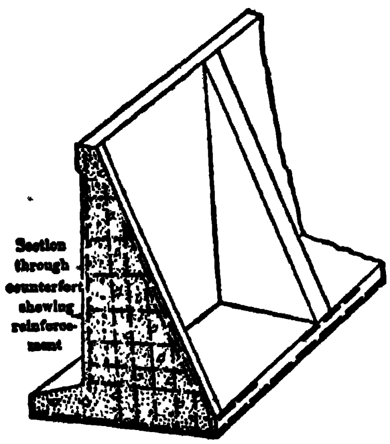

Fig 25. Counterfort Retaining Wall

Bottom projection is put on base to prevent sliding; also gives sufficient grip (Eq 15, Art 14) for vert bars below *a*. Spacing bars are used to preserve the required spacing of main reinforcing (by wiring bars to them), and to bind entire structure together; usually 0.5-in bars, 18 in to 3 ft centers. Temperature reinforcement, consisting of small longit bars (0.5-in here) having a total cross-sectional area of 0.3 to 0.6 of the area of exposed wall, and placed near exposed surface, localizes contraction cracks at frequent intervals (not visible) and no expansion joints are necessary. As in the gravity wall problem above, this section must be regarded as a minimum; *E* may be greater, act higher and also be essentially horiz, thus eliminating the vert component and requiring modifications in design.

Counterfort walls are as in Fig 25. The vert wall is designed as a continuous slab, loaded with the earth thrust and supported by the counterforts. Footing is also designed as a slab, loaded with the downward wt of the earth, and subject to the upward reaction of the soil and spanning between counterforts. The counterfort is subjected to a varying load on 2 faces, enough horiz and vert rods being usually put in to take the entire slab and footing reactions.

16. DAMS AND CULVERTS (7, 9)

A dam comprises 4 parts: the dam proper, spillway, outlet and gates. Sometimes the entire dam is a spillway and in some diversion works it is made up of a series of gates or outlets placed between piers. Dams are built of earth, timber, masonry, concrete and reinforced concrete. The design of dams can not be fully treated here; it requires extensive knowledge and experience, and is under state supervision in several states (9). Earth dams are built either with or without a masonry core. Their design, while formerly based largely on empirical rules and still depending on judgment and experience, has recently been improved through increased knowledge of soil physics and mechanics. The basic problem is the design of an earth fill of a form and on a foundation which will not settle excessively or shear under vert wt, even when much of fill is saturated, and will not permit dangerous seepage. The former requires coarse, stable material; the latter, the presence of fine, well compacted material to fill voids. If suitable materials are available for a mix of sand and gravel for stability, with enough fines and clay for low permeability, no core wall is used. Such dams are constructed: (*a*) by placing the fill in layers, with compacting by wetting and rolling with sheep's-foot rollers (study of soil characteristics and control of water used determines amount of rolling required); (*b*) by full or semi-hydraulic methods. Full hydraulic method is probably the cheapest, but is difficult to control and can be used only where suitable material is available at a sufficient height above the dam. Best material is a mixture of sand and gravel with 25–35% clay. This is sluiced to the dam site with hydraulic giants (Sec 10) and delivered to the dam at the up and down-stream faces from a trestle, either erected in the dam and built in as work progresses, or supported on scows floating in the pond of water which is constantly maintained over the entire section of the dam. The heavy material in the water is deposited at the edges, which are being built up by stones raked from the deposit, and by brush and stop planks. The finer material is carried in suspension in the water, finally settling in the central part of the structure and forming a dense embankment.

Essentials of design (9) are: (*a*) suitable foundation and bond between dam and foundation; if foundation is earth, its quality both to support dam and as to permeability must be satisfactory and all loose soil, boulders and stumps should be removed and the exposed surface roughened by plowing to give bond with fill; if rock, low concrete cut-off or core wall extending into fill may be needed to prevent seepage; (*b*) no earth fill can be

fully impervious to water, but line of saturation through the dam must be below its downstream face; (*c*) moderate slopes for embankment are thus essential; slopes may be from 1 on 2 to 1 on 4 or more; (*d*) elev of crest above highest possible water level must be sufficient to preclude possibility of overflowing. On the water side the slope is usually protected from wave action by dry rubble paving or riprap. The downstream side may be sodded or seeded to prevent wash. Top width is usually 5–30 ft, or about 0.2 the height +5 ft. Elev of crest above spillway is found by adding to the max depth of flood over the spillway the probable height for waves, and to this an allowance of 2–5 ft for frost. This insures that the material exposed to water action will be below frost action. Allowance for waves is: for a "fetch," or exposed water surface, of 0.5 mile, 2.5 ft; 1 mile, 3 ft; 2 miles, 3.5 ft. When suitable material is not available a CORE-WALL is necessary. A puddle core-wall is made by filling a trench left in center of dam with clay placed in 4 to 6-in layers, made plastic with water, and carefully worked by spading and ramming so as to make it homogeneous (Fig 26). Core-walls must go down to an impervious foundation and be securely bonded into it, and should reach to highest water level; they are placed near center or on upstream side of the center of the dam.

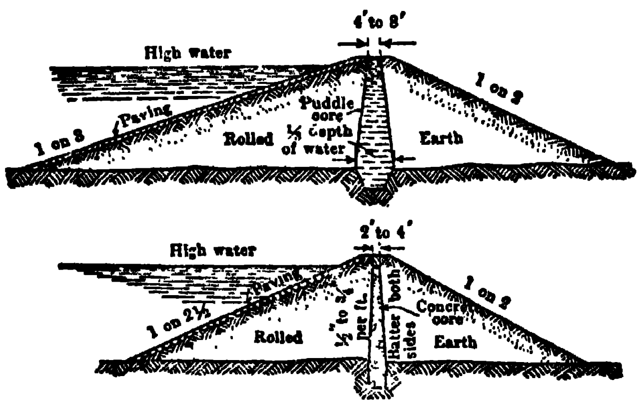

Fig 26. Puddle and Concrete Core-walls for Earth Dams

Rock-fill dams (Fig 27) are a Western type, used where no suitable earth is available, transport difficult and rock abundant. The bulk of the structure is loose rock, dumped into position or placed by derricks, the dam being made impervious by use of earth, lumber, concrete or steel. Where lumber is cheap 2 layers of 2-in planking are used, sometimes with tar paper between, the planks being spiked to stringers bolted to hori[illegible]s in the rock fill. For more permanent construction a steel face may be used, coated with cement or asphalt concrete. Concrete decking consisting of reinforced slabs with vert and horiz joints resting on concrete sills have been used in large dams.

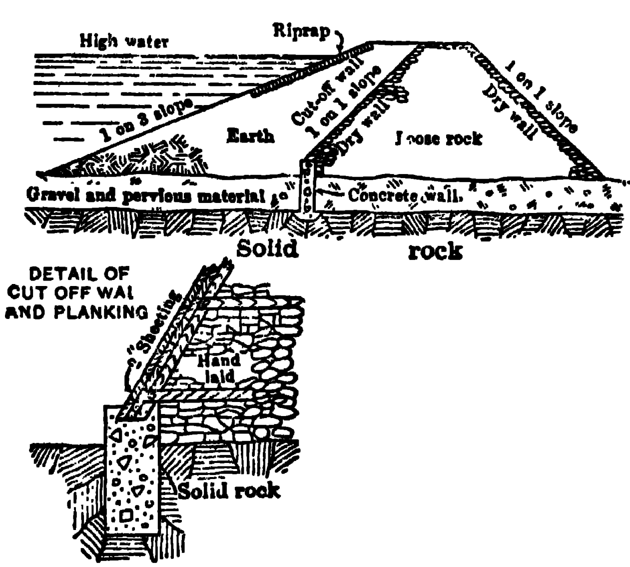

Fig 27. Rock-fill Dam

Masonry dams are now made of Portland cement concrete, this being generally less expensive than the rubble masonry formerly used or than cyclopean concrete (concrete in which large stones or "plums" are embedded). Modern practice emphasizes the importance of a dense concrete, to reduce percolation and insure greater permanency, and thus relatively dry mixtures with careful tamping to avoid segregation are advised.

Design. The basic form is a triangular section with upstream face vert, or nearly so, and downstream slope determined by base width. Principal forces acting are water press (Sec 38). For vert back, $P = wh^2 \div 2$ and wt of structure. Assuming sp gr of masonry $= \rho$, wt of sec per ft is $\rho wbh \div 2$. It is usually required that resultant R (Fig 28) pass inside $1/3$ point of base as in retaining walls. Moments about $1/3$ point give $Ph \div 3 = Vb \div 3$, from which $b = h \div \sqrt{\rho}$. For $w = 62.5$ and $\rho w = 140$ lb per cu ft, $\rho = 2.24$ and the required b is thus about 0.7 h. For extremely high dams, or dams on poor foundations, b is determined by allowable press rather than the above condition. Top of dam is made 2 or 3 ft above high water level, top width about 0.1 h by adding triangle shown in Fig 28. Other forces, which must frequently be allowed for (requiring greater b), are uplift press in foundation or joint between base and foundation and, more rarely, ice thrust. Uplift may vary from $C'wh$

lb per sq ft acting vertically upward at heel O, to zero at toe A, where C is 0.3–0.6 or more, ; on character of foundation.

Foundation. Small dams, to 20 ft or so in height, have been built on hardpan, compact sand or (with cut-off sheet piling) on gravel. In general and for higher dams a rock foundation is required. Design must always be adapted to foundation conditions and thus requires knowledge of site and experience.

Curved or arched dams of a sec similar to gravity are often used, especially for the higher structures. Curving a gravity dam does not add to stability or lead to economy unless arch action is provided for in the design and construction, that is, an arched-gravity sec is actually designed (see Bib).

Timber dams (Fig 29) are built of inclined timber cribs well fastened, filled with stone to give wt and decked with plank. Rough computations can be made to check stability and sliding. Brush dams, brush tied in bundles with butts downstream and weighted with boulders, often suffice for temporary construction. Buttress dams, of reinforced concrete with inclined reinforced concrete or arched deck supported by triangular buttresses at intervals of 15 to 30 ft, may be economical in special locations.

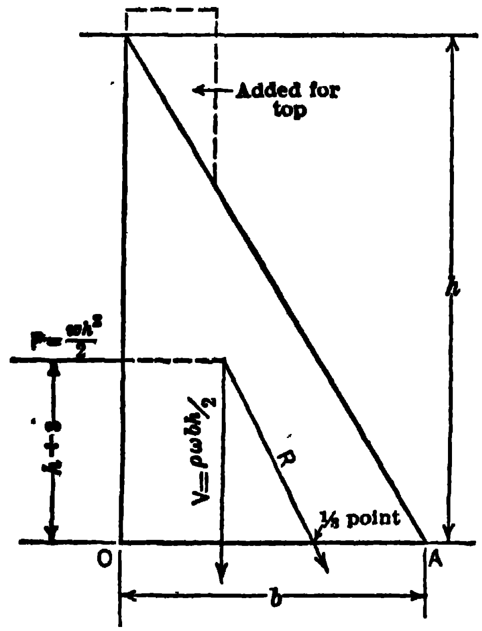

Fig 28. Gravity Dam

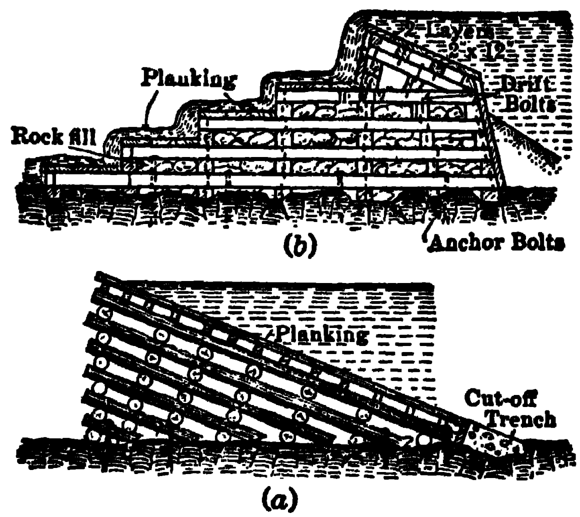

Fig 29. Timber Dams

Spillways, or waste weirs, must be able to pass safely flood flows, and are therefore designed with a liberal safety factor. When possible the spillway should be apart from main dam. Its length is usually fixed by flood width of the stream channel below, and probable depth of flow H can be found as in Sec 38, Art 10.

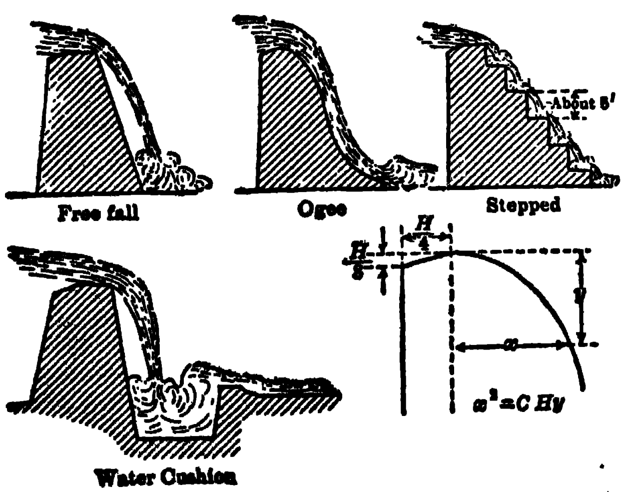

Fig 30. Spillways for Dams

Fig 30 shows types of spillways. When the stream bed is solid rock, the fall can be free, if not over about 10 ft high, although a height of 20 ft has been used. In the ogee, or reverse-curve section (an American type) the water leaves foot of dam with a direction parallel to stream bed, its velocity being destroyed by the backwater from below. Where no backwater exists, and stream bed is of soft or loose material, an apron of concrete or paving is necessary to prevent scour and undermining. Upper part of spillway curve is full enough to cause the overflowing water to adhere to the face of the section; otherwise a partial vacuum might occur, also hurtful vibration. Fig 30 shows the curve used, C being 1.6 for high, to 2.3 for low, dams. For gravity spillways, the section must be heavy enough for stability. The lower curve is often made the reverse of the upper. The water cushion, often used by English engineers, is nature's method in many natural waterfalls and is also used with ogee and sloping sections. The depth is generally made about ⅓ the fall; the width, 3 or 4 times the depth.

Outlets and gates should be kept away from the dam if possible, so an accident may not endanger the main structure. For low earth dams the arrangement shown in Fig 31 can be used; for higher dams an inlet tower near toe of inner slope is preferable. This allows water to be drawn from different levels, which is desirable for water-supply works. Screens are provided to keep out large rubbish and fish. Area of screen openings should be 2 or 3 times the area of the pipe, and veloc of flow through the screen should be low. Finer screens should be put on portable frames, for ready removal and cleaning.

Gates are generally of the sluice-gate type, obtainable in circular or rectangular form up to 6 ft diam, or 8 by 12 ft, and even larger. They move in vertical guides set in the masonry, and are operated by hand wheels, cranks, or electric motors. A blow-off outlet for draining the reservoir is essential.

Seepage around the outlet pipes of earth dams may cause failure; all parts should be accessible for inspection and repair. Pipes are bedded in concrete, with wide collars to prevent direct flow of water (Fig 31). In more costly construction the pipe is in a special concrete or masonry tunnel.

Headworks for a dam for diverting water into a canal are shown in Fig 32. A scouring sluice is essential, when much sediment is carried, which is deposited behind the dam due to decrease in velocity of stream at this point. Sediment can be kept from the canal by opening the scouring sluice during flood flows.

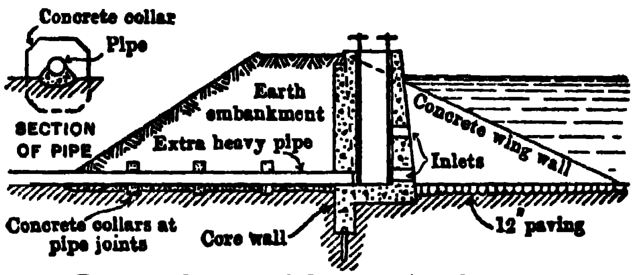

Fig 31. Outlet and Gates for Earth Dam

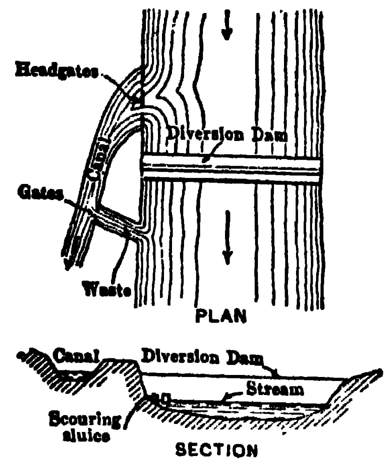

Fig 32. Headworks for Diversion Dam

Culverts are small openings to carry stream flow or drainage, under an embankment or roadway. Formerly C–I pipe or timber, masonry or concrete box sections were used. Today corrugated iron pipe is common, especially for smaller sizes, and concrete pipe for larger, but the iron type has been used up to a diam of 6 ft or more. End walls of concrete or masonry prevent scour and entrance of wash and rubbish. Most important point is selecting size of culvert. Diam less than 1 ft should seldom be used, as smaller sizes are apt to clog. Ample area is desirable and may be estimated from cross sec of stream in time of flood, as shown by high water marks. Culverts of larger size become small bridges and are designed as such (Art 14, 23, 29).

ANALYSIS OF FRAMED STRUCTURES

17. SIMPLE FRAMEWORKS AND LOADS (10, 11, 13)

Truss is a framework designed to carry loads over larger spans than are economical for beams. Fig 33 shows types for bridges; Fig 34, for roofs.

The loads from the floor of a bridge or covering of a roof truss are transferred to the panel points (where members join) by the floor beams or purlins. Hence, truss members do not carry loads directly; they are only subjected to longit stresses due to live load. But, since their own dead wt produces cross-bending, the truss members are subjected to combined bending and direct stress. As bending is unimportant except in large structures, it is customary to consider the dead wt of the truss as concentrated at panel points, and the truss members are designed simply for tension or compression, a − sign indicating compression and + tension.

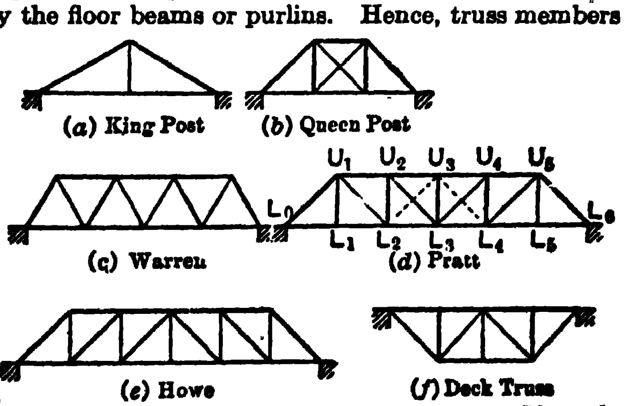

Fig 33. Typical Bridge Trusses (*a, b, c, d, e* are Through Trusses)

In bridge work, if the floor system is supported at the panel points of the lower chord it is called a THROUGH TRUSS, if by upper chord a DECK TRUSS. The principle of division into triangles is also used for the bracing of towers and other structures.

In the following analysis only simple trusses will be considered. Structures containing REDUNDANT MEMBERS and other special forms can not be investigated by ordinary methods, as the stresses depend upon the relative elongation of the different members and are computed by the Theory of Least Work. Thus, the braced bent in Fig 39 would be STATICALLY INDETERMINATE, if both diagonals were counterbraced members capable of taking both tension and compression, that is, were considered as acting simultaneously. Loading carried is of 2 kinds, dead load and live load.

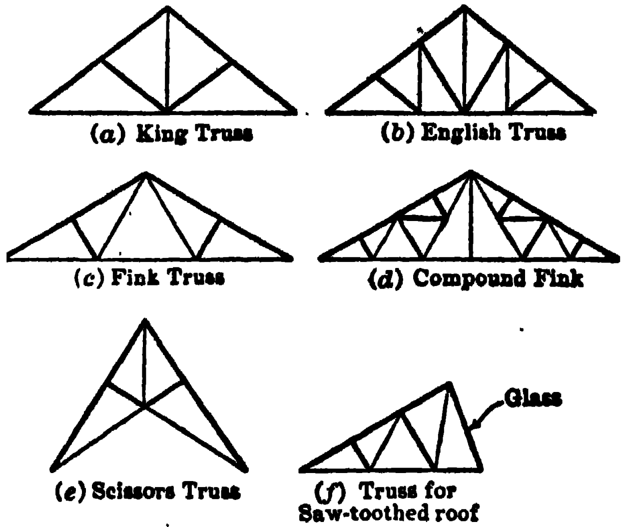

Fig 34. Typical Roof Trusses

Dead load is the wt of the structure itself, and can be closely determined. Table 7 is useful for computing dead loads. In designing, the dead wt must generally be estimated, and computations revised if the estimate subsequently proves to be in error.

For ROOF TRUSSES the approx wts are found as follows. For wooden trusses, $W = 0.5\ al\ (1 + 0.15\ l)$, where W = total wt of 1 truss, lb, a = distance c-c of trusses, ft, and l = span of truss, ft. For steel roof trusses, $W = 16\,\frac{wal^2}{s}$, where w is the load in lb per sq ft of horiz projection which the truss supports, including the wt of truss and bracing, and s is the working stress in tension, lb per sq in.

Snow, fresh	8 " "
Water	62.5 " "

For bridges many formulas are used, depending on type of bridge and loading. Data on the wt of girders and trusses may be found in "Bridge Engineering," by J. A. L. Waddell. For RR girder bridges, the formula $W = kl^2$ is often used, where k is 12–16

for aver loads and working stresses. Hudson's formula for RR trusses is $W = \frac{100}{3} Al$, where A = net area of the largest tension chord. In analyzing the stresses due to DEAD LOADS, the loads obtained from these formulas are divided by the number of panels, and considered as being applied at the panel points. LIVE LOADS are uncertain in amount, and are generally fixed by specification. Max possible loading must always be used.

Floor loads in buildings are usually designed for a uniformly distributed live load of 75–250 lb per sq ft, depending on type of building and on the local building code. For

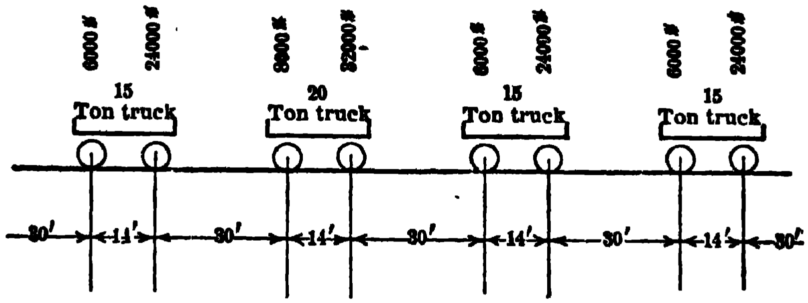

Fig 35. H–20 Loading for Highway Bridge

highway bridges, the so-called H-TRUCK-TRAIN LOADINGS are commonly used. Fig 35 shows arrangement of the H-20, from which the others can be prorated; 3 classes are used, H-20, H-15 and H-10, the particular truck train selected depending on importance of the highway. For RR bridges, a concentrated load followed by a uniform load are used, representing 2 locomotives followed by a train, and are known as E-50, E-60, etc, indicating the engine axle load. Fig 36 shows E-50 loading (for single track bridge half of each axle load is carried by each truss or girder). E-60 is used for second-class roads; E-72 is

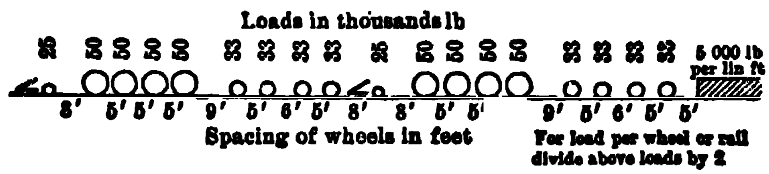

Fig 36. E–50 Loading for R R Bridge

recommended for first-class roads. To obtain E-72 from the diagram, multiply the axle loads given by 72 ÷ 50, the axle spacings remaining the same.

Wind load. For exposed structures, specifications range from 15 to 30 lb per ft of area exposed to the wind, the area taken being the vert projection. For sloping roofs, wind and snow effects are often combined in a single vert uniform load.

Snow loads must be considered in designing roofs in cold climates; in some structures temperature stresses also. Table 8 gives values in lb per sq ft of roof surface, of equivalent vert uniform load to replace combined wind and snow loads for calculating max stresses in roof trusses.

Table 8. Equivalent Combined Snow and Wind Loads (Vert)

Locality	Flat	20°	30°	45°	60°
Northwestern and New England States	40	35	24	26	28
Western and Central States	35	30	24	26	28
Southern and Pacific States	30	20	24	26	28

Impact stresses must be allowed for in structures subject to moving loads. This is usually done by multiplying the live load stresses by an IMPACT FACTOR. For highway bridges this factor I is often given as $I = \frac{50}{L + 125}$, where L is length in ft of the portion of span which is loaded to produce the max stress in the member considered. For RR bridges the impact factor is $I = (1 - 0.006L) + 0.2$. This expression takes care of both the lurching and direct vert effect, and is good for bridges less than 100 ft long.

18. METHODS OF TRUSS ANALYSIS (10, 11)

Algebraic method. Stresses in the members of simple trusses are found by applying the 3 laws of equilibrium for coplanar forces. $\Sigma V = 0$, $\Sigma H = 0$, and $\Sigma M = 0$ (Sec 36, Art 30–33). Two procedures are common, method of joints and method of moments.

Fig 37 shows half of a Fink truss. The loadings P, P, etc, are determined by adding to the roof load, brought to the joints 1, 2, 3, etc, by the purlins, 1/9 the total wt of the truss, which is supposed to be equally divided among the upper panel points. Vert load 3.5 P, acting downward at A, can be neglected, as it is carried directly by the support. By the method of joints (Fig 37a) a section xy is passed, cutting members A 1 and A 5. Since ΣV and $\Sigma H = 0$, by the resolution of forces, and since $R = 3.5\,P$, the stress in A 1 $= 3.5\,P \div \sin\theta$, and stress in A 5 $= 3.5\,P \tan\theta$. By method of moments, a section is passed generally cutting 3 members, the stress in one of which is desired, and the formula $\Sigma M = 0$ is applied, taking moments about the point of intersection of the other 2 forces.

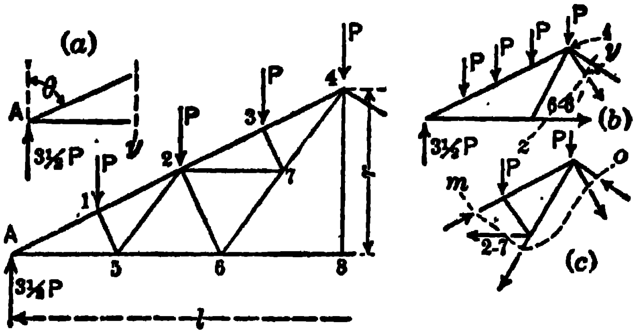

Fig 37. Truss Analysis by Method of Joints

Thus (Fig 37b), passing the section yz and taking moments about 4, $3.5\,P\frac{l}{2} - \frac{6}{8}Pl -$ (stress in 6–6′) $r = 0$, or stress in 6–6 $= Pl \div r$. The section passed may be either straight or curved. Thus (Fig 37c), passing the section mo and taking moments about 4, $(Pl \div 8)$ + (stress in 2–7) $r \div 2 = 0$, or stress in 2–7 $= Pl \div 4\,r$. For the common rise of 1 in 4 ($= r \div l$), the stresses in the various members found by the continued application of the above methods are shown in Fig 38 in terms of P. The member 4–8 serves simply to support member 6–6′ at center and is not an essential part of the truss and figures as carrying 0 stress. It actually carries 0.5 the wt of 6–6′.

In applying the method of moments to the braced bent in Fig 39, members AC and FD must be prolonged to intersection at O, outside the truss, and moments taken about O.

Thus, for the wind load shown, reactions are equal and may be found by moments about A or F. (Diagonal members are supposed to be in tension, and the dashed members are not taking stress for the loading shown.) To get stress in AE, take a sec through AB, AE, EF (Fig 39a). Taking moments about O, $P_1b + P_2(a + b) - AEx' = 0$, giving stress in AE. To get stress in DE, take sec through DE, BE and BA (Fig 39b), and moments about B; thus $P_1a - DEy = 0$, giving DE. To get BE, take same sec (Fig 39c) and taking moments about O, $BE\,(a + b) - P_1b - P_2(a + b) = 0$, giving BE.

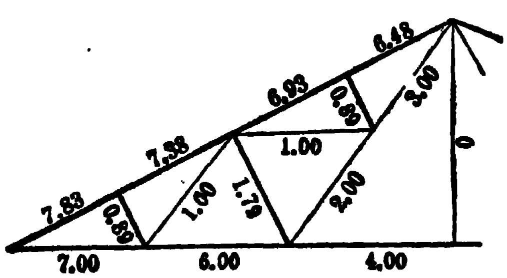

Fig 38. Truss Analysis by Method of Moments

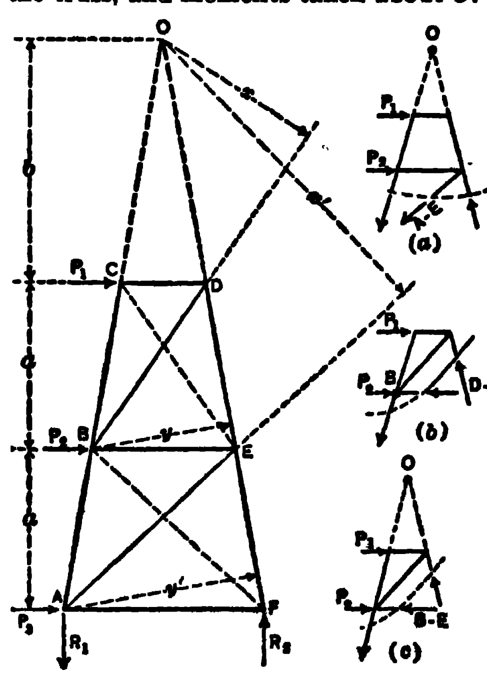

Fig 39. Analysis of a Braced Bent

Graphical method. This is often easier and shorter than the algebraic method, due chiefly to the Bow system of notation. There are 2 diagrams; one a TRUSS DIAGRAM, showing lines of action of the forces in connection with the structure itself, and the other simply a FORCE POLYGON. Reactions in many cases are determined graphically, but it may be simpler to obtain them algebraically by method of moments (see above).

Thus, take a simple kingpost truss (Fig 40a), carrying a concentrated load at its center. Following Bow's notation, the spaces between the lines of action of any 2 adjacent forces on the diagram,

or the space within any triangle the sides of which are lines of action of any forces, are marked by capital letters. Employing a right-hand system of reading, indicated by the curved arrow, the reaction at 1 is called AB, the concentrated load CA, the member 1–2 is BD, etc. Referring to the force diagram (Fig 40*b*), the reactions are evidently equal to 0.5 the center concentration. Starting at any point, the line *ab* is laid off upward from *a*, representing to scale the left reaction in direction and magnitude. Line *bd* is then drawn parallel to BD, beginning at *b*, and line *da* parallel to DA, beginning at *a*; their intersection fixes point *d*. In a similar manner the diagram is completed, as shown.

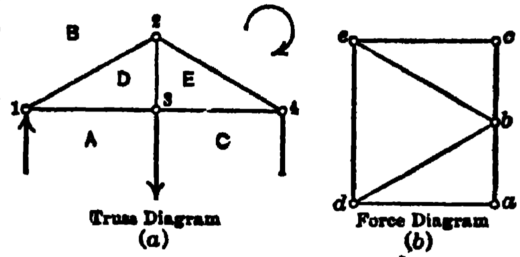

Fig 40. Graphical Method of Truss Analysis

The lines in the force diagram are now scaled off, giving the stresses in different members. The kind of stress may also be determined as follows. Considering any panel point, say 2, in the truss diagram, the member 1–2 is read DB. Noting *db* in the force diagram, it is seen that the direction from *d* to *b* is toward panel point 2, and DB is therefore in compression. Or, at panel point 1, member 1–3 is read DA, and, as direction from *d* to *a* is toward right or away from 1, this member is in tension. Analysis of stresses in hoisting headframes by the graphical method is shown in Sec 12.

19. ANALYSIS OF MOVING LOADS (10, 11)

For a fixed system of concentrated loads the max reaction is easily found, giving max shear, and the max moment is then computed by finding the section at which the shear passes through zero (this usually occurs under one of the concentrations known as the critical wheel), the moment at that point being a max. It is usual in small beams to design simply for max moments and shears, and to use the same section throughout. A moving load must therefore be so placed, with reference to the span, as to produce the max shear or moment.

Max reaction or shear occurs at the support when the loads are as near as possible to one end of the span. Thus, in Fig 41*a*, the 2 loads must be moved so that wheel 1 will be a very small distance from the support, and reaction equals $P_2y + P_1$. For a locomotive (as in Fig 36) the first driver must be over the support (Fig 41*b*) and be considered as acting just to the right of the support.

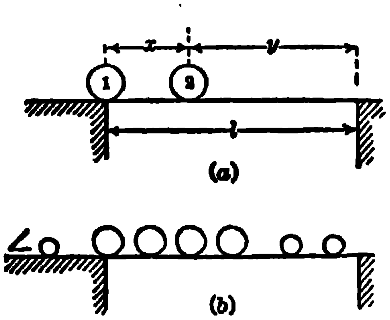

Fig 41. Analysis of Moving Loads

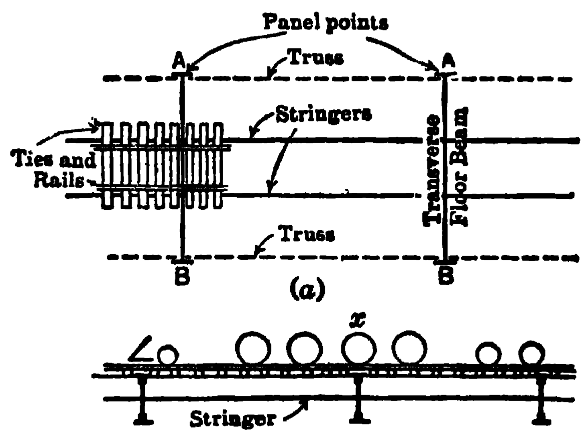

Fig 42. Live Load on Truss Bridge

Live load on truss bridges is transferred from the longit stringers to transverse floor beams AB which carry it to the panel points (Fig 42*a*). Beams AB must therefore be designed to carry 2 concentrations, at x and y, equal to the max reaction from the longit members framing in at these points. Sum of reactions from the 2 equal spans will be max when total load is max, and evenly divided between the spans. For a locomotive concentration this generally requires one of the middle drivers at x.

Max moment at any section in a beam occurs when total load is divided in proportion to distances of this section from each end of beam. Thus, max moment at sec xy (Fig 43) will occur when sum of loads to left ($= W'$) is to sum of all loads ($= W$) as l' is to l. It is sufficiently accurate to determine M by this CRITERION for center of beam, and call it the max moment. The max moment will not be at the center, but at a point such that the distance between this point and the center of gravity of entire load is bisected by the center of span (Fig 44*c*). EXAMPLE. Take 2 equal loads of 1 000 lb, 4 ft apart, span 10 ft. Max M at center is when 1 load is on either side of center, and equals 3 000 ft-lb (Fig 44*a*). Max possible moment is 3 200 ft-lb at point *e*, when load is placed as in Fig 44*b*. General formula for equal loads (Fig 44*c*): max M occurs where shear $= 0$, when

$x = (l + 2) - (a + 4)$, and will equal $(P + 2\,l)\,[l - (a + 2)]^2$. This holds to $a = 0.586\,l$, after which max M is for 1 load at center of span.

Stresses in truss members due to concentrated moving loads (Bib 10, 11, 12). Referring to Fig 33*d*, for example, the dead load stresses, or those due to a fixed live load, may be found by the methods of Art 18. But, if a moving live load is considered, it must be moved to positions producing max stresses in each member. Thus, for max stress in end post L_0U_1, the reaction of moving load at L_0 must be a max, and max stress then equals this reaction + *cos* of angle $L_0U_1L_1$. U_1L_1 is simply a hanger, carrying the max floor beam reaction at L_1.

For max live-load tensile stress in diagonal U_2L_3, the load is advanced from right so as to produce greatest shear in panel L_2L_3. The CRITERION for this (see above) is that the total load on bridge must equal n times the load on the panel in question. Stress in U_2L_3 will then = shear + *cos* of angle $L_2U_2L_3$. Max shear in U_2L_3 = reaction at L_0, minus the floor-beam reaction at L_2. This condition of loading also gives the max stress in post U_3L_3, which will equal the vertical component of U_2L_3, or the shear. For a load advancing from left, stress in U_2L_3 will be compression. This member can be made as a counterbraced member, capable of taking tension or compression, or to take tension only, and another tension member U_3L_2, called a "counter," can be put in, as shown by dotted lines.

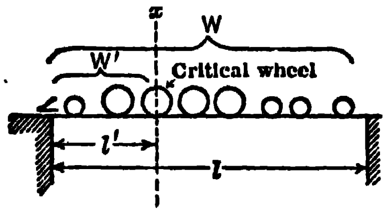

Fig 43. Max Moment in Truss (Approx)

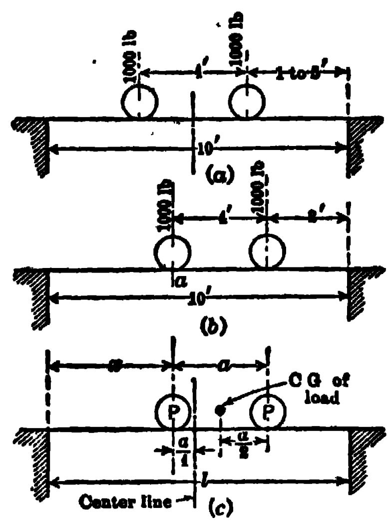

Fig 44. Max Moment in a Truss (Exact)

For max stress in a chord member, the load must be placed so as to produce the max moment in the chord. Criterion for this is the same as for max moment at any section of beam, or $W' : W$ as $n' : n$, where n = total panels in truss, n' = the number to left of section, W = total load and W' = load to left of section. For U_2U_3, stress = M + height of truss, where M = reaction at L_0 times its lever arm minus floor beam reactions at L_1 and L_2, each multiplied by their lever arms, the center of moments being taken at L_3, or any point in the panel L_2L_3.

TIMBER STRUCTURES

20. TIMBER (12)

Trade classification of woods: evergreens or soft woods (pines, spruce, hemlock, cedar, cypress, fir); hard woods (oak, chestnut, hickory, ash, walnut, maple, birch, whitewood). Some " hard woods " are softer than the so-called soft woods.

Pine. Most useful of all woods. WHITE or northern white, from northern U S and Canada: light, soft, not very strong, but easily worked; for interior finish, best grades for pattern making. WESTERN PINE covers timber sold as white pine, coming from Arizona to Washington. IDAHO WHITE, from northern Idaho, western Montana and eastern Washington; not as strong as white pine, but resembles it and used for same purposes. SOUTHERN YELLOW is of 2 principal kinds: Long-leaf is from southern coast, Virginia to Texas, heavy, hard, strong, close-grained, tough; used for heavy framing and floors; can not be used in contact with ground, or built in solidly in masonry, as it decays rapidly unless dry, and dry-rots unless open to air. Short-leaf or Carolina is used as substitute for long-leaf; variable in quality, the short-leaf being inferior. RED or NORWAY PINE, used for all construction purposes, is light, hard, coarse-grained. DOUGLAS FIR or OREGON PINE from north Pacific coast is the most valuable lumber of the Pacific region; used for structural purposes instead of eastern hard pines; two kinds, red more valuable than yellow; imported to east when large size or length is required.

Spruce. BLACK or eastern, from northern U S and Canada; light, soft, close-grained, tough in fiber; desirable for studs, joists and framing in buildings, also for piles, submerged cribs, etc, as it lasts well under water and resists destructive action of crustacea. WHITE, similar to black but not so common. WESTERN or SITKA, north Pacific coast. Giant spruce, soft, satiny, but inclined to be cross-grained; used for interior finish, fences, boats and cooperage.

Hemlock. EASTERN: brittle, splits easily, liable to be "shaky"; used in cheap, rough framing, as substitute for spruce, which it closely resembles in appearance. WESTERN: said to be harder and superior in quality, but liable to shrink and warp.

Redwood. Giant tree and most valuable timber of California; used for same purposes in West as pine in East; soft and splinters easily; durable for fence posts, telegraph poles and R R ties (tie plates are used on ties to prevent wear).

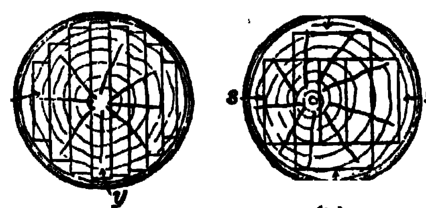
Cedar. WHITE or arborvitæ: soft, fine-grained, durable, but lacks strength and toughness; used for tanks, shingles, boats, fencing, cooperage. RED: small size, very durable but brittle, strong, pungent odor; used for fence posts, shingles, etc.

Cypress, similar to cedar, used in northern U S for shingles; in south as widely as pine in north.

Oak. WHITE, from eastern U S; heavy, strong, hard, tough and close-grained; liable to check if not well seasoned; used where great strength is required in framing, boat building, etc. RED oak is similar, except in color.

Miscellaneous. HICKORY is hardest, toughest and strongest of all American woods; for tool handles. ASH, for interior work; is unfit for outside, as it decays rapidly. ELM, tough and very close-grained; used in wagons, cars, boats, barrel-staves.

Structure and sawing. The mature, compact inner layers are called HEARTWOOD; the outer 0.25 to 3 or 4 in being SAPWOOD, soft, open, and full of sap which hastens decay. Bark should always be removed. The fibers of the tree are in circular layers separated by ANNUAL RINGS, which are interrupted by radial cells, communicating with the pith at center and the sapwood, and known as medullary rays.



(b)

Modes of Sawing Logs

Fig 45 shows modes of sawing common lumber from a log: (*a*) for plank of uniform thickness; (*b*) for joists, etc, of same thickness and width. The part of log section from which lumber comes is of great importance. Thus, in (*a*) piece *x* is liable to warp or curl, due to unequal length of fibers on 2 sides, and if used in flooring is liable to splinter off. *y*, the best cut, is said to be RIFT-SAWED or comb-grained; makes best and most durable flooring; *sss* are slabs. QUARTER SAWING, in plane of medullary rays, gives handsome finish.

Commercial sizes. FLOORING embraces 4, 5 and 6 quarter-in thicknesses, by 3 to 6 in wide, excluding 1.5 by 6. BOARDS, thicknesses under 1.5 in by over 6 in wide. PLANK, sizes from 1.5 to under 6 in thick, by 6 in and over wide. SCANTLING, sizes above 1.5 and under 6 in thick, and 2 to 6 in wide. DIMENSION TIMBER, sizes over 6 by 6 in. STEPPING, 1 to 2.5 in thick by 7 in and over in width. ROUGH-EDGE, or flitch, all sizes, 1 in thick and up by 8 in and up wide; sawed 2 sides only.

In U S, lengths increase by 2 ft; in Canada, by 1 ft. In dimension timber, sizes above stated may be obtained, but stock sizes vary in both dimensions by even inches; thus, 6 by 6, 6 by 8, 8 by 8, etc. All sizes less than 1 in thick are counted as 1 in, in computing quantity. The unit is the BOARD FOOT, 12 by 12 by 1 in.

Finish. Rough timber and lumber, sawed to standard size, shall be not over 0.25 in scant. Thus, 2 by 6 may be 1.75 by 5.75 in. In small sizes, this greatly reduces strength. Not more than 0.25 in is allowed for dressing each surface. The term *S* 1 *S* 1 *E* indicates that 1 side and 1 edge are surfaced; *S* 4 *S* means surfaced on 4 sides, etc. A 2 by 6 *S* 1 *S* 1 *E* is usually worked to 1 $^5/_8$ by 5 $^5/_8$ in.

Shrinkage. Shrinkage is greatest tangentially to the fibers, that is, circumferential shrinkage; radial shrinkage is less. Flat-sawed lumber (Fig 45*a*, *x*) may crack and shrink 3–10% of width, thus opening spaces between boards or flooring, if not thoroughly seasoned. Longit shrinkage is small, generally less than 0.1%, which must be considered in designing structures where settling is important; if possible, all timbers with horiz fibers should be eliminated from vert supports. Effect of moisture is the reverse, and should also be considered.

Seasoning. Natural seasoning, used for lumber for construction purposes, requires 1 to 3 years, depending on kind of lumber. Object is to remove moisture and dry up natural gums, thus guarding against shrinkage and decay. Lumber should be piled under cover, high and dry, thorough air circulation being allowed by placing strips between layers. WATER SEASONING consists in immersing timber in water about 2 weeks, to dissolve out soluble substances, and then air drying. Liable to make heartwood brittle or sapwood brashy. KILN-DRYING consists in placing lumber, usually only small sizes, in a kiln and exposing to a current of air at 100 to 200° F for 2 to 6 or 8 days. It generally produces inferior product, due to excessive drying of exterior and imperfect drying of interior.

Defects and inspection (2). Two things must be considered: quality and dimensions. Strongest and most durable timber comes from trees of slow growth, indicated by closeness

of annular rings. Best timber comes from heartwood; should be straight in fiber, free from large or dead knots, flaws, shakes and blemishes. Dull, chalky appearance, or disagreeable odor, indicates decay and bad timber. Good timber is sonorous when struck.

Table 9. Timber Sizes for Use in Design

Nominal size, in	American standard dressed size, in	Area of section, sq in	Wt per ft, lb	Moment of inertia, in^4	Section modulus, in^3

All properties and weights given are for dressed size only.
The weights given above are based on assumed aver wt of 40 lb per cu ft.

In inspecting, timber is graded according to number, position and kind of defects visible in any piece. Thus, lumber is graded as first, second and third clear, or as No 1 or No 2, depending upon STANDARD DEFECTS shown, as pin and standard knots, sap stains, pitch pockets or streaks, checks, wanes or shakes, sap. The number of defects allowed depends upon kind of inspection: square-edge, merchantable, prime and clear inspection (2).

Decay. Life of timber depends on manner and time of felling, seasoning and working, and is always subject to attack by insect and vegetable life. Best time to cut timber is in winter and drier summer months, when cells are dormant and amount of sap small. Alternate wetting and drying, heat and confined air, fungi, insects, and worms are the chief agencies producing decay. Well-seasoned wood, in well-ventilated and uniform condition as to moisture, should never decay. Constant immersion weakens and softens, but does not cause decay.

Dry rot is due to excretion of ferments by a fungus which attacks cell walls, and breaks them down in the presence of moderate warmth, dampness, or lack of ventilation. Occurs in wall pockets at ends of timbers and in cores of timber columns. WET ROT is caused by presence of moisture and warmth, which dissolves out cell walls in sapwood. COMMON ROT is due to improper seasoning without thorough ventilation, and is shown by yellow color at points of contact or yellow dust in checks and cracks. The most active worm is the TEREDO, or shipworm. It attacks timber in clear, unpolluted, sea water, from mean tide to ground level, and is especially prevalent on calcareous shores.

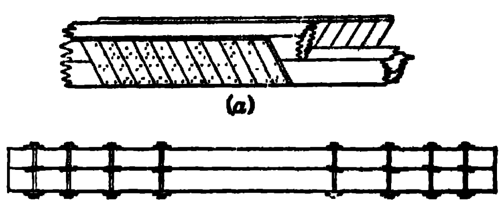
Preservation. CREOSOTING is the best preservative, and is also effective against the teredo. It consists in impregnating with dead oil of coal tar or distillates from the wood tars (creosote). Timber is first placed in cylinders and sap vaporized by steam. After 0.5 to several hr, steam and sap are drawn off by a pump and the cylinder filled with oil, at about 160° F. When gage stands constant, showing no more oil is being absorbed, the surplus is drawn off. Entire treatment takes about 24 hr. Amount of oil varies, with kind of wood and seasoning, from 5 to 12 or 18 lb per cu ft for green and hard timber. BURNETTIZING consists in impregnation with $ZnCl_2$, in a similar manner as for creosoting. About 0.24 lb of $ZnCl_2$ is used per cu ft. Not suitable for timber exposed to moisture, as the Zn will leach out. ZINC-TANNIN or Wellhouse process is same as Burnettizing, except that a small quantity of glue is added to the Zn, and after completing the Zn treatment a solution of tannin is run in under pressure, which forms, with the glue, a leathery coating, closing the pores and preventing leaching out of the $ZnCl_2$. Several other methods and variations in the above methods are in use. KYANIZING, or impregnating with Hg_2Cl_2 and $CuSO_4$, is also used. Timber may be made incombustible by injecting Fe_2SO_4 and a solution of $CaSO_4$ or Na_2SO_4.

21. COLUMNS AND BEAMS

Tests and strength. Timber shows wide variation in strength depending on kind and age of tree, moisture content, size of test specimen, imperfections and knots. Due to low resistance of timber to shear parallel to the fiber, relatively short, deep planking or beams must be checked for both bending and horiz shear.

Since $M = KS$ (Art 4), Tables 10–12 may be used directly in design. *Example.* Required safe uniform load for 6 by 8 in spruce beam spanning 4 ft. From Table 9, $S = 51.6$, from Table 10, aver K = say 1 000 lb per sq in; hence safe M = 51 600 in-lb; or, since $M = Wl \div 8$, with l = 48 in, total load is 8 600 lb; or, divided by 4, a safe load of 2 150 lb per ft. For horiz shear, using max from Table 10 of aver 100 lb per sq in, since V max = $3/2\ V \div bd$, the max permissible shear = 0.66 × 100 × 6 × 8 = 3 200 lb, and safe load per ft = 1 600 lb, which controls. Note. When ratio of depth of beam to span (1 : 8 in this problem) exceeds ratio of allowable shear to direct stress (1 : 10 as above), horiz shear rather than bending controls safe load. This is shown in Table 11 for plank floors (based on K = 1 000 and horiz shear = 100 lb per sq in), where values below the heavy line depend on bending; those above being computed for horiz shear.

Timber columns are usually of sq sec. *Example.* Design redwood strut 10 ft long to carry 50 000 lb. For a selected stick, if safe load (Table 10) is 1 000 lb per sq in, about 50 sq in or 7 in sq sec is required. With this sec, $l \div d$ = about 17 and safe stress would be 900, giving sec of 7.5 or, nearest commercial size, 8 by 8. For common timber a larger sec, say 8 by 10, would be required.



(a)

(b)

Fig. 46. Compound or Keyed Beams

Deepened, built-up, compound or keyed beams. When no timber of required size is available, beams of this kind are used for temporary work and sometimes for permanent construction, though trussed beams are much lighter. If 2 beams are superposed, they have only twice the strength of one, neglecting friction between them. But, if they are bolted together (Fig 46) they act as one beam of twice the depth, and are 4 times as strong as the single stick.

Compound beam in Fig 46a is fastened by sheeting of planks at least 1/8 the width of timbers, with nails extending at least 0.5 their length into the main members; it has a strength of about 70% that of a solid beam of same dimensions. Beams with hardwood or metal keys (Fig 46b), preferably of a wedged type, are 75 to 80% as strong as solid beams. The keys transfer the horiz shear from one beam to the other, and are of such size that the safe end compression is not exceeded. Spacing must be determined for the safe horiz shearing stress. Keys should be about 2.5 times as wide as thick, and beam should be about 0.5.

Design. *a.* Design cross-sec of beam for bending = 1.25 to 1.33 times that computed (to allow for effic of 75–80%). *b.* Compute external vert shear = V, at governing points. *c.* Compute intensity of horiz shear at neutral axis = $(3 \div 2\ V) \div bd$. *d.* Compute total horiz shear between

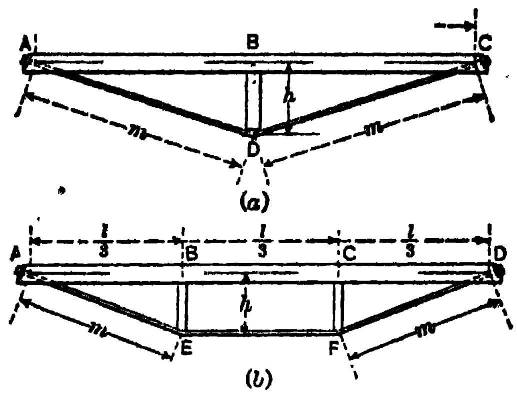


Fig 47. Trussed Beams

end and point of zero shear (total horiz shear = aver intensity between any 2 points × b × distance between points). *e.* Select number of keys (usually 5) and divide (*d*) by this number, designing keys for bearing accordingly. *f.* Draw vert shear diagram (horiz shear is proportional) and divide into number of equal areas (= number of keys) by vert lines. Place keys in back of these lines. *g.* Check design for shear between keys. *h.* Design bolts as for tabled fish-plate joint.

Trussed beams are economical for spans over 20 ft, where headroom permits, or for shorter spans where saving in wt is an object. King and queen-post trusses (Fig 47) are used. Usually the beam is a single unspliced piece, extending from end to end, with iron

No column shall be used in which the unsupported length is more than 50 times the least diam; l and d must be in same unit of measurement.

Strength of wood depends considerably on moisture content. For wet locations working stresses should be reduced according to conditions and timber used.

When the load is concentrated at the vert struts, that is, for panel point loading, the stresses are found as in Art 17 and members designed accordingly. The only bending stress is due to wt of members themselves, which can be ignored except for long spans and small live loads. A uniformly-distributed load is carried partly by the beam and partly by truss action. The stresses can not be computed by ordinary means, but may be found as follows. In Fig 47a, king-post truss, W = total load, lb, on beam uniformly distributed. Compression in $BD = 5\ W + 8$; compression in $AB = 5\ Wl + 32\ h$; tension in $AD = 5\ Wm + 16\ h$. Design AD and BD for these stresses. Divide compression in AB by area of beam $= bd$, giving unit direct compression in AB; add to this the extreme fiber stress due to load acting on AB as a simple beam $= 2.25\ Wl + bd^2$, and design AB so this total will not exceed allowable. All lengths are in ft, except b and d = breadth and depth of AB, in. When the truss is above the beam, AD will be in compression, BD and AB in tension, and the latter must be designed for max tension due to direct and bending stress, using same formulas. (Fig 47b) queen-post truss. Approximately, compression stress in BE and $CF = W + 3$; compression in AD = tension in $EF = Wl + 9\ h$; tension in AE and $FD = Wm + 3\ h$. Extreme fiber stress in AB, BC, or CD, acting as a beam, $= Wl + bd^2$.

22. FASTENINGS AND JOINTS

Nails are classified as cut and wire. For lumber liable to split, cut nails are better than wire. They should be driven so that the tapering sides bear against the bent ends of the wood fiber, thus preventing splitting and acting like a wedge. Wire nails may be clinched or bent down; cut nails can not be bent. Table 13 gives common forms, designated in size by the "penny" system (d), probably originally the number of lb to 100 nails. Number per lb varies with different makers. Cost about 2–5¢ per lb. Nails should not be depended on for important joints, even in temporary structures. Large cut or wire nails are known as SPIKES. Boat or ship spikes are also made, forged from square bars with square head and chisel point. R R track spikes have a special head.

A keg of nails or spikes weighs 100 lb. Table of boat spikes gives approx number in a keg of 200 lb.

Drift bolts are long, steel pins, generally round (square are used), with or without heads. 3/4 and 7/8-in diam are common sizes, but 1-in diam and up to 30 in long have been used. A hole should be bored 1/16 to 1/8 in less diam than bolt.

Treenails (wooden pins) are hard-wood pins, sometimes used as drift bolts, but commonly in mortise and tenon joints, etc. DOWELS are wood or iron pins extending into, but not through, 2 members, to connect them; they have neither point nor head. In heavy work, they are usually 0.75 to 2 in diam and 5 to 12 in long.

Screws comprise wood and lag screws. Wood screws are made to 6 in long, and some lengths in as many as 18 different diams. Thus, 3-in screws are from 8 to 26 gage (diam): 3.5-in, 8 to 26; 4-in, 8 to 30; and 4.5, 5, and 6-in, 12 to 30. Gage refers to special screw-gage, which is approx as follows: 6 = 0.14 in, 10 = 0.19, 15 = 0.26, 20 = 0.32, 25 = 0.39, and 30 = 0.45 in. For all large screws a hole should be bored less than diam of shank and about 0.5 its depth. For lag screws bore a hole equal in diam and length to shank, and then a smaller hole for about 0.5 length of thread. Lag screws have square or hexagonal heads, and are from 5/16 to 7/8-in diam for 3 in length;

5/16 to 1-in for 3 1/2 to 6-in length; 7/16 to 1 for 6.5 to 9-in; 0.5 to 1 for 10 to 12-in. Lengths vary by 0.5 in up to 8 in.

Bolts have round, square or hexagon heads, and are either rough or finished, rough being used for woodwork. Where used to prevent sliding of one member over another, the hole should be bored with a diam of 1/8 in less than the bolt, to give a close driving fit. Bolts have diam differing by 1/16 or 1/8-in. Where subject to vibration, lock nuts are used, or a nail is driven alongside the nut, or the thread may be "burred" to prevent nut working loose.

Washers (Fig 49) are important in timber work, to provide sufficient bearing area so that compression on surface of the timber may not exceed a safe value. They are of C I, steel or W I, and malleable iron. Common C-I washer is the Ogee (marked O G) form. Special washers can be cast when the number required warrants it. Steel and W-I washers are cut from plate, and are often too small and thin properly to distribute the bearing load. They should be about 4 times the diam of the bolt and 0.5 as thick.

Fig 48. Timber Fastenings

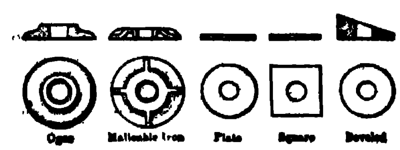

Fig 49. Washers

Table 14. C-I Ogee Washers (dimensions, in)

Diam of bolt	Diam of washer	Thickness	Wt of 100	Bearing area	Diam of bolt	Diam of washer	Thickness	Wt of 100	Bearing area
3/8	1 1/2	5/16	8.5	1.57	1	4	7/8	180	11.57
1/2	2	3/8	22	2.83	1	4	1	194	11.57
1/2	2 3/8	1/2	37.5	4.12	1 1/8	4 1/2	1	215	14.68

7/8	3 5/8	7/8	150	9 54	1 1/2	6	1 1/2	688	26.20

Anchor bolts have a thread cut at upper end to take a nut, lower end being embedded in the foundation. Neat cement grout has been shown to be best material for setting the bolt; if there is no vibration, plain rods may be used, proportioned for 15 000 lb per net section of bolt, or 100 to 150 lb per sq in of embedded surface of bolt. Embedment of about 20 diam is needed to develop full strength of bolt. For machine foundations, it is best to use a bolt with nut and large washer at lower end and build it into the concrete.

Resistance to pulling of nails and screws varies with character of wood, depth of penetration, and for screws with size of hole used. Cut nails have higher holding power than wire, and the safe load may be taken at 4d in yellow pine and 7d in oak, where d = penny number of nails driven across grain, to depth of 0.4 length; for wire nails, 2.5 and 4d. If subject to shock, the resistance is very low. For wood screws the safe resistance of a No 20 gage screw is twice that for a nail of same length. Lag screws show an ultimate resistance varying from 400 for white pine to 1 400 or more lb per sq in for oak; area being length

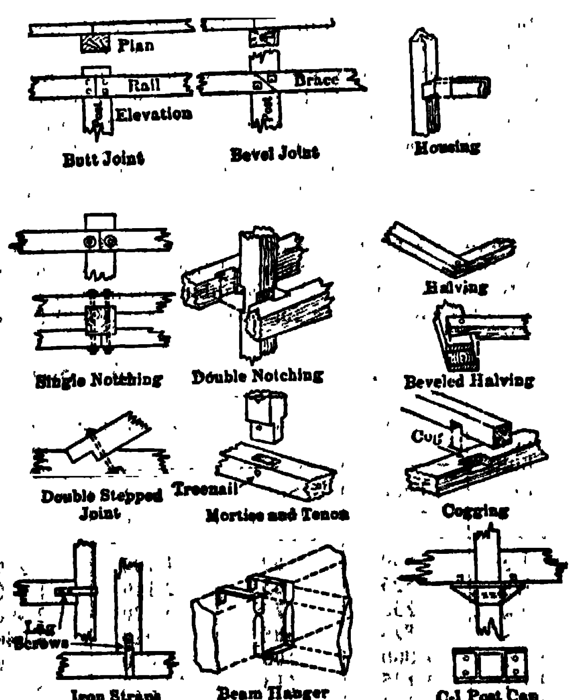

Fig 50. Timber Joints

(exclusive of point) times circumference of screw. Safe lateral resistance of nails is roughly twice the resistance to pulling.

Timber joints. (Fig 50, 51.) Butt joint is effective for compression members, the ends being secured by other connecting members or by fish plates. Notching is widely used, especially for cribs; sometimes called GAINING or "dapping"; or "sizing" when used in heavy framing to allow for inequalities in dimensions of timbers. HALVING is common in frame building construction, to join sills and wall plates. MORTISE AND TENON is a favorite joint for strength and rigidity. For 10 to 12-in timbers treenails should be 1 to 1.5 in diam, with a taper of $^1/_8$ to $^1/_4$ in. Hole in tenon should be about $^1/_3$ the length of tenon from shoulder, and slightly nearer the shoulder than that in mortise, so the pin will draw the timbers together. STEPPING is common in all kinds of framing.

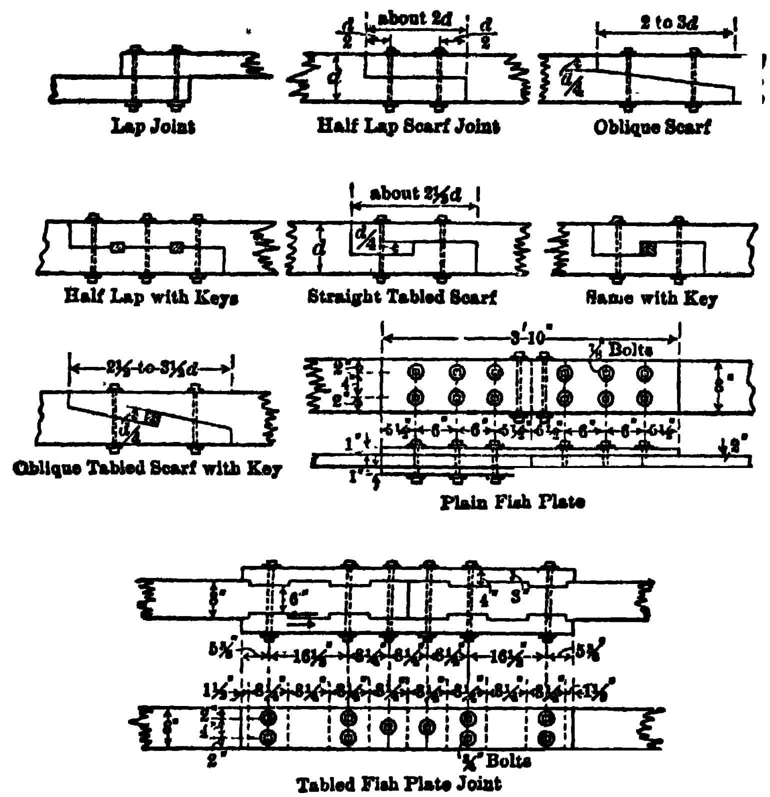

Fig 51. Lap and Scarf Joints

Metal straps are sometimes used in framing structures subject to shock. Metal plates are used in heavy construction, and for joints in structures like derricks, which are often taken down and set up again. Beam hangers and column caps are used in heavy floor construction. Lap joint is simple, but only used for connections in minor members, due to its eccentricity and consequent bending of pins or bolts. Half-lap scarf is used for joining members carrying small stresses, as guard rails on bridges, sills in buildings. Oblique scarf has more than double the strength of the half lap. Both joints are often used with fish plates in tension and compression members subjected to bending. Tabled scarf with key will take some tension, and when the amount is known the joint is easily designed for shear. Fish-plate joints, with wood or steel plates, are effective for tension. Bolts should be brought to solid bearing, to prevent timbers from buckling and to exclude moisture. Safe bearing loads per lin in are for safe bearing of 1 000 and 100 lb per sq in respectively. For other unit stresses, safe loads are obtained by proportion. For bending, the bolt is computed as a restrained beam with fiber stress of 22 500 lb per sq in (Table 15).

Design of a plain fish-plate joint (Fig 51). A tension timber to be spliced is 2 by 8-in longleaf yellow pine. Allowable stress, 1 200 lb per sq in net section. 2 fish plates of same material will have to be 1 in thick each. Number and size of bolts are found from Table 15. Thus, try 0.75-in bolts. Safe end bearing for the timber is 1 400 lb per sq in. Hence, safe bearing load on 0.75-in

Table 15. Strength of Bolts

Diam of bolt, in	Safe bearing, lb per lin in		Total safe uniform bending load on bolt, lb. a = thickness of member, b = thickness of fish plates					
	End grain	Side grain	$a = 2$ $b = 1$	$a = 3$ $b = 1.5$	$a = 4$ $b = 2$	$a = 6$ $b = 3$	$a = 8$ $b = 4$	$a = 10$ $b = 5$
1/2	500	50	1 100	740	550	370	280	220
5/8	625	63	2 160	1 440	1 080	720	540	430
3/4	750	75	3 720	2 490	1 860	1 250	930	750
7/8	875	88	5 920	3 940	2 960	1 970	1 470	1 180
1 1/8	1 000	100	8 820	5 880	4 410	2 940	2 210	1 760
1 1/4	1 125	113	12 560	8 390	6 290	4 190	3 140	2 510
1	1 250	125	17 250	11 500	8 640	5 750	4 300	3 450

bolt = 750 × 2 (= length of bearing) × 1 400 ÷ 1 000 = 2 100 lb. For bending, safe load = 3 720 lb; hence, bearing controls. Area of net section of member = 2 × (8 − 2 × $^7/_8$) = 12.5 sq in, assuming that bolts are placed in pairs and holes are $^1/_8$ in larger than bolt. Total tensile load = 12.5 × 1 200 = 15 000 lb, and number of 0.75-in bolts required = 15 000 ÷ 2 100 = 7. As an even number of bolts makes a better design, 6 $^7/_8$-in bolts will be used. Length of plate is determined by spacing of bolts, which tend to shear out a portion of the plate between planes tangent to top and bottom of bolt. Round bolts also tend to split the plates, so only 80% of safe shear with grain is used, or 80% of 150 lb per sq in = 120. Hence, the distance between bolt holes should be not less than 14 400 (= total load on net section for $^7/_8$-in bolts) ÷ [6(= number of bolts) × 2 (= thickness of 2 fish plates) × 2 (double shear) × 120 (shearing stress)] = 5 in, or, adding 1 in for bolt hole, = 6 in c to c and 5.5 for ends. The TABLED FISH-PLATE JOINT in Fig 51 was designed for a load of 32 tons in longleaf yellow pine. The design is as follows, using for tension 1 800, for compression on end of grain 2 000, and shear along grain, 250 lb per sq in. *a*. Find areas required for tension, compression and shear, or 64 000 ÷ 1 800 = 35.6, 64 000 ÷ 2 000 = 32, and 64 000 ÷ 250 = 256 sq in, respectively. 4 tables are usually effective, and the shearing area of each would be 256 ÷ 4 = 64 sq in. In order that the length of table shall be not less than $^2/_3$ its width (representing good proportions), the width of timber must be about 8 in, and the table a little over 8 in long to allow for bolt holes. Depth of tables must be 32 ÷ (4 × 8) = 1 in, to furnish necessary bearing area on their ends. Assuming $^3/_4$-in bolts and $^7/_8$-in holes, the net depth of main member for tension must be 35.6 ÷ (8 − 2 × $^7/_8$) = 5.75 in, making total depth of timber 8 in, or an 8 × 8 is needed. The fish plates, each taking 0.5 the total load and being of same material as main member, should be 0.5 as thick. Size of bolts may be roughly checked. Unlike the plain fish-plate joint, they transmit stress by tension. Thus, the pull on fish plate is approx through its center (see arrows in cut), and this is transmitted to the main member by end bearing on the tables, approx at their centers. This causes a moment of (6 400 ÷ 4) × (1.5 + 0.5) = 32 000 in lb per table, tending to cause it to rotate about its edge. This is resisted by tension in the bolt and compression on face of table. The lever arm of this couple may be taken as 0.5 the length of table, or 4 in, giving a pull on the bolt of 4 000 lb, assuming 2 bolts per table. A 0.75-in bolt is ample for this stress, using 15 000 lb per sq in, net sec. The washers should have sufficient area for bearing, using 550 lb per sq in. A standard 3.25 C-I washer has an area of 7.69 sq in, and will transmit a total stress of 4 230 lb, which is OK. Bolts should be pulled up to a tight bearing.

Special joint fastenings have been developed in recent years which greatly increase effectiveness of timber joints. These consist of various types of bushings in the form of washers, which are countersunk in the timber and increase the bearing diam of the bolts. When available or where size of construction warrants special purchase, these patented fastenings are advantageous.

23. TRESTLES, TRUSSES AND BRIDGES (12)

Trestles consist of posts framed together to form bents, supporting a floor system of stringers, ties, and guard rails. They are used for semi-permanent work, to avoid expenditure for permanent bridge or fill construction in the early days of a new R R, for making large fills, and in connection with mine dumps.

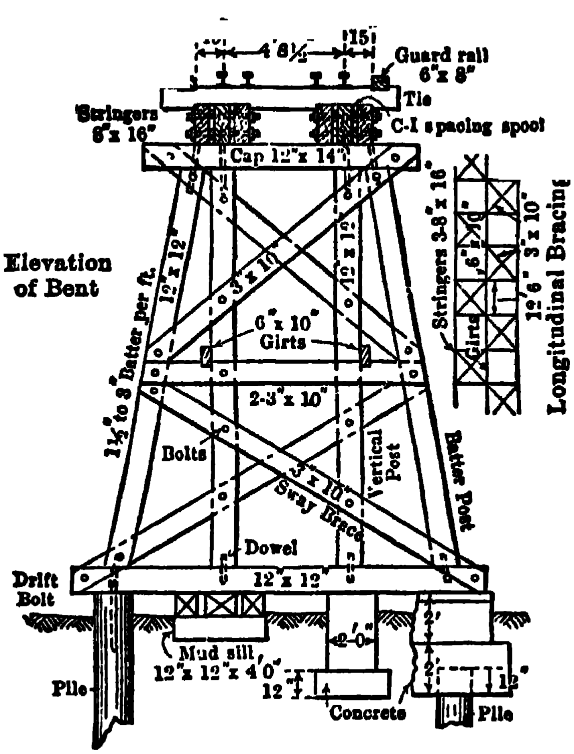

Fig 52. R R Trestle Bent

Fig 52 shows a trestle bent, with different types of foundations used indicated. Where piles are used they may be long enough to form the posts (pile-bent), being sway-braced as for a framed bent. Bents are built in stories of 15 or more ft high. Fig 52 is a 2-story bent. Posts may be designed as columns, but are made larger than computations require to allow for decay. Stringers should be continuous over 2 spans, and are designed for bending stresses. Bents are spaced 12–16 ft apart, depending upon wt of loading. For light mine cars, the construction would be much lighter than that shown, which is for R R work.

Roof truss of heavy design is shown in detail by Fig 53. Load from the rafters is carried to the panel points by the purlins; the stresses may be found (Art 17) for any assumed loading, and the members and details designed accordingly.

Small highway bridge, consisting of a queen truss with plank floor, is shown in Fig 54.

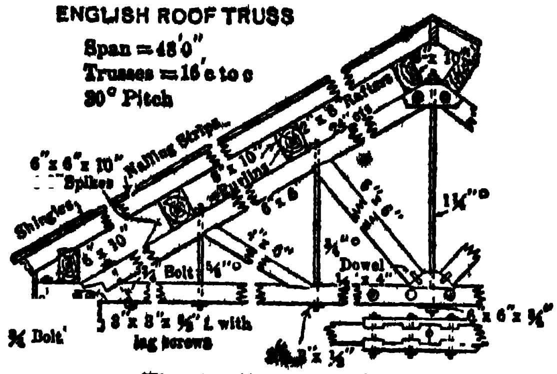

Fig 53. Heavy Roof Truss

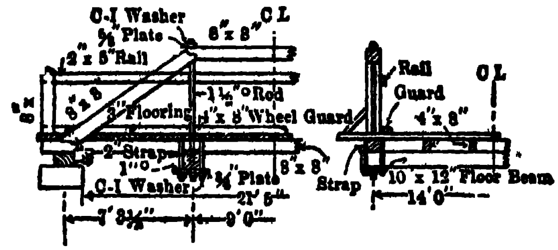

Fig 54. Small Highway Bridge

24. FRAME BUILDINGS (13)

Framing is of 3 kinds: (*a*) Mortise and tenon frame, in which the members are mortised and pinned together. This requires a large amount of labor and for light buildings has been practically abandoned; (*b*) Balloon frame, composed of lighter members, nailed together, and more quickly erected at lower cost; (*c*) Combination frame, in which main members are mortised as in (*a*) and the studding and bracing is nailed, used in the best modern construction. Fig 55 shows typical balloon frame for a 2-story house. Computations are rarely necessary. Sill is usually 4 by 6 in, halved at corners, on foundation walls or piers. Floor joists are of 2-in plank, 12 or 16 in c to c; for joists over 12 in deep, 3-in thickness should be used. Joists are braced laterally by cross bridging, 1 row for 8 to 16-ft spans, and 2 for 18 to 24-ft spans, with 1 by 3-in bridging, or 2 by 3 for 14-in beams, nailed with 2 10d nails. Corner posts, usually 4 by 4 or 4 by 6-in, are set up and temporarily secured by "stay lath." Studs are held by a temporary board nailed against inside. Studs are 2 by 4 in, usually 16-in centers; they are spiked to the sills at lower ends, and when practicable studs and joists are placed against and spiked to each other. Studs extend from the sill up to the plate, the second floor joists being supported on 1 by 7-in ledger boards, notched into the studs. The plate is usually of two 2 by 4-in pieces. Joints in studs are made by nailing a fish plate on each side. Studding is doubled at window and door openings. 1 by 6-in boards, notched into sill, post and studs, are used for corner braces. Rafters, 2 by 6 in, for lengths of 12 ft, 2 by 8 to 18, 2 by 10 over 18 ft, are spaced 16 to 24 in centers. Combination frame posts are usually 4 by 8 in, and the ledger board is replaced by a 4 by 8-in girt, framed into the posts, the studding being separate for each story.

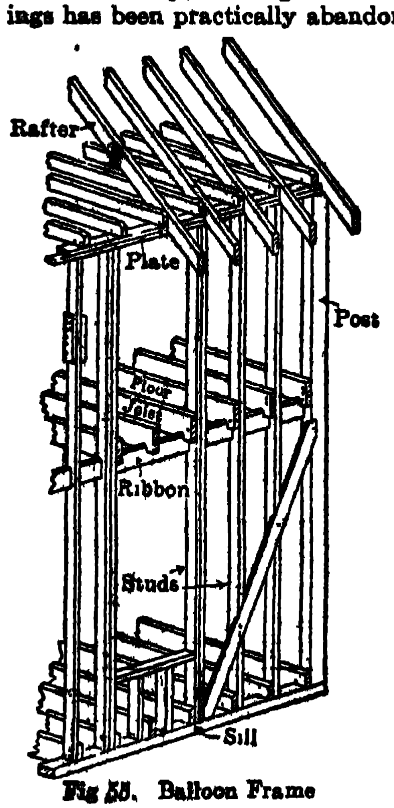

Fig 55. Balloon Frame

Partitions are usually of 2 by 4-in studding, spaced 12 to 16-in centers. In framing, it should be remembered that timber shrinks but little endwise of the grain, and sometimes as much as 0.5 in per ft crosswise. Where settlement is to be avoided, all horiz members should be eliminated from vertical supports of the buildings. Partitions should rest on the cap of the partition below when possible (not on the floor), or on a sole piece.

Covering. For cheap construction ship-lap is often placed vertically, with battens over the cracks. Beveled siding is commonly 6 in wide and laid 4.5 in to the weather. Molded siding (Novelty siding), is of 7/8-in boards, with 5/8-in lap. In best work, the frame is first covered with 1-in diagonal sheathing, which in turn is covered with building paper before the siding is placed. Shingles or corrugated sheets are also used for siding.

Shingle roof. Shingles vary from 16 to 24 in long, laid with 4.5 to 5.5 in (a little less than 1/3 the length) to weather. 4 bundles usually contain a "thousand" shingles, that is, the equiva-

lent of 1 M shingles 4 in wide, the widths varying from 3 to 14 in. Table 17 gives number of standard 4-in shingles for 100 sq ft of roof. Cost laid, \$8.00 to \$10 per square (= 100 sq ft).

Tin roofing. There are 2 common sizes of tin, 14 by 20 in and 20 by 28 in, latter being most used. The usual thicknesses are IC (No 29 gage) and IX (No 27). Value of tin roofing depends on amount of tin used in coating the iron. If well painted every 2 or 3 years it will last 25 or 30 yr. Laid with flat seam for flat roofs. Using 0.5-in locks, 1 box (112 sheets) of 14 by 20-in tin will cover 192 sq ft; 20 by 28-in, 399 sq ft. For steep roofs, a standing seam is used. With $^3/_8$-in lock, and 1-in standing seam, a 14 by 20 box will cover 168 sq ft, and the larger size 365 ft. Aver cost in place, including material and painting, \$15 to \$20 per square.

Table 16. Shingle Roofing

Length	Weather	No of shingles	No of shingle nails	Lb of shingle nails
14 in	4 in	900	1 800	4.5
16 "	5 "	720	1 440	3.6
18 "	5 1/2 "	655	1 310	3.3
20 "	6 "	600	1 200	3.0
22 "	6 1/2 "	554	1 110	2.8

Corrugated iron sheets, for roofs and sides of buildings, are made in lengths of 5, 6, 7, 8, 9 and 10 ft, and a covering width of 24 in. For siding, a side lap of 1 corrugation and 4-in end lap is usual; for 1 to 4 pitch roofs, 1.5 corrugations are used on edges and 6 in on ends. Usual corrugation is 2.5 in wide by 0.5 in deep, and for roofs No 20 and 22 gage are common. Sheets are made painted or galvanized, in No 12, 14, 16, 18, 20, 21, 22, 23, 24, 25, 26, 27, 28 U S Standard Gage thicknesses. Purlins should be less than 6 ft centers. Sheets, held by nails, or by steel straps encircling the purlins and placed 12-in centers, should be well secured at eaves and gable ends of roof to prevent their being loosened by wind. Safe uniform distributed load in lb per sq ft = 25 000 $td \div L^2$, where t = thickness of sheet, in, d = depth of corrugation, in, and L = unsupported length of sheet, ft.

Table 17. Corrugated Sheets (See also Sec 41, Table 21)

Description of sheets				Width, in		Sq ft of sheets to cover 100 sq ft			
Corrugations									
Width, in		Approx depth, in	No per sheet	Full sheet	Covers approx	End lap, in	Side lap corrugations		
Nominal	Actual						1	1.5	2
5	4 2/3	7/8	6	28	24	1	110	116	123
3	2 8/9	5/8	9	26	24	2	111	117	124

Standard lengths, 5, 6, 7, 8, 9 and 10 ft; max length, 12 ft for 1.25 to 5-in corrugations.

Tar and gravel roofing is often used for flat roofs. When laid on wood a layer of building felt (unsaturated) is first placed. This is covered with tarred felt, nailed down. Final covering, of 1 to 3 layers of tarred felt, is placed on the roof, each layer being thoroughly mopped down with hot pitch. Entire outer surface is covered with pitch, in which $^1/_4$ to $^5/_8$ in dry gravel or slag is embedded while hot (400 lb per square). 4 or 5-ply roofing costs \$15 per square. TAR PAPER, nailed on with large tin washers, costs from \$4 to \$6 per square. Tar paper shingles, surfaced with crushed slate, are common. Several patented forms are also used, costing \$2–\$4, up; for more permanent construction, slate, tile, and asbestos shingles.

Partitions and ceilings. When plaster is used, 2 coats (rough or scratch, and finish coats) are applied to lath. Lath is of wood (0.25 by 1.5 in by 4 ft) nailed to studding, or perforated sheet metal or mesh, or patented composition board. The rough coat is lime and sand mortar; finish coat, usually of special plaster. Patented wall boards (fiber and plaster board) have largely replaced plaster in cheaper work and cost 6–10¢ sq ft in place. Made in sheets usually 4 ft wide and 8 or 12 ft long. Metal ceiling (stamped steel sheets) is also available.

Flooring. Single flooring is usual, of 1-in tongued and grooved pine or Douglas fir, from 12 in down to 3 or 4 in wide. Where subjected to hard wear, as in halls, and not carpeted, edge-grain or rift-sawed flooring is best (Art 20). Flooring comes in many grades, depending on grain, knots, etc, and in lengths of 8 to 20 ft. Double flooring, for higher class work. In figuring the amount of flooring, generally add about 25% to area to be covered, to allow for face width being less than actual width, and for cutting to bring joints over floor joists.

Stairs. Usual rise, 7 to 7.5 in; max, 8 in. Tread = run + overhang (1.5 in), and run should be such that rise + run = 17 or 17.5 in. With no nosing (overhang), tread should be 10 to 12 in wide.

Door and window frames are placed in the openings left in the studding for the purpose; they are smaller in size than these openings so they can be set plumb and true. In cheapest construction, no frames are used, the windows and doors being set in the openings between studs.

Doors. Stock doors are 1 $^1/_8$, 1 $^3/_8$ and 1 $^3/_4$ in thick; 1 $^3/_8$ in is usual for inside doors less than 3 by 7 ft. Outside doors are 1.75 in. Common sizes are 2–3 ft wide and 6.5 to 7 ft high, varying by even in.

Windows. Double-hung windows have 2, 4, 8 and 12 lights and frames are 1 3/8 and 1 3/4 in thick, usually with 3/8-in parting strips. Two-light windows are for glass from 16 by 24 to 30 by 40 in; 4-light windows, 10 by 20 to 15 by 32; 8-light, 9 by 12–14 by 24; 12-light, 8 by 10–12 by 24. Windows are generally 4 in wider and 6 in higher than the width and combined height of glass. Single-thickness glass is about 1/12 in thick; double-thickness, scant 1/8 in, is usual for widths over 24 in.

Cost. Simple frame buildings, as outlined above, vary in total cost from 15 to 30¢ per cu ft, depending on finish.

Slow-burning or mill construction is often used for more important buildings, as for manufacturing and storage. Its chief characteristic is absence of small timbers. Floors are generally supported by heavy timber columns. Beam hangers and column caps are widely used (Art 25) and flooring is heavier. Such construction is carefully computed to carry required loads.

STEEL STRUCTURES

25. STRENGTH OF IRON AND STEEL (4)

Table 18 gives aver physical and mechanical properties of metals for structural work.

Cast iron is, in general, somewhat brittle, is subject to hidden defects, such as blow holes, cold-shuts, and shrinkage cracks, has relatively low tensile strength, no true elastic behavior and is used only for thick, heavy parts, as short columns, engine frames and bed plates and pipes. Good castings should have clear, sharp corners and should be soft enough to dent under a hammer. Better grades of malleable castings are used for small machine parts and pipe fittings.

Wrought iron is tough, ductile, malleable and easily welded, but can not be tempered. Formerly widely used, it has been superseded by low-carbon steel. WI pipe is said to resist corrosion better than steel; purer iron under various trade names, used for galvanized culverts, is best of all. Etching for 20 min with 3 parts H_2SO_4, 1 part HCL in 9 parts water, produces a characteristic fibrous structure in WI.

Table 18. Physical Properties of Iron and Steel

Values in thousands of lb per sq in, except as noted. T = Tension. C = Compression. S = Shear. t = Torsion. * Millions of lb per sq in. † Thousand lb per sq in.

Structural steel, first made in quantity by Bessemer process, is now largely manufactured in open-hearth furnaces. Low-carbon steel is used for work where ductility is required, medium grades in structural work, but high carbon is being more widely used in reinforcement bars and other work. Various special alloy steels have been used in large bridge construction, as nickel and silicon, but are not available for smaller structural work. In tool and machine design alloy steels (chrome and tungsten) are used; also special heat treatment and other refinements to seecure metal best adapted to needs and loads are characteristic of modern practice. A structural aluminum alloy (Table 18) is available, but has not yet been widely employed.

Specifications. Standard specifications of Am Soc for Testing Materials are generally followed. For bridge work, these limit material to open hearth make, with a phosphorus content not over 0.04–0.06% and sulphur not over 0.05%. A tensile strength of 55 000–65 000 lb per sq in, a yield point of 0.5 of this, or not less than 30 000, and an elongation in per cent in an 8-in length of 150 000 ÷ tensile strength, is specified. Rivet steel is of somewhat softer grade, with tensile strength of 46 000–56 000 lb per sq in. Certain limits are also placed on variations in thickness of plates and wt per ft.

usually designated by nominal outside dimensions and wt per ft as 15 I 42.9, indicating a 15 in I-beam weighing 42.9 lb per lin ft. For complete data on wide flange, regular, standard and special shapes, see *Steel Construction*, published by Am Inst Steel Const. Tables 19–22 give the regular shapes, made by all mills rolling these products; other shapes, wide flange, column sections, T's and Z's, are only occasionally rolled, and may not be in stock, or are rolled only on order. In the tables, I = moment of inertia, S = section modulus, and r = radius of gyration (Art 4, 5).

Examples. Steel makers' handbooks give tables for safe load for shapes used as beams and columns, but these estimates are easily secured from the data given. (*a*) Required size of I-beam to carry central load of 2 tons on span of 15 ft. From Table 1, $M = Pl \div 4 = 180\,000$ inch-lb. Assuming approx wt of beam as 15 lb per ft, there should be added for dead load about 5 000, making total $M = 185\,000$ inch-lb. From Art 4, $M = kS$, or required section modulus S, using a fiber stress $k = 18\,000$, is 10.3. From Table 19, this will require a 7-in I, of 15.3 lb per ft. (*b*) Find the safe load for an 8 by 6, 0.5-in L, 10 ft high acting as a column. From Table 22, least radius of gyration $r = 1.30$, hence $l \div r = 92$ and from Art 5 and 29, $p = 17\,000 - 0.485\,(l^2 \div r^2) = 12\,900$ lb per sq in. Also from Table 22 area of sec $= 6.75$ sq in, hence safe load $= 6.75 \times 12\,900 = 87\,000$ lb.

27. RIVETED CONNECTIONS (13, 14, 18)

Rivets are of low-carbon round steel rod, with one rounded head. Holes are punched or drilled, or subpunched and reamed, through the parts to be riveted together, and 1/16 in larger than nominal diam of the rivet shank. The rivet is inserted after heating to light yellow color (not over 1 950° F), is held in place by a tool fitting the rounded head, and the other head is formed by hand hammering, by a pneumatic hammer with cup-shaped head, or, in shops, by riveting machines.

Rivets are used: (a) to fasten together various shapes and plates thus building up composite sections, as girders and columns, having a larger area, and hence greater strength, than the standard shapes; (b) to join shapes or composite sections together to form framed construction, as trusses and floor systems; (c) in joining curved or other plates to form boilers, pressure vessels and pipes.

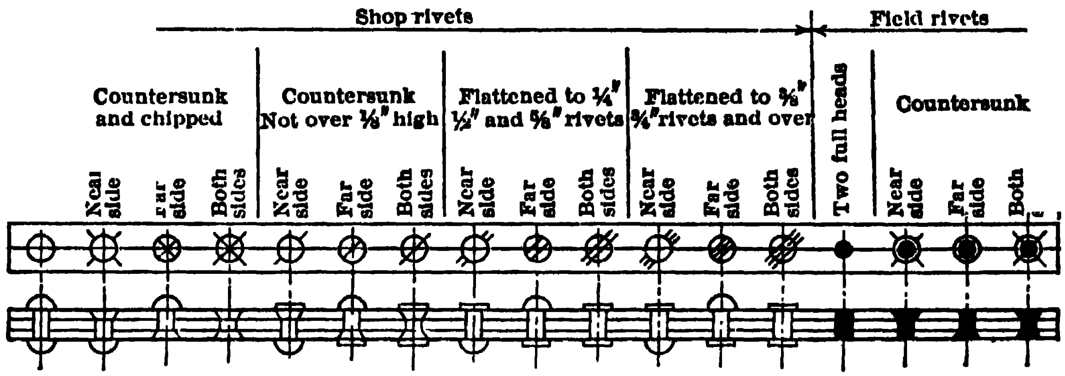

Fig 57. Conventional Signs for Riveting

Bolts are used in holding parts together temporarily, or for minor connections, but rivets are preferred for important work. The nominal diam of rivets varies from 0.5 to 1.5 in by eighths, the common size in structural work being 0.75 in. Fig 57 shows the types of rivets and conventional signs used to designate them.

Spacing and clearances. Rivets are placed in rows, the center lines of each row being known as the gage line. Pitch is the distance c–c of rivets in a row. Standard gage lines are used for angles (Table 23) and in standard beam connections. To leave space to

Table 23. Standard Gage Lines

Usual Gages for Angles, in															Crimps
Leg	8	7	6	5	4	3½	3	2½	2	1¾	1½	1⅜	1¼	1	$b = t + 1\frac{1}{2}''$ Min = 2"
g	4½	4	3½	3	2½	2	1¾	1⅝	1⅛	1	⅞	⅞	¾	⅝	
g_1	3	2½	2¼	2											
g_2	3	3	2½	1¾											

form the rivet head, a certain minimum pitch is required and minimum clearances between the gage line and outstanding flanges and crimps. The minimum dist between centers should be at least 3 × diam of rivet, but is preferably 0.5 in greater. This applies to rivets in 1 row, or to diagonal dist between staggered rivets in 2 or more rows (chain riveting refers to identical spacing in 2 or more rows).

Stresses. Riveting is so designed as not to subject a rivet to tension, but to cause it to act in shear. Strength of a rivet is thus measured by its shearing resistance ($R_s = \pi d^2 f_s \div 4$), or its resistance in double shear ($R_{2s} = 2R_s$), or by the capac of the metal pierced by the rivet to carry the press produced by the bearing of the rivet shank against it; $R_B = dtf_b$, d being the rivet diam, t length of bearing or thickness of plate pierced by the rivet, and, (A I S C specifications) f_s = 15 000 and f_b 32 000 lb per sq in for machine-driven rivets.

Tension joints. In these the main sec of the plate is reduced by the rivet holes and the ultimate strength of a joint designed with enough rivets is thus determined by the net sec of the plate.

Example 1 (Fig 58a). A lap joint with two 7/8-in rivets $b = 3$ and $t = 0.5$ in. Net sec is $b - (d + 1/8)tf_t$, where f_t is the allowable tensile stress, taken as 20 000 lb per sq in, and an allowance of 1/8 in for the rivet hole. This gives (3 − 1) (1 ÷ 2) 20 000, or 20 000 lb, which, for a fully riveted joint would be the max load. But, as there are only 2 rivets, the safe load in single shear (area of 7/8-in shank = 0.601 sq in) = 2 × 0.601 × 15 000 = 18 030 and in bearing = 2 × 7/8 × 1/2 × 32 000 = 28 000 lb. Hence R_s controls and, since strength of the full plate = 3 × 1/2 × 20 000 = 30 000 lb, the effic of the joint = 18 030 ÷ 30 000 = 60%.

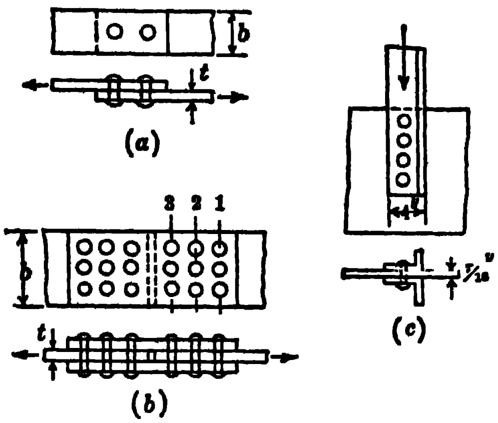

Fig 58. Riveted Connections

Example 2 (Fig 58b). A double-strap butt joint, with 9 7/8-in rivets, $b = 12$, t of main plate = 0.75 and of straps = 0.5 in. Assuming that the stress is uniformly distributed to the rivets, R_s = 2 × 9 × 0.601 × 15 000 = 162 400 lb, as the rivets are in double shear. Also R_B on side plates = 9 × 2 × 7/8 × 1/2 × 32 000 = 252 000 lb. As f_b may be increased 25% (AISC) for the center plate, which has support from both side plates, R_B for center plate = 9 × 7/8 × 3/4 × 40 000 = 23 620 lb. Finally the tension in the net sec of the main plate is (12 − 3 × 1) (0.75) × 20 000 = 135 000, and in straps = (12 − 3) (2 × 0.5 × 20 000 = 180 000 lb. Hence tension in the net sec of main plate limits the working load on this joint. Since the gross sec of main plate will carry 180 000 lb, the effic of the joint is 135 000 ÷ 180 000 = 75%.

A fuller analysis of this design will show that the stress is not carried uniformly, as assumed, but, because of the varying elongation of the plate between lines of rivets, the rivets in row 1 (Fig 58b) carry most of the load and those in row 2 the least. The design can be increased in effic to approx 90% by using tapered straps and a different arrangement of rivets.

Compression joints. There is no essential difference in design, except net section is unimportant and shear or bearing usually control.

Example 3 (Fig 59c). Two 4 × 3 × 3/8-in angles acting as a compression member and carrying 50 000-lb load are connected to a 7/16-in plate (gusset plate), as is common in designing joints in framed structures.

Find the number of 0.75-in rivets required. R_{2s} is found to be 13 250 lb, and R_B on the 7/16-in plate is 13 100 (allowing 25% increase as above), and for the 2 angle legs is 18 000 lb. Hence R_B on the 7/16-in plate controls and the number of rivets required is 50 000 ÷ 13 100 = 4. For more detailed analysis, particularly of eccentrically loaded joints, see (13).

Standard connections have been adopted for standard I-beams (Table 19), as shown in Table 24. There is also given the minimum span for uniformly distributed loads, below which the strength of the connection (assuming 0.75-in rivets) determines safe load on the beam rather than its cross-sec in bending.

Table 24. Standard Two-angle Connections

28. WELDED CONNECTIONS (19).

Use of gas or arc welding for connections in steel construction is now common. Joints are formed by fusing additional metal along the edges of parts to be joined, or, less often and in smaller parts, by spot welds. Fig 59 shows typical joints, those requiring special

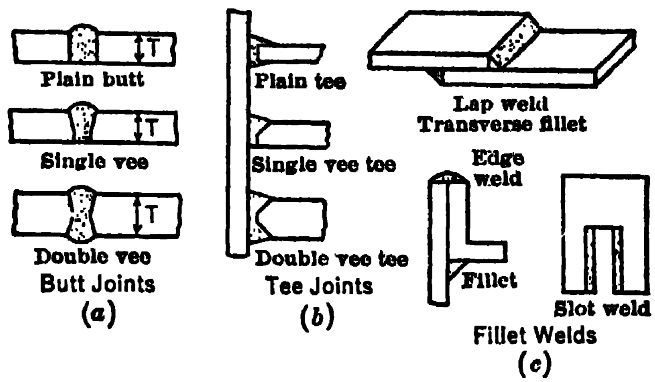

Fig 59. Types of Welded Connections

preparation of the edges V types being used for the heavier thicknesses, double V for over 0.5 in.

In forming the weld (Fig 60) the tool is moved continually forward, fusing the *base metal* to a penetration of 1/32–1/8 in, while *welding metal* is added to build up the *bead*. If properly timed there will be no overlap (due to surplus welding metal), or undercut (due to lack of metal), and a bead is formed of uniform contour with a surface free from oxide coating and marked with a series of ripples with a *crater* at the end, where the operation stopped. In gas welding, the limit of thickness

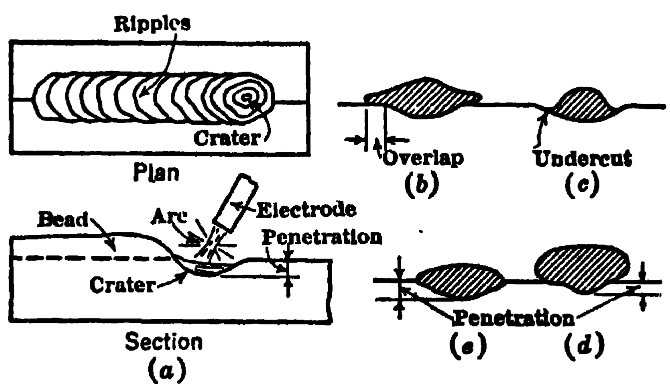

Fig 60. Welding Nomenclature

is determined by size of the molten pool of metal which can be maintained. In arc welding, single layers seldom exceed 1/8 in, but any total thickness can be built up in multi-layers. Fillet welds of 0.25 in are made in one pass.

The operation requires intense heat and thus extreme local expansion, followed by cooling and shrinkage. Annealing to relieve residual stresses is desirable, but rarely possible. To minimise

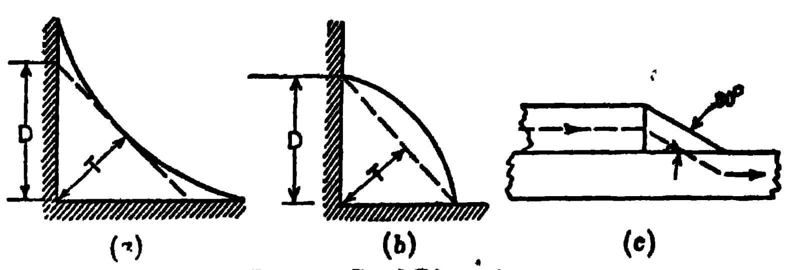

Fig 61. Bead Dimensions

these stresses, the parts should be free to move with the contracting metal, and the design of the joint and sequence of the operation (reducing the length of weld metal deposited in one operation, welding opposite sides in short lengths or simultaneously) must be planned to allow for heat effects. Inspection involves overlap, undercut, burned metal, quality of surface and depth of bead, but skill is

essential. For further details, see "Procedure Handbook of Arc Welding Design and Practice," of Lincoln Elec Co; also (19).

Design. The computation of welded joints is far simpler than for riveted connections. In butt welds (Fig 59 *a* and *b*) there is a surplus of metal, termed *reinforcement*, the weld sec being thicker than the plate but dimensions of latter (Tee, Fig 59*a*) control design.

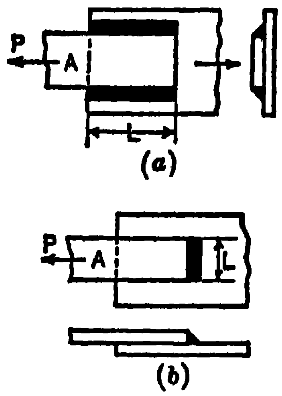

Fig 62. Design of Fillet Welds

Example. In fillet welds dimensions are determined by minimum included triangle, as in Fig 61 *a* or *b*, where D = depth of weld and T = throat or minimum sec. Assuming that longit shear is uniform, if f_s = shear value of weld, lb per sq in, strength of weld in lb $P = Tf_sL$, or $= 0.7Df_sL$, where L = length of weld. Using allowable shear on throat (Am Welding Soc), f_s = 11 300 lb per sq in, a 0.25-in weld will carry 2 000; a 3/8, 3 000, and a 0.5, 4 000 lb per lin in. Thus for the joint in Fig 62*a*, in which a 0.5-in plate 6 in wide is connected by 0.5-in side fillet welds to give a tensile stress of 20 000 lb per sq in, the total load = 0.5 × 6 × 20 000 = 60 000 lb, and the total length of weld $2L$ = 60 000 ÷ 4 000 = 15 in, to which 0.5 in is added on each side to allow for crater, making L = 8 in. Another type of welded connection for this joint is the transverse weld (Fig 62*b*), where a transverse fillet is used. A better stress distribution is secured by using a 30° weld (Fig 59*c*), rather than the usual 45° sec. Although the stress on the throat area is combined tension (allowable tension in welds (A W S), 13 000 lb per sq in) and shear, it is generally assumed that shear controls as in longit welds.

29. COLUMNS AND GIRDERS (13)

Although much larger steel sections are now being rolled than in the past and, whenever available, solid rolled sections are used, it is necessary when larger areas are required, or for special members in frame construction, to build up composite sections of plates and angles. Special wide-flange beam sections up to 36 × 16.5 in are rolled and wide-flange H-column sections are now used.

Girders are built-up of a web plate with flange angles and cover plates (Fig 63), giving, in effect, a large I section. The basic computations are the same as those for smaller

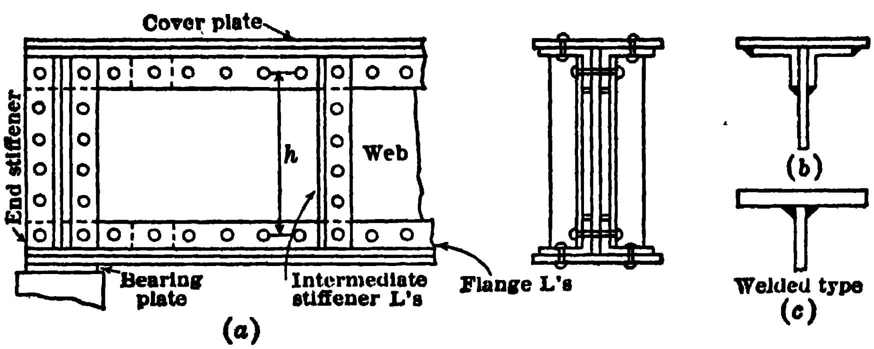

Fig 63. Girders

beams except: (*a*) while the web plate and flange angles are usually of uniform thickness, the cover plates may be reduced in thickness (number) toward the supports, in accordance with the decreasing moment; (*b*) the web will require intermediate stiffener angles to brace it against buckling due to shear under heavy loads. For details, see (13). Effective depth d, in $M = KI \div d$ (Art 4), is measured between centers of gravity of flange sections. Where a welded girder section is used, the most economical form is that of Fig 63*c*, rather than a section like the riveted form in Fig 63*b*.

Struts or compression sections in lighter framed construction are often composed of two angles back to back, as in steel roof truss (Fig 64).

Washers, the same thickness as gusset plates, are used to permit riveting of angles at such intervals that $l \div r$ (Art 5), or 2 angles considered separately, shall not exceed that of composite section (Fig 65). For axially loaded columns with $l \div r$ not over 120 (required for main members) the safe load (AISC) per sq in $= p = 17\,000 - 0.485\,(l^2 \div r^2)$, while for bracing and less important members, where $l \div r$ may reach 200, $p = 18\,000 \div (1 + l^2 \div 18\,000r^2)$. For details of design of heavier bridge and building columns see (13).

Tension members are also frequently made of standard sections (as angles in Fig 64) instead of round rods, due to ease of making riveted connection and increased stiffness given to entire

frame. Tie rods, with or without turnbuckles, and with threaded or loop ends, are also used, while in heavier construction with pin joints eye bars are often employed.

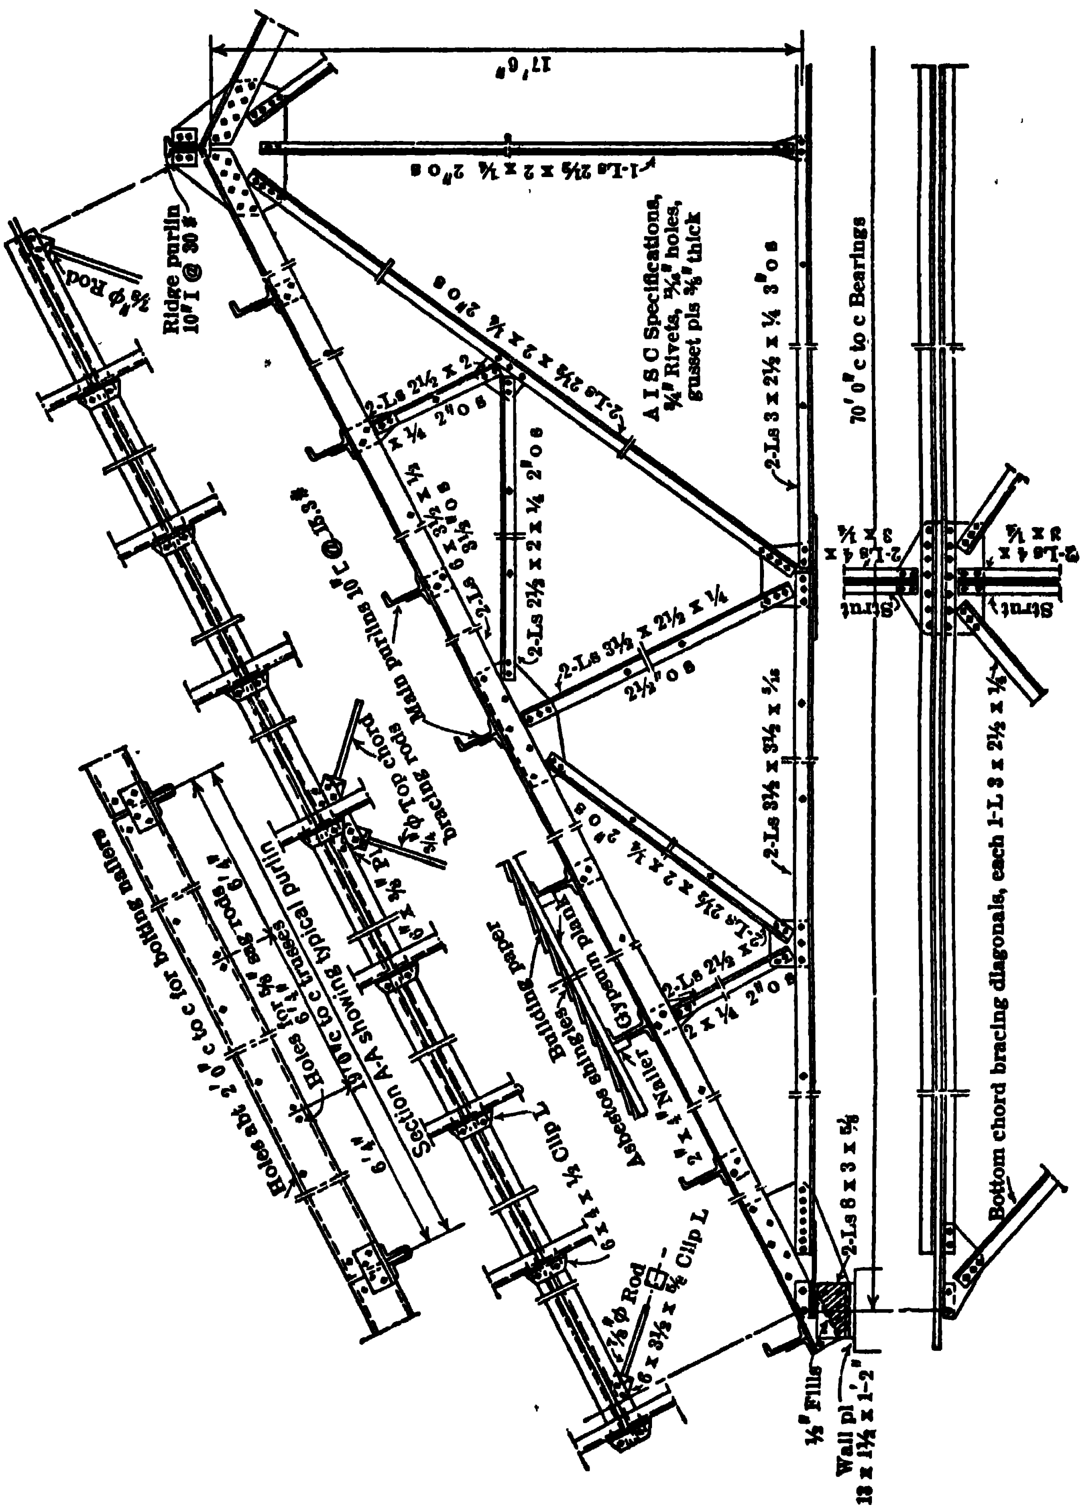

Fig 61. Steel Roof Truss

30. BRIDGES AND BUILDINGS

Bridges. For relatively light loads, the possibility of using 2 or more standard I-beams should always be investigated. Built-up girders are used for R R loadings in spans to 120 ft or more, the depth, usually about 0.1 the span, being limited by shipping conditions

(bridge and tunnel clearances). When possible, ties or floor should rest on top of beams or girder (*deck construction*), but clearances may require more costly *through* construction. Trusses are used only for larger spans. In former practice spans to 150 ft were generally built with riveted joints; longer spans pin connected, for easier erection. Solidly riveted connections are now usually employed for greater rigidity. For details of steel bridge design see (13).

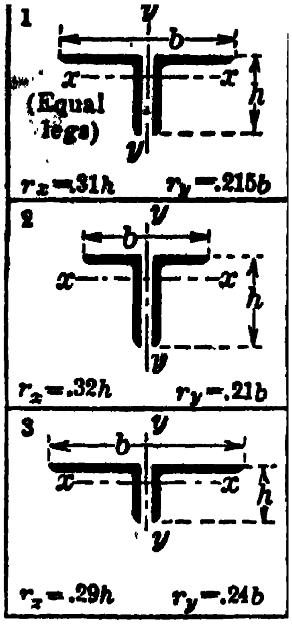

Fig 65. Compression in Angles

Buildings. Steel mill buildings are of 3 types: (*a*) steel truss and braced columns, covered with corrugated iron (Art 24), or thin concrete walls, supported by the steel frame; (*b*) same as above, except columns are braced by thin self-supporting masonry walls; (*c*) steel roof trusses, supported on masonry walls.

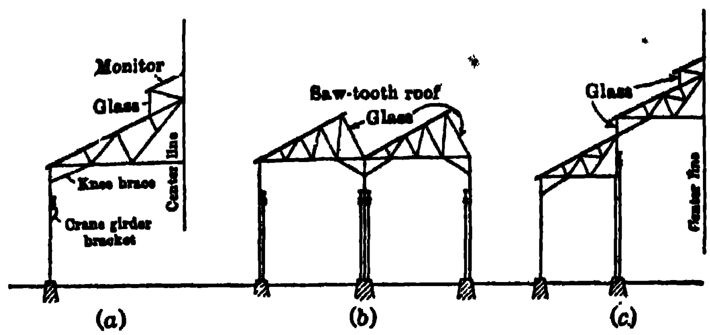

Fig 66. Forms of Steel Buildings

Fig 66 shows 3 common forms. Saw-tooth roof is usually so designed that the glass has a northern exposure. Fig 67 shows cross-sec of a building of type (*a*), with wind force acting against it. Dead and snow-load stresses in the roof truss are computed as in Art 17, but column, brace, and wind stresses depend largely on wind load and condition of fixity of columns. Fig 67 shows conditions when columns are assumed as usual as fixed at upper and hinged at lower end. Wind load is taken as acting at panel points, the individual loads being W_1, W_2, W_3, W_4, and W_5. The resultant W, acting at height h, is found by taking moments about the column base, the forces required for equilibrium being shown. In column P_1 max moment producing bending is just below the knee brace, and $= Wb \div 2$; the column must be designed (Art 6) to allow for this, in addition to direct

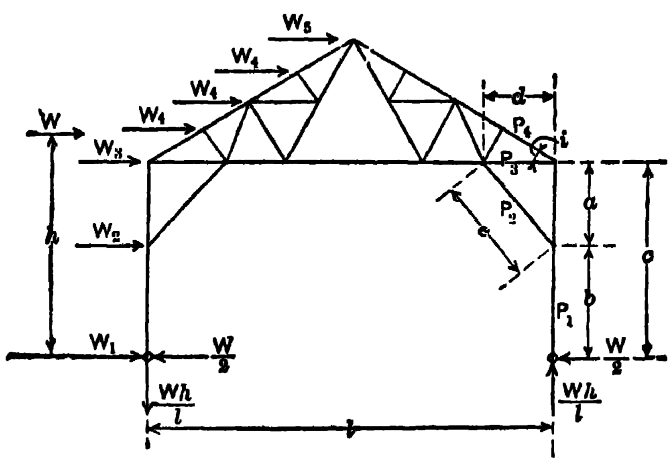

Fig 67. Distribution of Wind Pressures on Roof Truss

load from truss. The shear above brace $= Wb \div 2a$, and below brace $= W \div 2$. Direct stress due to wind below the brace is $Wh \div l$; above brace $= (Wc \div 2d) - (Wh \div l)$; in brace, $P_2 = Wce \div 2ad$. Member $P_4 = (Wc \div 2d) - (Wh \div l) \operatorname{cosec} i$. Chord $P_3 = P_4 \cos i - Wb \div 2a$. Stresses in other members are found by applying forces P_2, P_3, and P_4 and solving by methods of Art 18.

In many mill and factory buildings the column design is complicated by need of providing an overhead crane, to be carried by crane track girders supported by brackets attached to inside of columns. Crane loads thus produce excentric loading on columns; also a side thrust of 5–10% or more of lifting capac of the crane should be provided for, together with some impact allowance (17).

PETROLEUM PRODUCTION METHODS

BY

S. F. SHAW

CONSULTING ENGINEER, WESTGATE OIL CO, ANGLO-CANADIAN OIL CO, LTD, ETC

Note.—Numbers in parentheses in text refer to Bibliography at end of this section.

PETROLEUM PRODUCTION METHODS

1. PETROLEUM DEPOSITS

Geological occurrence. Oil deposits are found in sand strata, and in beds of porous limestone where structural conditions permit accumulation and retention of oil and gas. These conditions are: (*a*) sufficient structural relief, (*b*) a porous body (sand, limestone, or in a few cases porous serpentine), of sufficient thickness and porosity to form the necessary reservoir; (*c*) source beds, whence the oil has migrated to the reservoir (1).

Structures favorable to oil accumulation are anticlines, domes, monoclines, terraces, lenses, faulted areas, part dome and part fault, and unconformities. Fig 1 shows a classic

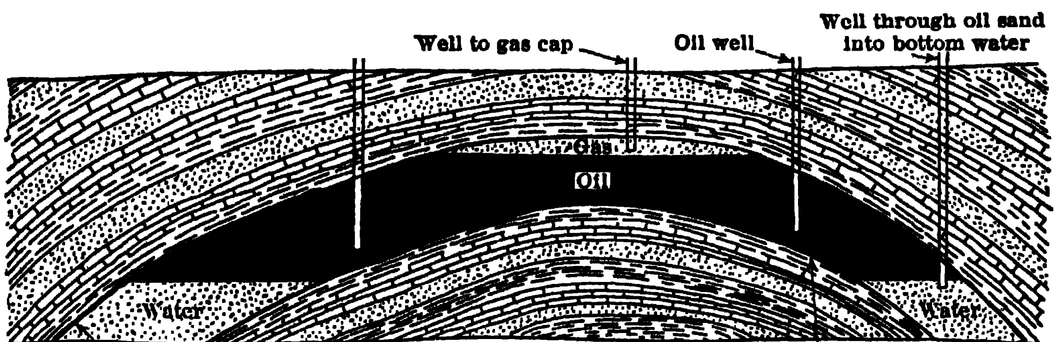

Fig 1. Ideal Vert Sec through Dome containing Oil, Water and Gas

example of an oil reservoir, in this case a sand stratum with cap-rock preventing the upward escape of oil and gas. Free gas occupies the upper part of the dome, underlain by the horiz oil deposit, below which is the "edgewater," preventing oil and gas (now under considerable press) from escaping down the slopes of the dome. This is either water which has backed into the reservoir, or (in part) water displaced by oil and gas (2).

Oil and gas in underground reservoirs are usually under pressure, roughly equal to press in a water column of same depth below surface, though there are many cases of press greater or less than required by this rule. Examples are given in Table 1. Pressures observed in early years were probably "casing-head pressures," not actual "bottom-hole pressures," which are more accurately recorded today with instruments lowered to the well bottom. The last 7 examples in Table 1 (except Oklahoma City) were taken with bottom-hole press bombs, and their close approach to water-column press of 0.434 lb per sq in per ft of depth is noteworthy.

Table 1. Pressures of Gas in Various Reservoirs

In general, oil under press contains gas in solution, the quantity varying with the press and the character of oil. High-gravity oils usually contain more gas than heavier oils. "Saturated" oil contains all the gas that can be dissolved at the reservoir press, and any excess must then exist free, in a gas-cap at top of the geologic structure. "Undersaturated" oil has less than the max gas content at the existing press. Fig 2 shows the

quantities of gas dissolved in oils of various fields; for example, that dissolved in one bbl of oil in the Seminole field under 1 000-lb press is 290 cu ft.

When a reservoir is tapped, oil rises in the well to the height corresponding to reservoir press, provided the gas above the oil column can escape from the casing head. If enough gas is associated with the oil, the oil will flow naturally from the well, until reservoir press has declined to the point where the gas content can no longer lift the oil to the surface, whereupon the well will flow in heads and finally cease altogether. In deep deposits, the gas content seems to increase sufficiently with depth to maintain more rapid flow than in shallow wells. After natural flow ceases, artificial means must be provided to lift the oil.

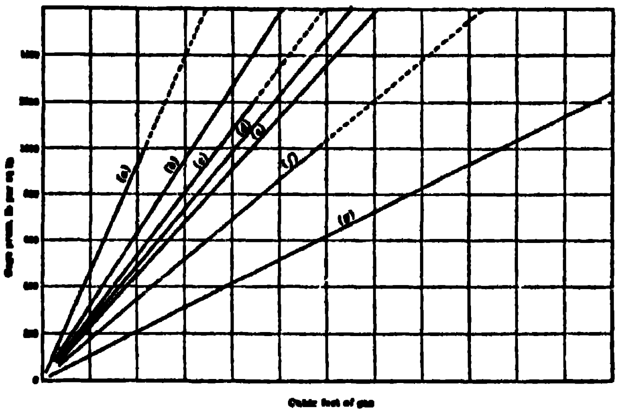

Fig 2. Cubic Feet of Gas Dissolved in One Barrel of Crude Oil. (*a*) Raccoon Bend, Tex, 20.3° API. (*b*) Sugarland, Tex. (*c*) Raccoon Bend Crude, 32.1° API. (*d*) Oklahoma Crude, 31° API. (*e*) Wyoming Crude, 36° API. (*f*) Seminole Crude. (*g*) Hobbs Crude

Methods of extracting petroleum described herein are classed as primary or secondary, depending chiefly upon age of the well and degree to which oil has been extracted. These classes were formerly more sharply distinguished, but are now beginning to overlap. Primary methods include natural flow and direct-lifting methods, beginning with completion of the well and ending when these methods can no longer extract oil profitably, but must be supplemented by secondary methods of repressuring (Art 12, 13).

PRIMARY METHODS OF EXTRACTION

2. NATURAL FLOW

In most fields, a completed well will flow naturally for a period dependent on the quantity of gas associated with the oil, depth of well, reservoir press and diam of casing. If the quantity of gas is large enough and can automatically adjust itself to the quantity of oil entering the well bottom, natural flow may continue throughout the life of the well, and such cases have been known (3). Usually, the quantity of gas declines until the well stops flowing or "dies," whereupon artificial means of lifting the oil are necessary.

Depth of well is an important factor in the duration of natural flow, since a definite amount of work must be done for each foot through which the oil is lifted, whence (other conditions being constant) the deeper the well the greater the quantity of gas required to lift a bbl of oil (4). For a given flowing press, assuming that the casing is delivering oil at its most effic rate, the greater the diam of casing the less gas is required to lift a bbl of oil. Table 2 shows ft-lb of work developed by a perfect gas, when expanding isothermally from a given gage press to atmosphere. Gas associated with oil is not a perfect gas, nor does it expand isothermally, but in each case its characteristics bear a definite relation to isothermal expansion; whence, for any one well the observed characteristics of flow, and the flowing effic, based on isothermal theory, provide a measure of lifting effic accurate enough throughout the period of natural flow. Between wells of the same pool there is little difference in the factors for deviation of compressibility under flow conditions.

Flowing press at the sand face is another important factor. If this press declines until the associated gas has too little energy to lift the oil to the surface, the well ceases continuous flow. It may then flow intermittently, as gas accumulates from time to time at the well bottom in sufficient quantity to lift the accumulated oil, but this flow is uncertain and subject to almost no control; whence, at this point some artificial means of lifting is usually necessary (5). But flowing press may be partly or fully maintained by the gas associated with the oil, or by water (if under press head) at the edges of the field, tending to drive oil to the well. In general, when a well is opened and begins natural flow, some of the oil and gas near the well bottom is drawn off, lowering press at the sand face and allowing reservoir press to drive or push more oil to the well; this process continuing until, at some rate of flow, reservoir press is balanced by the press required to drive oil through the sand to the well and through the casing and discharge piping at the surface (6).

Desired production of oil governs the manner of "producing" the well. For max production the well is opened wide at surface, and back press at that point is held to a minimum. If there is enough associated gas to maintain a high rate of flow, the well is

flowed through the casing (7). Sometimes the sand at the well bottom is loose and enough may enter the well eventually to choke it (as in many wells on Gulf coast and in Calif), in which case it may be necessary to choke back the flow, by partly closing the discharge valve at surface, or by inserting a "choke" or "bean" or "flow-nipple" in the discharge line. Choking may also be effected by using a diam of well tubing suited to desired flow.

When there is an oversupply of oil, it may be necessary at times to choke or restrict the production of a well, usually effected by running tubing inside the casing, of a diam likely to be used later when producing the well artificially. Closer control of the rate of flow is obtained by inserting in the flow-line a choke or flow-nipple, of diam suited to the rate desired. During the past ten years the large oversupply of oil has made it necessary to restrict the production of large wells, and various methods of prorating the restricted production equitably between operators have been applied. From data obtained during these years of proration, some engineers hold that restriction increases the ultimate recovery of oil, especially where there is a strong water drive; on the theory that the right degree of restriction would so adjust the advance of the water as to maintain reservoir press, while sweeping the oil gradually to the wells, thus maintaining natural flow throughout their life (8). Some engineers also believe that under restriction the gas-oil ratios are held to a minimum, thus tending to maintain higher reservoir press than when the wells are produced at max capacity; but, it has been observed in many fields that flowing at max capacity has not increased, but rather reduced, the gas-oil ratio. Whether ultimate recovery is increased or reduced by restricting production is a question which continued observation during the next 10 or 15 years may tend to decide. Meanwhile, as long as a large oversupply of oil exists, production must be restricted regardless of ultimate recovery, and the restriction will be applied to large flowing wells rather than to small wells operated by artificial lifting methods. "Kick-off" valves (Art 4) are used in flowing wells when gas press and volume have declined until the wells will not start flowing after they have been shut in for a time, or else flow in a surging condition.

3. PRESSURE MAINTENANCE

Maintenance of reservoir pressure and indefinite natural flow without any resulting disadvantage would be the ideal mode of producing oil (9). If no oil or gas were drawn off, the reservoir press would be maintained indefinitely; and a lowered rate of production means a slower decline in press, though this may serve only to spread production over a longer period.

Reservoir press depends upon quantity and press of gas associated with the oil, activity of the water-drive behind the oil, degree to which the reservoir sand or rock becomes compacted as oil and gas are removed, and effectiveness of returning some fluid (gas, water, or oil) to the reservoir. It has been held that, with an active water-drive, some restricted rate of production can be found at which the water will follow up the oil without loss of press, thus maintaining this press on the oil and gas in the reservoir (10). To the extent

that this balance is achieved, restriction is of benefit whenever the longest possible maintenance of natural flow is desired, such flow being usually the cheapest known method of production. Restriction where there is a strong water-drive is found in the East Texas, Hobbs, Rabbs Ridge, Anahuac and other fields.

Reservoir pressure can be maintained to some degree by injecting into the reservoir a volume of fluid (oil, water or gas) equivalent to the volume removed (11). The usual method is to inject gas into the highest wells on the structure, thereby forcing the oil down to the lower wells. To do this, the gas produced with and separated from the oil is used, being recompressed and returned to the input wells (12). Also, oil or water can be injected into wells lower on the structure, to push oil upward to those higher.

In Persia, heavy crude oil (left after tapping the gasolene) has been injected into the reservoir, tending to maintain press to the extent that it replaces oil and gas removed. In a few fields, a large part of the gas produced has been returned for the same purpose (as in Colombia, Perú and Sumatra, operated by subsidiaries of Standard Oil Co of N J). Much oil in the Talang Akar-Pendopo field, Sumatra, has been produced by the press maintenance method, with apparently favorable results. The method has also been applied to the Tepetate field, Louisiana (13) and the Sugarland (14) and Raccoon Bend fields in Texas, of which the last named has not responded very well; but results in the Sugarland field seem encouraging enough to suggest continuing until exhaustion of the pool, or until definite conclusions can be reached. Data of these last two fields are in Table 3. The South Burbank (15) and Keokuk Falls (16) fields, Okla, are operated by returning a large part of the gas produced with the oil, though perhaps the latter field is not suited to the method. Results in the South Burbank field are not yet definitely established.

4. GAS-LIFT, CONTINUOUS FLOW

Air- or gas-lift was tried and used on a small scale soon after the first commercial wells were produced in Penna (1865), and in early days on the Gulf Coast, at Humble, Evangeline, Goose Creek, Orange, West Columbia; in various Calif fields, as Huntington Beach, Kern River, Long Beach, Santa Fe Springs and Seal Beach; in Okla, at Blackwell, Burbank, Oklahoma City, Seminole, Wewoka, etc; abroad in Argentina, Canada, Colombia, Perú, Rumania, Russia, Sumatra, Trinidad and Venezuela.

Gas-lift follows natural flow in logical sequence; used to good advantage where natural flow has ceased, or has fallen off for lack of gas with the oil. Its principle is identical with that of natural flow itself, and of the air-lift for raising water; for theory and details, see Sec 15, and Bib (17, 18). Tubing is installed inside the well casing, and air or gas injected, either through the tubing (the oil flowing between tubing and casing), or vice versa.

Casing sizes for gas-lift are 5 1/2 to 9 5/8 in; tubing sizes, 4 in down to 1 in or less; in general, casing size should increase with well depth (19). In the Seminole field (20), usual sizes were 5 1/2 and 6 5/8-in casing with 2-in tubing, 7-in casing with 2 1/2-in tubing, and 8 5/8-in casing with 3- and 4-in tubing; the oil usually flowed between tubing and casing, for lifting as much oil as possible, but in periods of restricted production it was lifted through 3- and 4-in tubing. In Oklahoma City, sizes are 6 5/8-in casing with 2-in tubing; 7-in casing with 2- and 2 1/2-in tubing; and 8 5/8, 9- and 9 5/8-in casing with 3-in tubing. In early years in this field, when production was greatly restricted and reservoir press still high, oil was flowed through the tubing in some wells, through the casing in others, but when press had declined from 2 600 lb to 700 lb or less, the oil was usually raised through the annular space, to obtain larger production with less vol of gas per bbl than by raising through the tubing (21). General type of well hook-up for gas-lift used in the Tonkawa, Seminole and Oklahoma City fields is shown in Fig 3. Variations were made to suit local conditions.

Quantity of gas required to raise oil by continuous gas-lift depends on well depth, flowing press at bottom of tubing, size of casing and density of oil. Table 4 shows the quantity required to lift a bbl of oil at max flow.

Table 4. Approx Quantity of Output Gas for Lifting One Bbl of Oil, When Producing at Max Capacity

Flowing pressure, lb per sq in	Cu ft gas per bbl of oil							
	Burbank 2 900 ft	E Texas 3 600 ft	Seminole 4 000 ft	Corpus Christi 4 100 ft	Lucien 5 200 ft	Okla City 6 500 ft	Turner Valley 7 000 ft	Buckeye 7 900 ft
2 080	.....	.....	.....	.....	.....	.....	40	110
1 500	.....	.....	.....	.....	55	110	144	240
1 000	17	40	70	95	160	290	327	480
800	53	70	123	157	255	430	487	680
600	100	140	230	268	425	690	744	1 080
500	145	200	330	374	572	950	1 000	1 480
400	225	300	480	563	805	1 230	1 300	2 020
300	388	490	750	870	1 310	1 700	2 000	2 660
200	692	930	1 410	1 570	2 370	2 580	3 182	3 850
100	1 810	2 650	3 240	3 580	4 670	6 000	7 900	8 570
50	4 350	5 330	6 190	6 720	9 500	13 000	15 300	18 300

The above quantities are total, including gas associated with the oil and flowing with it into the well; the latter should be deducted to find the quantity to be injected for lifting purposes. Thus, a Seminole well producing at 200 lb flowing press, with 800 cu ft of gas accompanying the oil, requires an input of 1 410 minus 800, or 610 cu ft per bbl (Table 4).

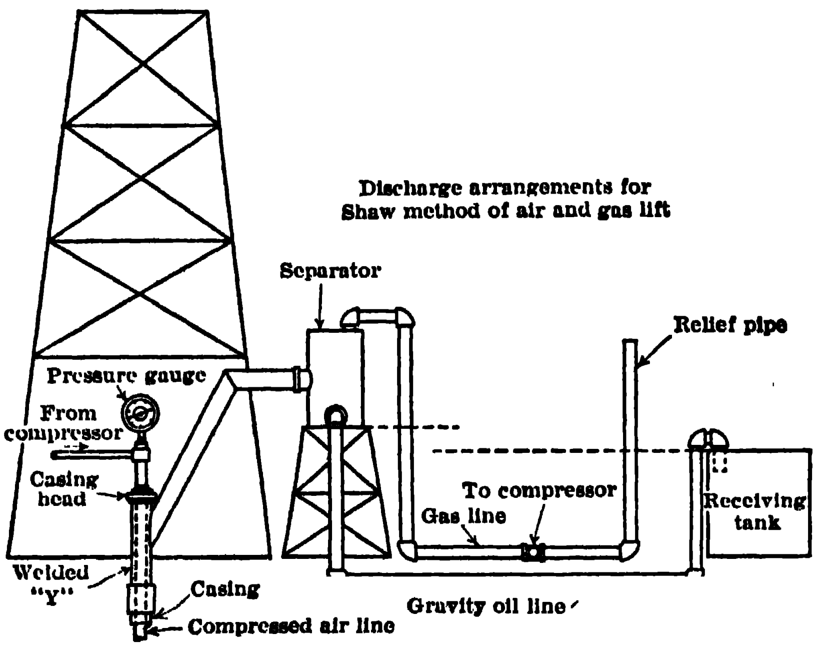

Fig 3. General Layout for Gas-lift

For gas-lift, the capacity of tubing and casing in two fields follows the formula $P = CB^n$, wherein P = flowing press at bottom of tubing, in lb per sq in, B = bbl of oil lifted per 24 hr, and C and n for various sizes of tubing or casing are as follows:

Table 5. Constants in Formula for Capacity of Tubing and Casing

Casing	Tubing	Seminole Field		Okla City Field	
		C	n	C	n
Oil flowed through tubing..........	3-in	10.22	0.465	14.21	0.4722
" " " "	4-in	3.965	0.507	8.018	0.510

8 5/8-in..........................	4-in upset	1.166	0.62	......	......
9-in O D..........................	3-in	......	......	1.479	1.6267
9 5/8-in O D......................	3-in	......	......	1.139	0.625
9 5/8-in O D......................	4-in	......	......	1.525	0.620

Gas for lifting may be supplied from large centrally located plants, from small plants on the individual lease, or from gas wells; the last named furnishes the most satisfactory supply if press and volume are sufficient (22, 23, 24).

"Kick-off" valves are used to start wells on gas-lift, when the press is higher than can conveniently be handled by the gas-line press. They are inserted in couplings in the tubing at intervals of about 300 ft, with the uppermost approx at the static fluid level in the well. When press in the fluid column exceeds that in the gas column by a predetermined amount, the valve opens and allows gas to enter the liquid column, starting it on gas-lift and thus lowering its press at the valve, which then closes. Gas is admitted to the next lower valve, and the liquid blown off. This process continues until the bottom of the tubing is reached, when all valves are closed and the well flows by means of gas entering lower end of the tubing.

Ultimately in most fields, gas will have to be compressed in a plant installed for the purpose. For a number of wells within a 1/2-mile or even 1-mile radius, a central plant effects savings; which may be partly offset, however, by friction loss in pumping gas to the wells, unless large-diam pipe is used (25 to 29).

Table 6. Cost of Compressor Plants in Various Oil Fields

	Total cost	Displacement per day, cu ft
Seminole Field		
Small compressors, electric driven	$ 26 000	2 000 000
" " " "	46 000	4 000 000
" " " "	55 000	6 000 000
90-hp direct-driven gas-engine compressors	80 000	3 600 000
165-hp " " " " "	25 000	1 700 000
165-hp " " " " "	200 000	10 000 000
Oklahoma City Field		
Small compressor, electric driven (used)	12 500	2 000 000
90-hp direct-driven gas-engine compressors (new)	41 000	2 700 000
90-hp " " " " " (used)	23 000	2 700 000
190-hp " " " " " (new)	32 500	2 000 000
165-hp " " " " " (used)	18 000	2 550 000
230-hp " " " " " (new)	83 000	6 700 000
East Texas Field		
Small compressors driven by 50-hp electric motors (used)	2 500	400 000
90-hp direct-driven gas-engine compressors (new)	8 500	600 000
90-hp " " " " " (used)	4 000	500 000

In Seminole field the required compressor capac was about 1 500 000 to 2 000 000 cu ft displacement per day per well, when producing 1 000 bbl or more per day (30). In Okla City field, the displacement per well is as high as 6 000 000 cu ft per day, when producing 12 000 bbl or more, and about 3 000 000 cu ft per day, when pressures have so declined that only 200 bbl can be lifted. To the present time, the allowable 20 bbl per day per well in the East Texas field has made unnecessary the use of large plants for lifting the oil. Compressors often serve only to start the wells flowing, after which they continue on natural flow. In the East Texas field, a gas-lift compressor of 500 000 cu ft per day displacement will serve up to 20 wells, if near the plant, thus making the aver installed cost about $450 per well (31).

Operating costs, not including deprec, of compressor plants in Okla City field are as in accompanying table. Lifting cost of the gas is equal to quantity of gas per bbl of oil, multiplied by cost for 1 000 cu ft. Thus, at Seminole, to lift oil by 100-lb bottom-hole press required a total output consumption of 3 240 cu ft per bbl (Table 4), of which 800 was the aver quantity of formation gas accompanying a bbl of oil, leaving the required input gas at 2 400 cu ft per bbl. At 1¢ per 1 000 cu ft, the lifting cost of gas would be 2.4¢ per bbl.

Plant	Total M cu ft per year	Total operating cost	Cost per 1 000 cu ft gas, cts
A	422 662	$ 8 059	1.91
B	3 150 737	29 025	0.92
C	4 262 661	31 429	0.93
D	3 250 438	33 390	1.02
E	2 039 155	20 300	1.00

Gas-lift without modification is termed "continuous" or "straight" gas-lift; when in connection with auxiliary centrifugal or plunger pumps, a "combination" gas-lift (Art 5); and when gas is admitted to the well at intervals, it is an "intermittent" gas-lift (Art 6).

5. COMBINATION GAS-LIFT METHODS

The gas-lift Reda pump combination method (see Art 7) has thus far been the most successful (32). An electric-driven centrifugal pump, suspended from a string of tubing, is lowered into the well. A "packer" (seal between tubing and casing) is set at 100 to 1 000 ft above bottom of casing, and perforations in the tubing above the packer allow oil to pass through the pump into the casing. Gas pumped down the tubing issues with the oil through the perforations and lifts the oil from packer to surface. Below the packer, the action is strictly that of a centrifugal pump; above, it is that of continuous gas-lift.

Much oil has been raised in Okla City field by this method, even after reservoir pressures declined to 100 lb per sq in or lower, and it operates with reservoir press as low as 25 lb, provided an excessive quantity of sand or gas is not drawn into the pump (33). In a well with reservoir press of 50 lb, completed with 9 5/8-in O D casing and 3-in tubing, a production of 4 500 bbl per day was maintained for some time. Consumption of gas and power for various capac rates in the Okla City field is given in Table 7. The combination Reda pump has been successful in Beebe, Hendricks, Powell, Seminole, and various pools in Kansas, especially where much liquid is handled.

Table 7. Consumption of Gas and Power in Combination Gas-lift Reda Pump

Well	Bbl per month	Input gas				Electrical current			
		Cu ft per month	Cu ft per bbl	Cost per M cu ft, cts	Cost per bbl, cts	Kw-hr per month	Kw-hr per bbl	Cost per kw-hr, cts	Cost per bbl, cts
A	98 390	139 586	1 490	1.35	2.01	59 730	0.61	1.955	1.19
B	50 680	91 967	1 810	0.69	1.25	35 520	0.70	1.75	1.22
C	24 850	55 956	2 250	1.05	2.36	22 520	0.91	1.55	1.41
D	15 030	36 025	2 330	1.02	2.38	13 830	0.92	1.75	1.61

Gas-lift hydraulic-pump combination method has been used in the Okla City field to a limited extent, but enough to indicate its possibilities (34). A Kobe hydraulic pump is attached to end of a section of 4 or 5-in tubing, suspended in the well from 3-in tubing, which is sealed to the casing by a packer usually placed within 500 ft of lower end of casing string. The 3-in tubing (perforated just above the packer) encloses 1 1/4-in tubing, through which "power-oil" is passed to operate the pump, lifting oil from bottom into the casing above the packer; whence gas injected between the 3-in and 1 1/4-in tubing lifts it to surface. In a 6 500-ft well, with reservoir press of about 50 lb, and 9-in casing, this method produced 1 500 bbl or more per day.

Sucker-rod pump in connection with gas-lift. The pump is suspended from 2 1/2 or 3-in tubing, and a packer seals off the well between tubing and casing. Perforations in the tubing above the packer allow injected gas to mix with the oil, thus lifting it to surface. The lowering of press enables the pump to speed up and handle a greater load. This method, employed a short time in the Seminole field, was abandoned because slits were cut in the tubing by sliding of the rods against the tubing. Apparently, gasified oil was less effic as a lubricant than dead oil.

Norod plunger pump. The plunger is driven by a compressed-gas piston pump, lowered on a string of tubing, with packer set between tubing and casing, and the compressed gas passing through the pump joins the oil above the packer, thus raising the oil through the casing.

6. GAS-LIFT, INTERMITTENT FLOW

This type of gas-lift has been employed in several forms, of which 5 are described below (35, 36).

1. Gas entering the tubing lifts oil through the casing without chamber, packer, or valve at bottom of tubing. The gas is admitted intermittently, by manually operated or automatic time-controlled valves at surface (Table 8).

2. A tubing string is run into the well, with a chamber at lower end and a valve at bottom of chamber. A packer is set between casing and tubing, close to lower end of casing. Gas is admitted to the tubing intermittently, thus closing the valve, displacing the oil from the chamber into the casing above the packer, and then lifting it to surface. This is the Clark "bottom-hole intermitter" (Table 9) (37).

3. Gas is admitted to the annular space between tubing and casing, thus forcing the oil through the tubing to surface. No chamber or packer is used (Table 10).

Table 8. Intermittent-flow Gas-lift, Without Auxiliary Devices

Well	Depth	Casing diam, in	Tubing diam, in	Bbl per day	Cu ft input gas per bbl

F	4 308	4	2 1/2	125	7 800
G	4 344	3	1 1/2	45	5 500

4. Two strings of tubing are run concentrically. A chamber, with valve at its lower end, is suspended from the outer string. Smaller tubing extends close to bottom of chamber. Gas is admitted to the annular space between, thus closing the valve at bottom of chamber, driving the oil in the chamber into the inner tubing and lifting it to surface (Table 11).

5. Hughes plunger-lift (Fig 4). A tubing string, reamed to smooth bore, is run into the well. A valved plunger, fitting closely to the tubing, drops to the bottom through the column of oil, and strikes a bumper which closes the plunger valve. The gas admitted to the casing then lifts the plunger to surface through the tubing, with its accumulated load of oil, and drops down for another load (39) (Table 12).

Table 12. Intermittent-flow Operation of Hughes Plunger-lift

Well	Depth	Tubing diam, in	Bbl per day	Cu ft input gas per bbl	Casing press, lb
A	1 829	4	400	465	...
B	3 977	2 1/2	168	....	128
C	3 848	2 1/2	160	323	109
D	3 939	2 1/2	52	280	83
E	4 193	4	84	1 560	32
F	5 159	2 1/2	114	....	71

K	6 231	2 1/2	30	7 150	35
L	6 736	3	140	2 700	108
M	6 800	3	105	1 140	68
N	7 803	4	468	1 645	260
O	8 200	4	250	3 340	300

Formula for capacity of Hughes plunger-lift is $P = CB^n$, where P is the press, lb per sq in at bottom of tubing, and B the bbl of oil lifted per day. Values of constants C and n are given in accompanying table.

Constants in Formula for Capacity of Plunger-lift

Ft depth	Tubing, diam, in	C	n
3 900	2 1/2	2.906	.7408
6 500	2 1/2	4.292	.7738
6 500	3	3.381	.7497
6 500	4	2.085	.7417

Various devices are employed to admit gas intermittently to the well, the usual ones being controlled by a clock mechanism opening and closing a pilot valve, which opens a diaphragm-operated main valve. Another type consists of a cylinder, in which water is displaced by compressed gas from a compartment at one end to another at opposite end, thus causing the cylinder to tip down and open the pilot valve, which in turn operates a diaphragm-valve in the pipe carrying the gas supply. The number of tips per hr is regulated by a valve placed between the two compartments, thus controlling the quantity of water or oil passing in a given time.

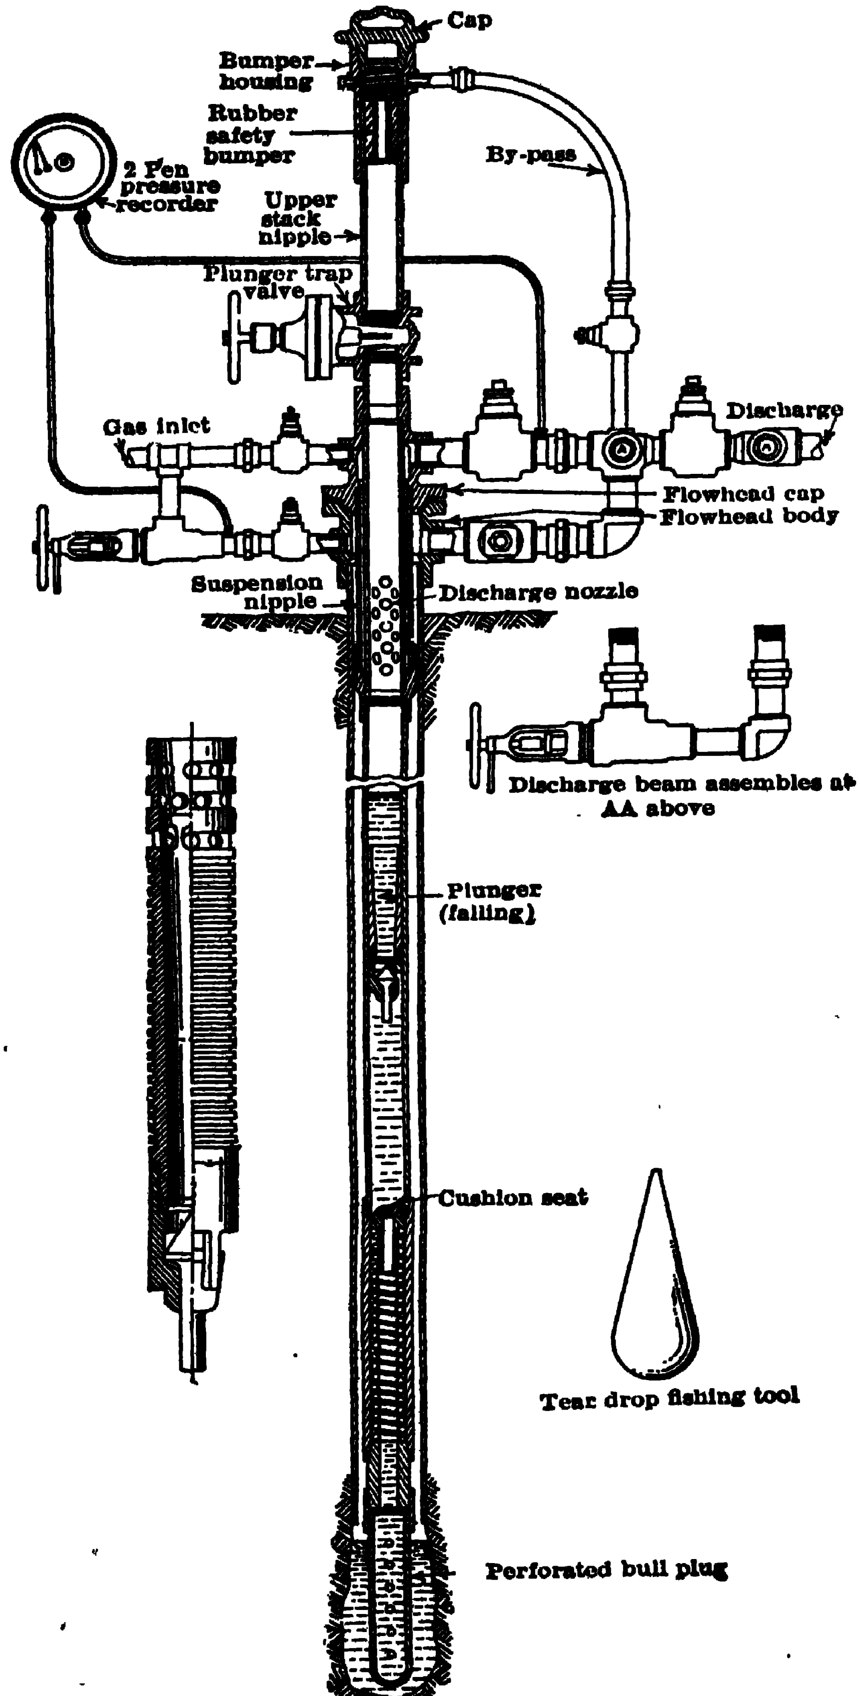

Fig 4. Hughes Plunger-lift

7. CENTRIFUGAL PUMPS

Submerged electric-driven centrifugal pump is used in several fields (Fig 5). In connection with gas-lift it is termed the gas-lift Reda combination method (Art 5); when without gas-lift it is called "straight" Reda pump. The unit consists of a multi-stage centrifugal pump, with the shaft connected directly to an elec motor through a protector section. As the entire assembly is of small outside diam, it can be run to bottom of a well having standard sizes of casing. In operating position the assembly is suspended by standard tubing, submerged in the fluid of the well, with a cable extending to surface, for supplying electricity to motor. Operation of the motor is controlled by a switchboard at surface, having several automatic-control features. In the unit's usual form, the Reda motor is below the pump, but in one type of assembly the pump intake is at the bottom, thus permitting max production from wells of very low fluid level.

The motor is of the squirrel-cage, induction type, operating at 3 600 rpm, and filled with oil for lubrication and cooling. The protector, between motor and pump, contains a spring-backed piston, grease chamber and oil chamber; it equalizes internal and external press and excludes well-fluid from the motor. The pump is a vert assembly of centrifugal impellers and diffusers, enclosed in a steel housing; their number, type and size being determined by the vol of fluid to be raised and the required discharge head. The electric cable is oil proof, unaffected by hydrostatic pressure, steel armored, and flexible enough to permit easy spooling.

The Reda pump is installed by lowering the motor-protector-pump assembly into the well on the tubing like a working barrel, the cable being supported by clamping it to the tubing at intervals. Surface end of cable being attached to switchboard, the pump is ready for work. Reda units now in operation are of 7.5 to 97.5 hp. Largest volume handled is 14 000 bbl per day; the smallest, 18 bbl. The "straight" Reda pump has been largely used in the Okla City field, handling 400 or 500 to 1 200 bbl per day, with an elec consumption of 2 1/2 to 6 1/4 kw-hr per bbl lifted, if no water is mixed with the oil (40, 41) (Table 13).

Table 13. Operation of a "Straight" Reda Centrifugal Pump

Well	Bbl per mo	Total kw-hr	Kw-hr per bbl	Cost of elec current, cts	
				Per kw-hr	Per bbl oil
A	19 300	50 791	2.62	1.72	4.51
B	14 600	48 900	3.34	1.45	4.84
C	7 000	31 850	4.55	1.55	7.05
D	4 620	28 620	6.17	1.75	10.8

8. HYDRAULIC PUMPS

Hydraulic plunger-pumps are coming into use for lifting oil under certain favorable conditions. The most successful thus far is the Kobe (42), a triplex pump mounted on a filter tank and operated by electric motor or multiple-cylinder gas engine (Fig 6).

Table 14. Data on Wells Equipped with Kobe Hydraulic Pump, Oklahoma City

Well	Pump size	Diam tubing		Bbl per day		Pump, speed, r p m	Pump vol effic, %	Kw-hr per bbl fluid	Power cost, ¢ per bbl fluid*

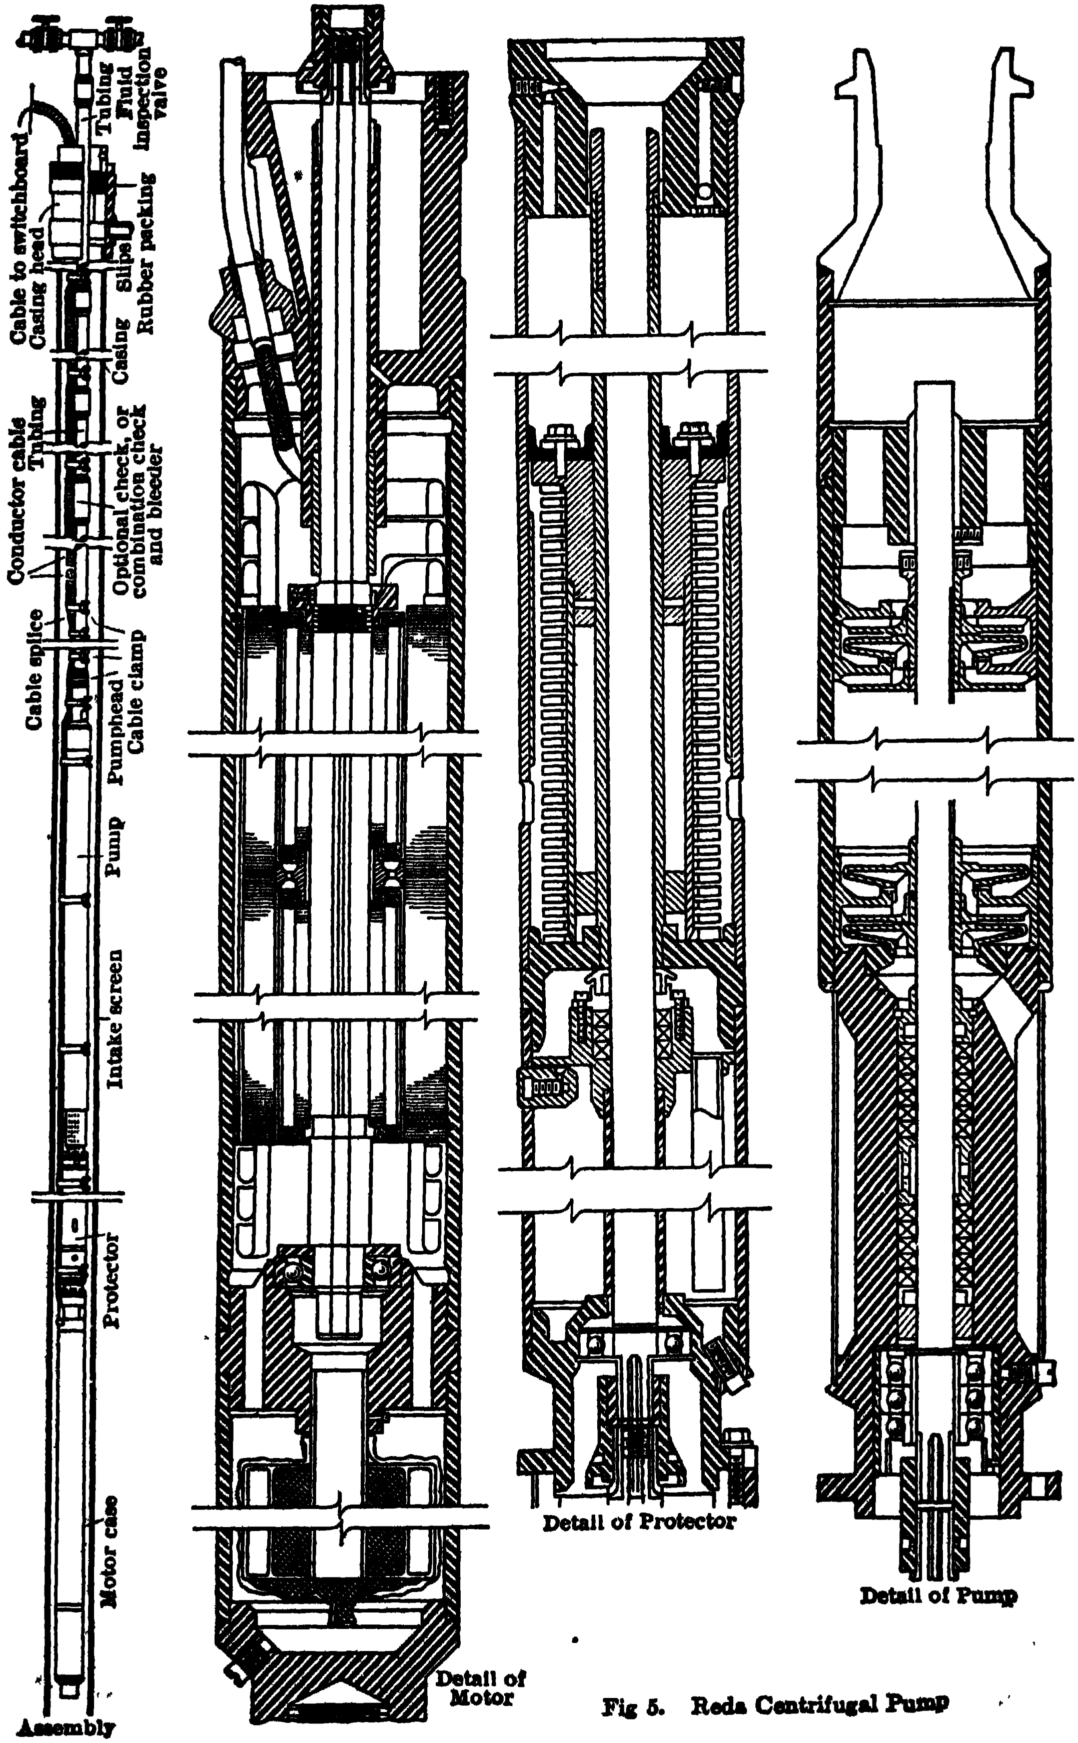

Fig 5. Reda Centrifugal Pump

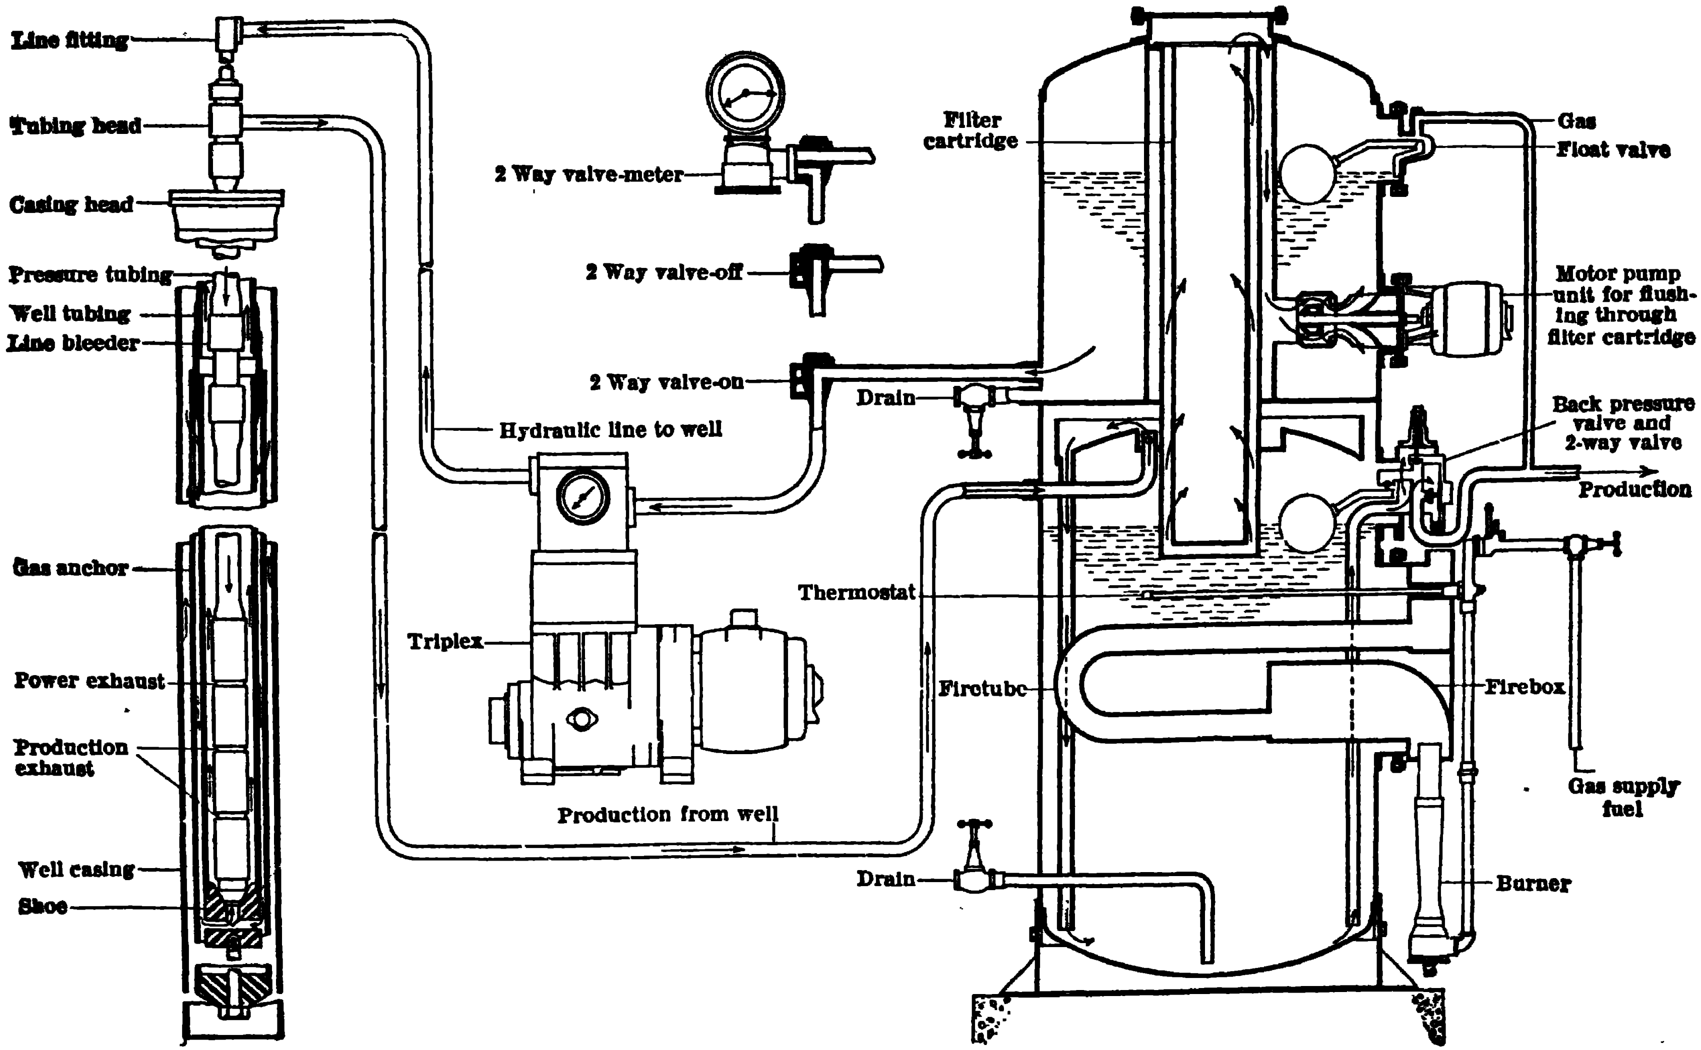

Fig 6. Kobe Hydraulic Pump Layout

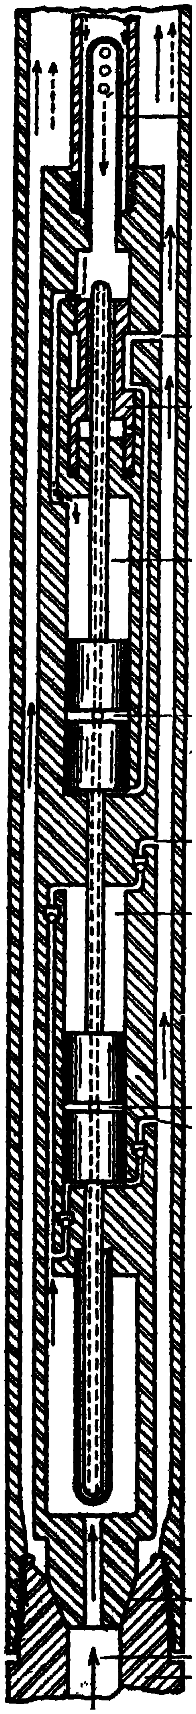

Fig 7. Details of Kobe Hydraulic Pump (see Fig 6)

The bottom-hole Kobe production unit is a double-acting plunger pump connected directly to a fluid engine (Fig 7). The only mechanical connection between the pump and the surface is a string of small-diam tubing, to conduct the power fluid to engine. The surface power unit, supplying fluid under the desired press, consists of a filter-separator system (when required) and a combined prime motor and triplex pump. In equipping a well for this method, a full string of tubing (the "production string") is installed with a gas-anchor and seating device at its lower end. The bottom-hole engine and pump form a single unit, inserted within the production string and run to the bottom on a smaller string (the "pressure string"). The power fluid, conducted down through the pressure tubing, is discharged to surface through the annular space between the two strings, being mixed with the fluid pumped from reservoir.

In the Oklahoma City field the fluid from the well passes through a heater and then to a filter, whence enough filtered oil is returned to the well bottom to actuate the fluid engine. Usually the quantity of power oil is approx the same as that of the oil produced from the well. In this field, when using 3-in tubing with 1 1/4-in inner tubing, the pump has a max capac of 300–400 bbl per day (43). With 4-in tubing and a 2-in inner tubing, the max capac is 700–800 bbl per day (Table 14).

9. SWABBING AND BAILING

Swabbing is often used for lifting oil in the interval between cessation of natural flow and completion of permanent equipment with some artificial lifting method. A close-fitting rubber swab, enclosed in a wire cage on the end of a wire line, is run down into the fluid as far as will provide a safe load for the hoisting equipment to raise. The oil passes through a check valve into the swab, as it is lowered. The valve closes, and the rubber flattens out against the casing or tubing walls, making a fairly tight seal when the swab is lifted. Upper end of swab has a pin-joint connection with the drilling tools, to provide enough weight to carry the swab rapidly down the well and then to sink it into the oil.

This method has been widely used in the Boryslaw field, Poland, for depths to 5 000 ft. There are usually two independent hoists, so that no time is lost if one is disabled. Some wells have 3 engines, two driven by steam, one by elec motor. These installations are rather elaborate, as the lifting speed is high. Sand can be lifted with the swab, but wear is rapid and the rubber must frequently be replaced. The load of oil, especially when mixed with sand, must not be too great to be lifted properly; the casing has sometimes had to be pulled from the well to remove the swab, when frozen in the pipe by the load of sand.

Bailing is sometimes used to lift oil, when accompanied by much sand, as in the Baicoi field, Rumania. The bailer consists of 10 to 40 ft of pipe, of a diam permitting free passage through the casing, and allowing gas to pass freely between casing and bailer. At the lower end of bailer there is a dart-valve,

through which the oil passes when bailer is lowered, and which is seated tightly when being hoisted. Bailers range from 4-in diam to sizes that will pass through casings as large as 14 in.

In the Baicoi field, many holes were very crooked, partly due to movement of sand in the steeply dipping formation, and bailers with flexible joints were used. Oil and sand are dumped from bailer into mine cars, from which the sand is ladled by hand and trammed away. When production at Baicoi declined, thus causing less movement of sand, bailers were replaced by pumping jacks actuated by central power.

Bailing is rarely practicable, due to cost of wire ropes, which must often be replaced, and also to their tendency to wear slits in the casing of a crooked hole. The bailer rope winds on the hoist drum, which is 3 to 5 ft or more in diam. For high speed in deep wells, considerable engine power is required.

10. SUCKER-ROD PUMPS WITH INDIVIDUAL DRIVE

These have been common since the first discovery of oil in the U S. Probably 75% of pumping wells in this country use sucker-rod pumps, and perhaps 60% of the world's oil production is raised by this method. There has been little change in the principle, but great improvements in design and effic of equipment. Stresses on the sucker-rods increase at some geometrical ratio with the depth (21). However, as in the Oklahoma City field where depths of as much as 6 500 ft are reached, sucker-rod pumps often lift 300 bbl per day; sometimes 500 bbl (44).

The sucker-rod pump has a working barrel with hollow plunger, and a standing valve at the lower end of a string of tubing. It is actuated by the sucker rod and contains a traveling valve like the standing valve. The valves are steel balls on metal seats, inclosed in a cage screwed to the seats. The plunger is operated by a rod-line, $^1/_2$–1 in diam, suspended from a walking beam or other device at surface. On up stroke the standing valve opens, allowing fluid to follow the rising piston into the barrel. The traveling valve is shut, causing all fluid above the plunger to be raised. On down stroke, the standing valve shuts and the traveling valve opens, allowing oil in the barrel to pass through the plunger. The pump is actuated by an individual engine, or by a "pumping-jack" driven from a central power plant serving several wells. A few wells have air or steam piston heads, or hydraulic lifts. In many cases, a rod-line may be hitched to an individual walking beam unit, and connected to another well having a pumping jack. As many as 3 or 4 wells have thus been operated.

These pumps are now common. Notwithstanding the heavy press against which they work, and the constant tendency for sand to enter the pump, together with the difficulties due to frequent presence of corrosive liquids and gases, these pumps operate efficiently at the end of a sucker-rod string a mile or more in length (45). INSERT-PUMPS are of such diam that they can be run inside the tubing, so that the tubing need not be pulled if the pump only is to be removed (46). The pump is set on a tight-fitting seat at bottom of the tubing. FLUID-PACKED PUMPS, without a plunger, have two concentric cylinders, one sliding up and down over another close-fitting cyl. They are effective for large volumes of oil and water. CASING PUMPS are used for lifting large volumes against a moderate head. A packer (Art 5) is set on the tubing within the casing near bottom of well, the oil being thus lifted into the casing. Above the packer, the sucker-rod string travels through the casing without use of tubing.

Sucker-rods are of best grade steel or wrought iron; diam from $^1/_2$ or $^3/_4$-in for wells to say 1 000 ft deep, to 1 in for wells of 6 500 or 7 500 ft, like those at Okla City, and some even deeper in Calif. Rods are in lengths of 30, 25, and 20 ft, with box-and-pin joints, and tapered threads to make a tight fit quickly. For very deep wells, 1-in rods are often used to about 2 000 ft; then $^7/_8$- or $^3/_4$-in to the bottom. Too wide a range of tapering is not good practice. Care must be taken to prevent bends or kinks in the rods, and avoid striking them by a heavy blow, which might cause breakage in rods carrying a heavy load (47). Crooked holes are troublesome for sucker-rods. Box-and-pin joints become badly worn and subject to frequent breakage. This can be partly overcome by using sucker-rod protectors, but most operators depend on case-hardened joints to effect a minimum of galling.

"Polish rod" is the connecting link between the pumping jack, or walking beam, and the string of sucker-rods. It passes through a stuffing box in the top of the tubing, to its connection with the sucker-rod string.

Tubing is usually 2 or 2 $^1/_2$ in diam, though some wells use tubing of 3 in or more for large-scale pumping. For small production in shallow wells the tubing is 1 $^1/_2$ or 2 in; 2 $^1/_2$ in tubing has been used for greatest depths thus far reached. In shallow wells standard couplings can be used; for depths of 3 000 to 6 000 ft or more, the ends of the tubing lengths are upset to strengthen the

threaded coupling and lessen danger of breakage, especially when the string is being pulled from a hole in which sand or debris has caved around the tubing (48).

Gas anchors are attached to lower end of tubing in gassy wells, to allow gas to dissociate from the oil, so far as possible, before it enters the working barrel. The anchor surrounds the barrel, the oil passing through perforations in upper part of the anchor, then downward to the pump intake. Gas thus separated passes out of the anchor into the casing and then escapes through the casing head. Gas collecting in the working barrel, especially in a pump having considerable clearance between the standing and traveling valves, tends alternately to expand and compress, thus reducing the pump's capacity.

Gas anchors should be designed with care; they are commonly more harmful than beneficial, due to faulty design or application. Mere length beyond 5 or 6 ft has no advantage, unless space for a sand trap is required. Constrictions in line of flow through the anchor should be avoided, as consequent press drop due to frictional resistance tends to bring gas out of solution. The anchor must not have protuberances nor a large diam, which might cause difficulty in pulling out of the well. In low-fluid-level wells, it is desirable to place the anchor around the working barrel, rather than below it, to obtain the effic resulting from max submergence.

Tubing-catchers usually accompany long strings of tubing, to prevent the string from dropping to the bottom if accidentally released while being run down, or if the tubing parts. Upset tubing is now common for deep wells, to reduce danger of parting, but it is best practice to use tubing catchers on all strings in deep pumping wells, as the full weight of the column of oil and that of the tubing must be sustained by the string.

Tubing anchors are sometimes used in deep wells, especially if crooked, when there is a tendency for the tubing string to creep up and down with the sucker-rod strokes, or if sand lodges between the plunger and working barrel, thus freezing them together. This creeping action wears the tubing collars and casing walls. Anchors are set about 1 000 to 1 500 ft above lower end of tubing, to prevent the tubing from creeping lower. Though not always effective, many operators favor them.

Prime movers for pumping are of many makes and designs, comprising steam, gas, gasolene and oil engines, and elec motors (49). Steam engines were formerly common, the usual fuel being oil or gas obtained from the property. At present, steam is generally limited to cases where the drilling engine is retained only until the well is thoroughly tested; then if it proves profitable, more effic equipment is substituted. Gas engines are the commonest, the fuel being nearly always available from the well at no cost. They comprise slow-motion horiz, 2-cycle engines of 10 to 90 hp; vert 2- or 3-cylinder, 2-cycle engines up to 60 hp, working at 300 to 600 rpm; and multiple-cylinder 4-cycle engines to 80 hp at speeds of 600 to 1 800 rpm (50). Slow speed 2-cycle horiz engines, as the Bessemer, Fairbanks-Morse, Frick-Reid, Superior, Titusville, and Weber, have had wide use. Vert 2-cycle engines at 300 to 600 rpm, which came in during 1936, include the Cooper-Bessemer, Clark Bros, Fairbanks-Morse, Superior, Weber, and others. Multiple-cyl 4-cycle engines have been used for several years, the best-known being the Buda, Case, Caterpillar, Climax, Hercules, International, and Waukesha. OIL ENGINES are seldom used except where gas is very scarce (51). ELEC MOTORS are widely and increasingly used, despite the fact that elec power must generally be purchased. Facility in starting and stopping motor-driven pumps has much in their favor, and lost time caused by engine trouble is minimized. First cost is usually larger than with other types of drive.

As the engine speed is never that at which the walking-beam travels, there must be a reduction in speed, for which the band-wheel is commonly used. Between band-wheel and engine pulley there is a counter shaft and pulleys. If the engine serves other wells also, the counter shaft has a reversible clutch. At one end of the band-wheel shaft is a crank with several holes, so that the pitman can provide the desired length of stroke to the walking beam. Also, at one side of the band-wheel, there is a grooved pulley over which a manila rope runs to the bull-wheel. (For details see Sec 9.) Reduction-gear units were recently introduced in place of the band-wheel (52). Some have a grooved pulley and rope for driving the bull-wheel; or the grooved pulley and bull-wheel are replaced by a portable pulling unit. Reduction units are made by the Continental Supply Co, Foote Co, Lufkin Foundry, National Supply Co, Oil Center Supply Co, Oil Well Supply Co, and others. They are generally used with multiple-cyl engine, or electric motor (53). Flat belts have been used, but the present tendency toward the V-belt drive, between motors or multiple cylinder engines and the reduction unit, is preferable.

Walking beams are usually of steel (Sec 9, Art 5).

Counter-balances of various types are used to balance the weight of sucker-rods and column of oil. The "grasshopper" type is common; also pieces of cast-iron, bolted to the reduction unit crank, or to the opposite side of crank arm on band-wheel shaft. Proper balancing is important for uniform loading on the engine, and the most effic filling

of the working barrel with oil (54). Several types of hangers are used to obtain a vert pull on the "polish rod," from which the sucker-rods are suspended, the movements of the beam being varied for same purpose. The Parkersburg long-stroke unit imparts a vert motion by toggles attached to the beam.

Miscellaneous parts. Cushions are used to dampen the strain on the polish rods at end of stroke; sucker-rod rotators, for turning polish-rod and sucker-rods a certain number of degrees at each stroke, to cause uniform wear on the rods at boxes, and prevent the plunger from wearing along one side; wobbler stuffing-boxes, sometimes used where the polish rod enters the tubing, to take up irregularities in the motion and thus prevent side movement of the casing head. GARBUTT RODS, inserted in the plunger, make contact with the standing valve-cage when the rods, plunger and standing valve are pulled, but are not practical where the oil is grassy or must be pumped at high speed, owing to the danger of overtravel which might cause the rods to strike the standing valve-cage. Double-ball traveling valves are used to reduce wear and gas-locking, and to distribute better the load pressure.

Portable servicing units are used when rods or tubing must be pulled, or other work done. They comprise hoisting facilities for greater speed than is obtainable with an ordinary pumping outfit. But, if frequent pulling jobs are necessary in a deep well, it may be better to install a special hoist than to risk loss of considerable production while awaiting arrival of a portable outfit.

Costs. In the Okla City field, most wells employ portable units, built in sizes costing up to $15 000 or more. A walking-beam outfit, including a self-servicing hoist, costs $1 000 for a shallow well, to $15 000 for a 6 500-ft well. For a 6 500-ft well, pumping units driven by small, vert, medium-speed gas engines, cost installed about $10 000.

Cost of a steam-engine, walking-beam pump in the Coalinga field, Calif (55) is: engine, 23-hp complete, $296.09; boiler, 40 hp, $473; boiler connections $116.15; engine house, concrete foundations, lumber and labor, $66.80; total $952.04.

Cost of gas-engine outfit for a pumping well in the Midway-Sunset field is: engine, with pipe and fittings, $2 025; circulating tank, 50 bbl, $170; cement $45; labor, including foundations, hauling and setting engine, $155; miscell, 5%, $119.75; total $2 514.75.

Aver cost for equipping 367 wells in Mid-Continent field: gas engine, 35 hp, $1 950; foundations and floor, 16 cu ft at $35, $560; connecting and erecting $200; water tank, setting up and grading, $165; gas and water pipe, 800 ft at 35¢ per ft, $280; total $3 155.

Aver cost for equipping 241 wells with elec motor: motor and control $1 355; foundations and floor, 8 cu yd, at $35, $280; transformers, switches, etc, $275; electric lines $120; connecting and erecting $100; turbo gear, ratio 5 to 1, $775; flexible couplings $175; shaft, pulley and bearings $100; total $3 175.

Cost of installing a walking-beam pump unit in Okla City field in 6 500-ft well: pumping unit $4 400; vert, 2-cyl, 2-cycle gas engine, $1 700; house $280; foundations $150; installation, labor, and hauling $500; pipe $100; fittings $200; belting $95; gas regulator $20; pulling winch $90; guards $75; platform $25; stuffing box $10; polish rod $10; polish-rod grips $20; pump $300; gas anchor $10; gas cleaner $10; sucker rods $1 300; water tank $125; total $9 410.

A self-servicing pumping outfit, comprising a 75-hp horiz 2-cycle gas engine, with clutch, geared pumping unit, steel walking beam, bull-wheel, pump, and rods, installed in a 6 500-ft well, costs approx $15 000.

Capacity of sucker-rod pumps depends on diam of working barrel, length and speed of stroke, clearance in working barrel, and other smaller factors (56). Speed of stroke can be increased in shallow wells, as there is not enough friction between rods and tubing to prevent the sucker-rod string from dropping back rapidly on down stroke. Large-diam pumps can be used in shallow wells, capable of a large production. Speed in shallow wells is 10 to 30 strokes per min; length of stroke, 6 to 48 in. Number of strokes in deep wells: 10 to 25 per min; length of stroke, 36 to 132 in.

Tubing in shallow wells is usually of smaller diam than in deep wells, as there is less friction loss in a short length of pipe. After natural flow ceases, shallow wells usually require a pump of small capac. In 2 000-ft wells, a 4-in pump suspended on 5 1/2-in casing-string lifted about 2 000 bbl of fluid per day, but breakages of moving parts were excessive. Capacities of shallow wells range from almost zero to 2 000 bbl per day. In deep wells, as in Okla City field, the capac varies from say 10 bbl per day (the lowest limit economical to pump) to 500 bbl; aver, between 100 and 200 bbl per day (57).

Space between standing and traveling valves should be as small as possible, to minimize accumulation of gas between the valves. The valves should be spaced after the well pumps up, due to tendency toward excessive overtravel at that time; if their proper position has been previously determined, the well should be pumped slowly to prevent pounding down. GAS-LOCKING, which causes low effic (58), is reduced by close spacing;

by proper design of pump to give the least possible space between the standing and plunger valves; by minimizing all constrictions, bends, and small diameters in the stream ahead of the traveling valve; by obtaining the max ratio between stroke of pump and pump clearance; by using oversize valves or multiple valves; and by obtaining the max submergence. OVER-STROKING is caused by inertia of the sucker-rod string and is affected by speed and length of stroke, and weight of the rods. Overstroking may be beneficial, if the barrel is long enough to prevent pounding down. It is increased when there is no oil in the tubing, or by using heavy rods, or by reducing the friction loss with large-diam tubing, or by faster stroking. For a given "polish-rod" displacement, a long, slow stroke gives less overstroke than a fast short stroke. SUBMERGENCE of a pump should be as large as possible; thereby greatly increasing its capac (59). The amount of submergence can often be ascertained by closing in the casing to different back pressures, and observing the production made under these conditions. DYNAMOMETERS are used to determine the load on the sucker-rod string throughout the stroke. By observing the chart of a dynamometer test, many pump troubles can be discovered and corrected (60).

STEELS of various alloy are used for rods, pump, etc, depending on the prevailing conditions. For ordinary strength and minimum corrosion, manganese steel generally suffices. When extra strength is required, chrome and nickel steels are used; for very corrosive conditions, wrought iron, chrome, and galvanized steel.

11. SUCKER-ROD PUMPS DRIVEN FROM CENTRAL POWER PLANT

In groups of wells, connected to a central power plant, the pump is operated by an engine or elec motor (see Art 10). The engine is usually belt-connected to a band-wheel, carrying one or more eccentrics from which transmission lines, or "pull-," or "shackle-rod," run to the different wells (61). A counter-shaft, with friction clutch, is usually interposed between engine and band-wheel belt. From one to 40 shallow wells can thus be operated. The pull-lines are usually $^1/_2$ to $^3/_4$-in steel rods, which are preferable to wire rope, as they stretch less; discarded sucker-rods are also often used. The pull-lines

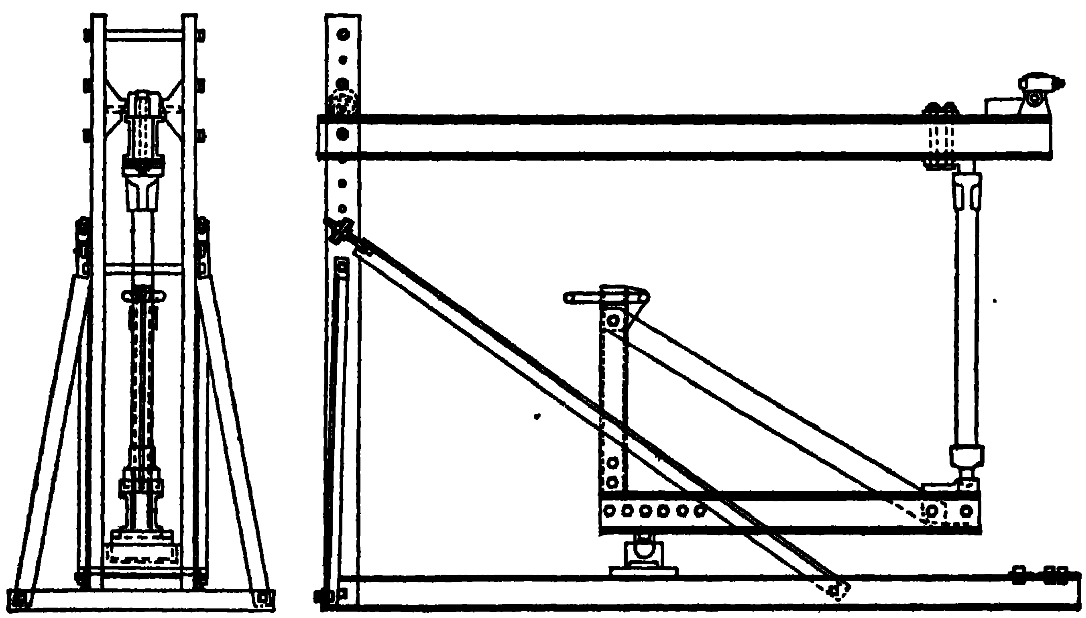

Fig 8. Oklahoma Pumping Jack. (Permission of National Supply Co)

are best run on rollers or guides. Various types of angle turns, rockers, or swings are used for changing direction of a line, to avoid objects that can not readily be removed; such turns may also afford a better balance for the band-wheel.

Pumping jacks above the well operate the sucker-rod string through the pull-rod line (62). The jacks in common use are the Oklahoma (Fig 8) and the Jones and Hammond (Fig 9). Speed of stroke, 10 to 20 per min; length of stroke, which is 12 to 24 in, can be adjusted by changing the hook-up of the rod-line in the pumping-jack frame. In these two types of jack a vert pull is rare, because of the short stroke; but is sometimes made by a "mule-head," where the polish-rod is attached to the jack. Special forms of

jacks, made by Jensen Bros, National Supply Co, and others, are substantially built, and cause a vert pull on the Polish rod.

Sullivan pumping head is a special form of sucker-rod pump, having a single-acting cylinder, suspended in the derrick by pull-rods, the piston-rod being attached to the sucker-rods. The piston, actuated by compressed air or gas, imparts a straight-line reciprocating motion to the rods. Intake air or gas lifts the rods and fluid, forcing the piston upward. Then the valve mechanism reverses and sufficient discharge press is maintained to support the load during the down-stroke.

The unit comprises the compressor, heater, and pump-head. For installations having an individual or central compressor plant, the discharge from the pump-head is piped back to the compressor intake, giving a low-compression ratio and resultant low-compression hp (63). Throughout

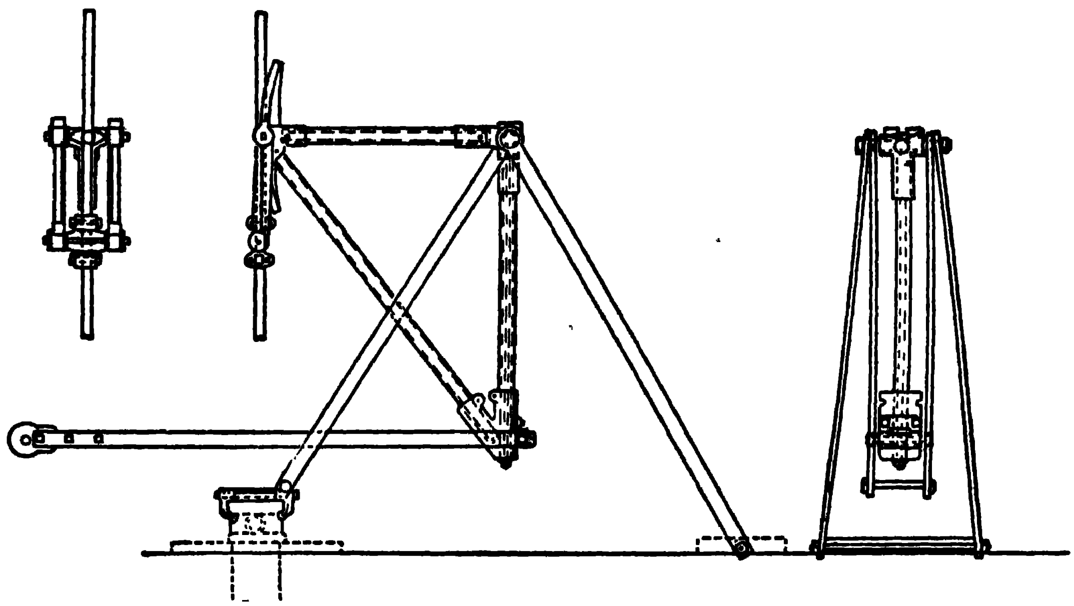

Fig 9. Jones & Hammond Pumping Jack (Permission of National Supply Co)

the entire cycle, the sucker-rod is protected by a cushion of compressed air or gas. The Sullivan head, used in Ill, Mich, Okla, Tex, and elsewhere, gives good service (64). Several in the Okla City field have pumped at depth of 6 500 ft for the past 3 years, the equipment cost, not including the compressor, being about $3 900.

Simple steam-heads are sometimes used, but waste power unless the steam lines are well insulated and freezing at the exhaust prevented in winter. The head may be driven by compressed air, if it can be supplied at low cost. Tendency to freeze is lessened, but not entirely eliminated, due to moisture in the compressor intake air. These heads have been used for years in the Bradford, Penn, field.

12. REPRESSURING WITH AIR OR GAS

Advantage of repressuring a depleted oil field with compressed air was discovered by Dunn and Smith in 1911, when compressed air was injected into a well in Ohio. On reopening the well after a time, considerable oil was raised by the escaping air. This experiment was followed by injecting gas into an input well, and allowing it to find its way through the sand to a producing well; resulting in increased production. The method then spread through Ill (65), Ohio, Penn (66, 67) and W Va, but was not applied in the Mid-Continent and other producing areas until about 1924 (68). It was successful also in certain shallow fields in Kansas and Okla (69) between 1926 and 1930, and has since spread to most oil-producing districts of the world.

Factors entering into repressuring. No definite procedure for all cases has yet been developed. Some operators inject the gas down the dip; others at the upper part of the structure; still others arrange the input wells in patterns distributed through the area to be repressured. Data as to whether a given area has been depleted, or enough oil remains to warrant repressuring, are obtainable by drilling new wells between the old ones, coring the sand, and finding the degree of oil saturation in the areas between wells. Porosity of the sand is important for determining whether the gas will permeate readily

or not. Uniform porosity and sand thickness are generally favorable for repressuring, but presence of much water is unfavorable (70). In fields where repressuring has given good results, there has been a definite increase in both daily production and ultimate recovery (Fig 10).

Old wells used as intake wells present no difficulties in some fields, while in others it is better to drill new wells. To use an old well for intake, the casing should be tight, to prevent escape of gas into sands other than those being repressured. As the deeper sands have usually been under

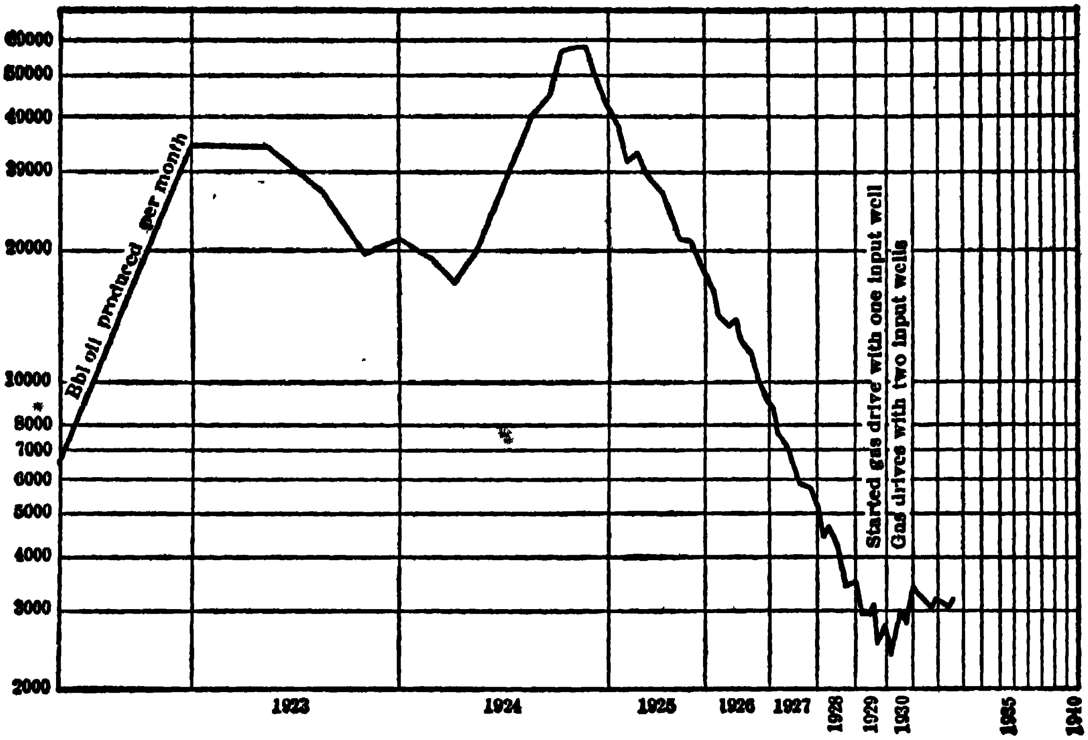

Fig 10. Effect of Gas Drive (Repressuring) in the Burbank Pool, Okla

higher initial press, larger wells are generally found at these greater depths, and the recovery percentage by primary methods is greater than in shallow sands. Hence, it is reasonable to expect less favorable results from repressuring deep wells than shallow ones. If the recycled gas contains much gasolene, its extraction may go far toward paying for repressuring.

Compressed air or gas is used for repressuring. Compressed gas makes less emulsion, if water has encroached, and insures a fuel supply for the engines, uncontaminated by air and less liable to contain explosive mixtures. But, as air dissolves in oil less readily than in gas, it may have a better driving effect.

Pressures employed in different fields range from 50 to 500 lb per sq in; perhaps 200 lb is a fair aver. But in maintenance operations, the press may reach 1 500 lb, as at Sugarland, Texas, or 3 000 lb or more, as in the Tepetate field, La (13), though these do not present the type of repressuring considered here.

* Indicates vacuum, in of mercury.

Volume of gas for repressuring depends upon several factors, that can seldom be determined quantitatively until actual operations have been under way for some time.

If the oil sand is thick, and much gas has been removed during the flush stage of production, the reservoir must often be flooded with a large vol of gas before any results are obtained. If the sand has low permeability, the vol required may be less, but with a higher injection press (Table 16).

For pressures to 50 or 75 lb per sq in, single-stage compression can be used, if intake press is not less than atmospheric. For press to 300 lb, 2-stage compression is usual; above 300 lb, and if the plant is to operate several years, 3-stage compression gives lower costs. With 3-stage at 300 lb, operating effic increases about 7 1/2% over that of 2-stage, and effic increases with the discharge press.

Cost question for repressuring is important. To handle gas at high press, equipment and operating costs are both greater, thus increasing cost per bbl of oil. Hence, pipe lines on surface and in the well must be designed to minimize friction losses. Compressing gas for repressuring costs 1/2¢ to 10¢ per 1 000 cu ft, depending upon size of plant, operating press, and kind of power for the compressors. To compress 25 000 000 cu ft of gas per day to 300 lb per sq in, operating costs are about 1/2¢ per 1 000 cu ft, assuming that gas engines are employed and fuel gas is available on the property at no cost, as is often the case in oil fields. For a plant handling 1 000 000 cu ft per day at 300 lb and with fuel gas at no cost, operating costs will be about 2¢ per 1 000 cu ft (72). If electric power is purchased, the first cost for machinery will be considerably less than for internal-combustion engines, and plant upkeep will be less than for gas or oil engines; but cost of electric power will range from 3¢ to 5¢ per 1 000 cu ft of gas compressed to 300 lb (Table 18).

13. WATER FLOODING OF OIL SANDS

This is being employed for secondary recovery in a few fields of the U S, where profitable production by other methods has almost ceased. So far as known, this method was first used at Bradford, Penna, where it has had its greatest success, and where its usefulness is supposed to have begun accidentally, due to water breaking into nearly exhausted areas, thus unexpectedly increasing the output. The method consists in forcing water

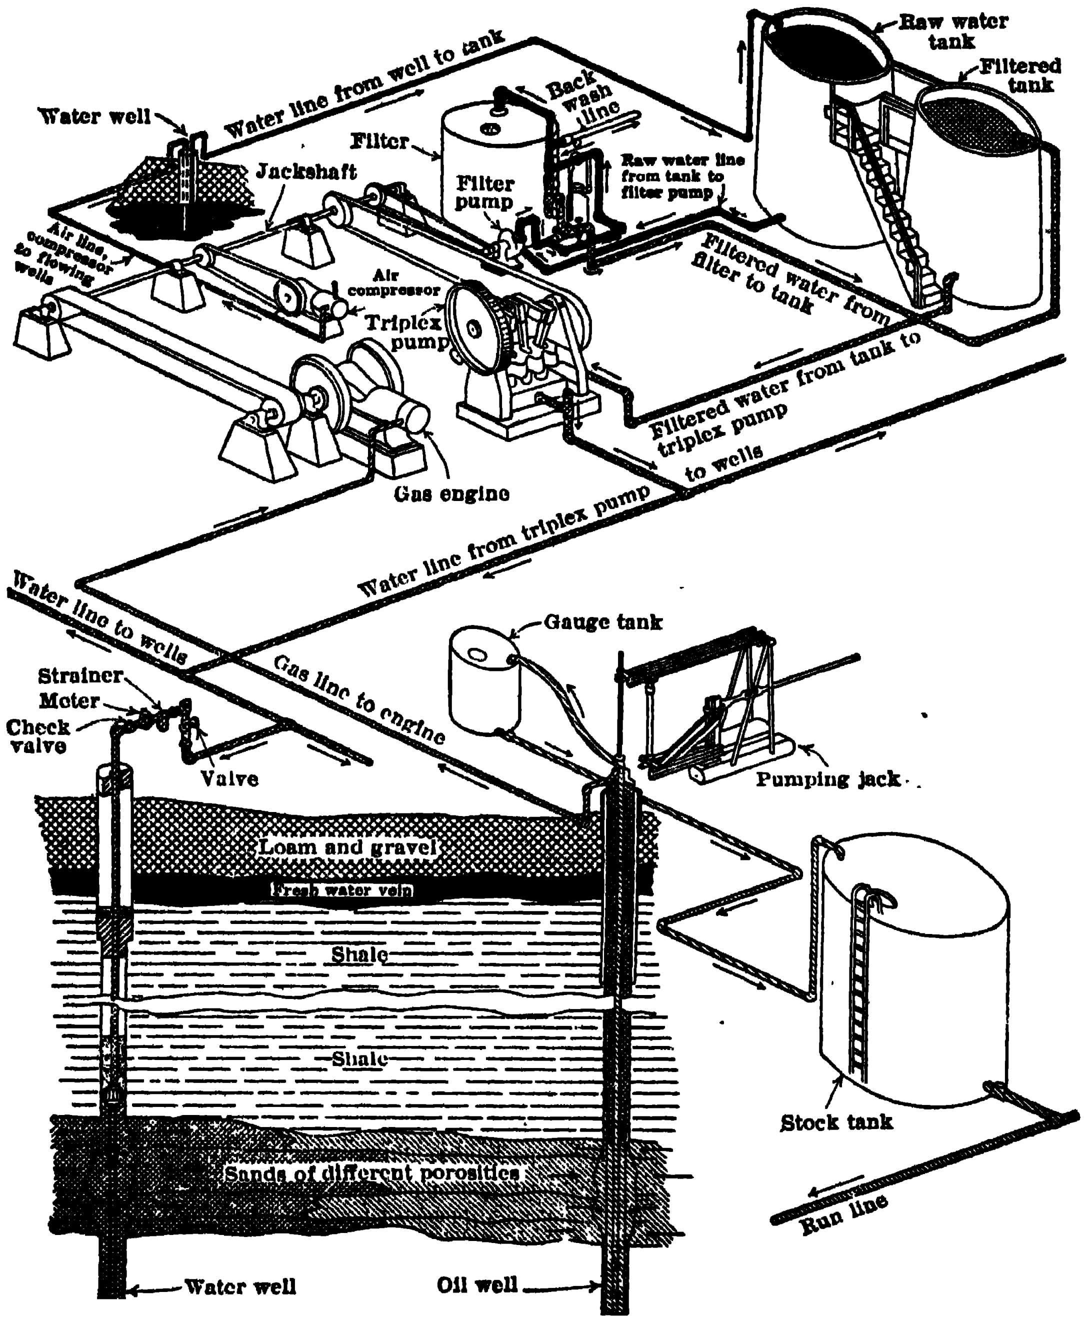

Fig 11. Water-flood Layout in Pennsylvania (Permission of *The Oil Weekly*)

into the oil sand, to drive the oil to a producing well, where it is lifted to surface (Fig 11). Flooding was introduced into the Nowata area, Okla, in 1931, by Bert-Collins and the Carter Oil Co, by whom tests were made near Chelsea. Since 1935 tests elsewhere in that area have produced good results.

Modes of flooding oil sands in the Bradford field are: (1) circle-flood; (2) line-flood; (3) 4-spot; (4) 5-spot; (5) 7-spot (73). The circle-flood might be termed a hit-and-miss

method, as it consists in injecting water into a well selected almost at random, which is surrounded by oil-producing wells, without any systematic procedure; but it can be developed into one of the other methods by spacing the water wells at regular intervals. After finding that production could be thus increased, a study of the factors involved indicated that a systematic arrangement would better serve the purpose. The next step was the line-flood, in which water wells were drilled in a line below the oil wells. The water, introduced in measured quantities, moves up the slope through the sand, pushing the oil into the oil wells, from which it is pumped. When the flood reaches the oil wells, another line of water wells is drilled and process continued until the field is depleted.

Probably the most common method is the 5-spot, as it conforms best to property lines. When a series of 5-spot wells are laid out, they develop into line-floods. As a rule, the sands are quite compact, and permeable in only a low degree; hence, the flood advances slowly, sometimes not more than 50 to 100 ft in a year, unless large volumes of water under high press are pumped into the wells.

In adopting water-flooding a careful investigation of the conditions in the oil sands must be made, to determine the chances of success. Conditions tending to success (74) are where: (1) the oil sand is a continuous, uniform body; (2) porosity is not less than 7% (at Bradford, it is about 11 1/2%); (3) permeability is such that the water will advance through the sand uniformly, and the oil move ahead of the waterflood and not be impeded by too great irregularities in sand conditions; (4) flood can begin at a point low on the structure and move up the dip; (5) flood can move from thin to thick sand sections, if there be such variations; (6) there is little water in the reservoir to be flooded; (7) there is no gas stratum depleted of its gas content, and into which the water would enter. In such case the gas sand must be packed off before the flood is started; (8) the initial gas-oil ratio has not been unusually high, which might indicate that relatively little water would be required to fill the spaces once occupied by gas. If much gas is associated with the oil, there is a fair chance that the oil has been largely extracted by movement of gas toward the producing wells; (9) oils of low viscosity move ahead of the water-flood more freely than those of high viscosity, which have greater resistance to displacement; (10) oils not forming permanent emulsions act better in water-flooding than others. The cost of breaking down permanent emulsions may be serious; (11) an ample water supply is necessary for flooding, obtained from a source containing no dirt or salts that would clog the sands. Dirty water must be settled, or filtered, and salts removed, especially if they precipitate and thus impede the flow.

Water-intake wells are prepared by drilling and shooting the sand, to reduce movement of water from the well into the sand. In the Bradford field, 2-in tubing is usual, packed off and the packer cemented in place. The water injected is measured, and a continuous, permanent record kept of the quantity injected through each well. It is usually distributed to the wells by vert triplex pumps; sometimes by centrifugals.

Delayed drilling is sometimes more satisfactory than repressuring. The water wells are drilled in the pattern deemed advisable, and water is pumped into them until the oil is forced into the area of the oil wells to be drilled. Wells may flow naturally for a time, so that enough recoverable oil is extracted by flowing to make unnecessary the use of lifting equipment. This method has shown a recovery as much as 20% greater than with ordinary water-flooding (75).

Back-pressuring has been employed in water-flooding to prevent so high a rate of production as to lower the press to the point requiring lifting equipment. With back-pressuring, oil is extracted more slowly, the output peak being delayed.

For profitable operation in the Bradford field, Penna, the minimum quantity of oil that must be recovered, besides cost of leasehold, is 3 000 to 3 500 bbl per acre. In the Mid-Continent, 6 000 to 7 000 bbl per acre should be recovered to insure profit, unless the wells are very shallow, thus giving low development cost. Natural flow and pumping in the Bradford field are said to have recovered about 35% of the contents of the reservoir, and water-drive accounts for an added 25 to 35%.

In Cody's Bluff field, Nowata Co, Okla, oil wells are spaced at one per 2 1/2 acres, with water wells on 5-spot patterns, which means another set of wells on basis of one well to 2 1/2 acres. This is close spacing as compared with practice in deeper sands, but seems necessary here for satisfactory recovery (76). Delayed drilling of 45 to 75 days is being done at Cody's Bluff in the Bartlesville sand, at depth of about 500 ft, and sand thickness of 40 to 50 ft. The water is treated and filtered before use (77).

Cost of preparation for water-flooding in Penna is about $3 000 per acre (78). Pressures for pumping the water reach 1 600 lb per sq in. The water is treated before pumping into the sand. One lease of 160 acres, making 40 bbl per day, was increased to 3 000 bbl per day by applying flooding.

14. PETROLEUM MINING

Ordinary mining methods were applied to production of petroleum long before the present-day practice of drilling wells. Shafts were sunk or tunnels driven into the oil-bearing strata, or along outcrops and surface seepages. The oil was collected in pits, or skimmed from underground pools of water. This procedure has been followed for many years in Rumania, Russia, Burma, Japan and elsewhere.

In ancient times, oil mining accounted for most of the total production; now, only a very small percentage is so obtained. Underground mining methods are still employed in the Pechelbron field, Alsace (79, 80), at Wietse, Germany (81), and in Canada and Texas.

According to recent data, the total production at Pechelbron is about 520 000 bbl per year, of which 230 000 bbl are recovered by mining. In 3 mines of the district there are 6 shafts, 495 to 775 ft deep, with some 90 miles of underground workings. Other data show that about 17% of the Pechelbron oil comes from borings from the surface, 43% from drainage of oil into mine drifts, and much of the remaining 40% is recoverable when the sands are finally hoisted out and washed. Similar practice is followed at Wietse.

At Bustenari, Rumania, 3-ft diam shafts have been sunk by hand to oil-bearing sands, at depths of 200 to 800 ft. On reaching sand, small holes are drilled ahead from the shaft to locate bodies of oil, gas or water, thus averting danger to the miners from sudden inrushes.

In the Nacodgoches field, Tex, oil is mined through shafts, 6 by 7 ft section. Good showings were found in one shaft at 60 to 70 ft depth. Another shaft has recently been sunk to 225 ft to an expected oil sand (82).

Ranney process (83). A shaft is sunk to rock, either above or below the oil sand, and cross-cuts are driven at regular intervals. In holes drilled from the cross-cuts to the sand, pipes are inserted to convey the oil to a central point, whence it is pumped to surface. Through other holes compressed air or gas is injected into the sand, to force the oil into the oil pipes.

15. TREATMENT OF OIL

Following is a very brief summary. Oil containing no water or gritty matter can usually go direct to the purchasing pipe-line company; hence, called "clean pipe-line oil." Sand accompanying the oil, especially if fine, must be removed to the degree where oil is acceptable to the pipe-line company. In certain fields of Rumania, the oil contains so much sand that it is discharged at the well into mine cars for settling, the sand being conveyed by other cars to the dump. Often the oil is run to a series of connecting pits, the sand settling out as it flows through them. Thick viscous oil tends to retain sand or rock particles, and requires considerable time for settling. In the U S it is settled in large pits; or, if very heavy, it must be heated, or diluted, to remove sand.

Emulsification of the oil usually follows entrance of water into the well. Emulsions may form while flowing through the sand; by leakage of water and oil through valves; or by flowing through restricted passages, as flow nipples and sharp turns. Emulsions due to low water percentages (10% or less) present more serious treatment problems than high water percentages; also, low-gravity oils are usually more difficult to treat than high-gravity.

Emulsified oil is treated by heating, chemical or mechanical means, or electrical dehydration (84). Heat is a factor in most methods. Unless the liquid from the well is already at 100° to 150° F (as in some Gulf Coast fields), it is heated: (*a*) while flowed through a boiler; (*b*) by mixture with hot water in a tank under thermostatic control; or (*c*) heated in a flow-treater, where separation takes place. To the hot liquid, flowed to a "gun-barrel" or treatment tank, a small quantity of treatment compound is added, such as "Breaxit," "De-Hydro," "Tret-O-Lite" or "Vez," causing separation. Clean oil overflows to the stock tank and thence goes to pipe-line; water is siphoned (at a rate to maintain fairly constant tank level) from the bottom of the gun-barrel tank to a settling pond, where any oil or basic sediment contained is caught and pumped back, the clear water being discarded or (if used for heating) returned so far as needed to circulation (86).

Cost of a treatment plant in the East Texas field, using a 750-bbl gun-barrel tank, 24 ft high, with capac of 40 to 80 bbl per hr, is as follows (87): 750-bbl steel tank gun-barrel $1 083.65; heating boiler $500; centrifugal circulation pump, electric-driven, capac 80 bbl per hr against 40 ft head, $138; connections and fittings $409; labor $219; teaming and trucking $78.80; gas regulator and thermostat $76.70; total $2 505.15.

A recent development in treating oil is the use of special "flow treaters," through which the emulsified oil passes. In these, constant heat is maintained by gas-fired burners set within the treater shell, and under thermostatic control. Discharge of water, oil, and gas from the flow-treater is controlled by pilot-operated diaphragm valves, and fluid-level

control-valves. Exceptionally clean separation is thus obtained in the Okla City, Seminole and other Okla fields.

Mechanical treatment. One method consists in passing the emulsified oil through a tank filled with excelsior, on its way to the tank battery. At Sulphur Bluff and Talco (Texas) both heat and chemical treatments are applied before the oil goes to the excelsior-filled tanks (87). In some fields, where oil containing much water is discharged under press, free water is removed before the oil goes to treatment tanks, by a water "knock-out" with a choke at its end. This permits the water to be blown out periodically, the knock-out being operated manually, or automatically by the water level in the vessel.

Electrical de-hydration is sometimes employed, the oil being heated before entering the apparatus, as in the Luling field, Government Wells, Cayuga, and other Texas fields. Cost of an elec de-hydration unit is $1 500 to $3 000 (55).

Treatment costs range from a fraction of a cent to 20¢ per bbl of oil. Heating in open tanks or pits costs 15¢ to 20¢ per bbl. Cost of electrical treatment, 1 1/2¢ to 3 1/2¢; of chemical treatment, from a fraction of a cent to perhaps 5¢ per bbl.

16. TRANSPORTATION OF OIL

Petroleum is moved from the oil field to refineries by pipe lines, RR tank cars, automobile trucks, barges or tank ships. Most oil goes through pipe lines, of which there is a network in the different oil-producing states, with connections to trunk lines for interstate transport to refineries in the central and eastern states. From individual leases the oil is collected by gathering lines, through which it is pumped, or flows by gravity, to a field-central pumping station. Thence it goes to the main pumping system, unless the field-central station is a unit in that system (88, 89, 90, 91, 92).

Booster stations are maintained at points along main lines, to avoid necessity for excessive initial press. In level country these stations are 10 to 30 miles apart, depending on diam of the pipe line and quantity of oil handled.

Reciprocating or centrifugal pumps are used, the latter being now preferred. Pumps are driven by gas or oil engines, or elec motors, depending on kind and cost of power available. Storage tanks at each booster pumping plant take care of temporary accumulation exceeding capac of the plant, or for storing oil during a shut-down for repairs. Heaters are provided at booster stations, when the oil is very viscous, as in a few Calif fields.

Pipe lines range from 4 to 12-in or more in diam, and pressures up to 800 lb per sq in are sometimes used in pumping stations. Temperatures of the oil at pumping stations are 120° to 180° F, dropping to from 60° to 120° at end of a pipe-line station, before the oil is taken up by the next booster pumps. Pipe-line capacities range from 15 000 to 25 000 bbl per day, when pumping through an 8-in line, and operating under normal conditions. For further details relative to influence of viscosity in flow through pipes, see Sec 38 Art 2.

15. Weights and Measures

(See also Circular 47, U S Bur of Standards, on Units of Weights and Measures, July, 1914)

Avoirdupois Weight

Grains	Drams	Ounces	Pounds	Hund'd-wt	Net tons	Gross tons
1	0.03657	0.002286	0.000143	0.00000127	0.00000007134	0.0000000637
27.34375	1	0 0625	0.003906	0.00003488	0.000001953	0.000001744
437.5	16	1	0.0625	0.00055804	0 00003125	0.00002790
7 000	256	16	1	0.0089286	0.0005	0.0004464
784 000	28 672	1 792	112	1	0.056	0.05
14 000 000	512 000	32 000	2 000	17.857	1	0.89286
15 680 000	573 440	35 840	2 240	20	1.12	1

1 lb avoir = 1.215278 lb troy. 1 net ton = 2 000 lb = 0.892857 gross ton.

Troy Weight

Grains	Pennyweight	Ounces	Pounds
1	0.041667	0.0020833	0.0001736
24	1	0.05	0.0041667
480	20	1	0.0833333
5 760	240	12	1

1 lb troy = 0.822857 lb avoir. 175 oz troy = 192 oz avoir.

Apothecaries' Weight

Grains	Scruples	Drams	Ounces	Pounds
1	0.05	0.016667	0.0020833	0.000173611
20	1	0.333333	0.0416667	0.0034722
60	3	1	0.125	0.0104167
480	24	8	1	0.0833333
5 760	288	96	12	1

The lb, oz, and gr are same as in troy wt. Avoir gr = troy gr = apothecaries' gr.

* U S gal. British imperial gal = 277.410 cu in, or 10 lb avoir of pure water at 62° F and barom at 30 in. British imperial gal = 1.20091 U S gal. 1 fluid dram = 60 minims = 0.125 fluid-oz = 0.0078125 pint. 1 fluid oz = 480 minims = 8 drams = 0.0625 pint.

Metric System

Measures of Length, Capacity, and Weight

Length	Kilometer	Hecto-meter	Decameter	Meter	Decimeter	Centimeter	Millimeter
Capacity	Kiloliter or Stere	Hecto-liter or decistere	Decaliter or centi-stere	Liter or millistere	Deciliter	Centiliter	Milliliter
Weight	Kilo-gramme	Hecto-gramme	Deca-gramme	Gramme	Deci-gramme	Centi-gramme	Milli-gramme
	1	10	100	1 000	10 000	100 000	1 000 000
		1	10	100	1 000	10 000	100 000
			1	10	100	1 000	10 000
				1	10	100	1 000
				0.1	1	10	100
				0.01	0.1	1	10
				0 001	0.01	0.1	1

1 myriameter = 10 kilometers = 10 000 meters. 1 tonne = 1 000 kilogrammes = 100 quintals = 10 myriagrammes. 1 gramme = 1 cu centimeter of distilled water at its max density at sea level in latitude of Paris and barom at 760 millimeters. 1 liter = 1 cubic decimeter.

15. Weights and Measures (*Concluded*)

Square or Surface Measure

Square kilometer	Square hectometer or hectare	Square decameter or are	Square meter or centiare	Square decimeter	Square centimeter	Square millimeter
	100	10 000	1 000 000			
	1	100	10 000	1 000 000		
	0.01	1	100	10 000	1 000 000	
	0.0001	0.01	1	100	10 000	1 000 000
	0.000001	0.0001	0.01	1	100	10 000
		0.000001	0.0001	0.01	1	100
			0.000001	0.0001	0.01	1

1 sq myriameter = 100 sq kilometers = 100 000 000 sq meters.

Cubic Measure

Cubic decameter	Cubic meter or stere	Cubic decimeter or liter	Cubic centimeter	Cubic millimeter
1	1 000	1 000 000	1 000 000 000	
0.001	1	1 000	1 000 000	1 000 000 000
0.000001	0.001	1	1 000	1 000 000
0.000000001	0.000001	0.001	1	1 000
	0.000000001	0.000001	0.001	1

1 cu meter = 1 kiloliter = 1 stere.

* (10^{-3}) † (10^{-2}).

1 joule = 10 million ergs = 10 million dyne-centimeters.
1 knot = 1 nautical mile = 6 080 ft per hour.
1 horse power = 550 ft-lb per second.
1 kilowatt = 1 000 watts = 1 000 joules per sec.
1 cheval-vapeur = 75 kilogram-meters per sec.
1 B t u = heat necessary to raise 1 lb of water 1° F.
1 calorie = heat necessary to raise 1 kg of water 1° C.

19. Chinese Measures

Following is the system of weights and measures adopted by China in pursuance of the imperial rescript of August 28, 1908.

MEASURES OF LENGTH

Chinese		Metric	
1 Hao	equals	0.0032	Centimeter
1 Li	"	0.032	"
1 Fen	"	0.32	"
1 Ts'un	"	3.2	Centimeters
1 Ch'ih	"	0.32	Meter
1 Pu	"	1.6	Meters
1 Chang	"	3.2	"

MEASURES OF SURFACE

Chinese		Metric	
1 Hao	equals	0.006144	Are
1 Li	"	0.06144	"
1 Fen	"	0.6144	"
1 Fang pu	"	0 0256	"
1 Mu	"	6.144	Ares
1 Ch'ing	"	614.4	"

MEASURES OF CAPACITY

Chinese		Metric	
1 Shao	equals	0.0104	Liter
1 Ko	"	0.1035	"
1 Sheng	"	1.0355	Liters
1 Tou	"	10.355	"
1 Hu	"	51.7734	"
1 Tan or Picul	"	103.5469	"

MEASURES OF WEIGHT

Chinese		Metric	
1 Hao	equals	0.0037301	Gram
1 Li	"	0.037301	"
1 Fen	"	0.37301	"
1 Ch'ien	"	3.7301	Grams
1 Liang	"	37.301	"
1 Chin (catty)	"	596.816	"

20. Japanese Measures

Kwan, = 3.75 kg or 8.2673336 lb avoir, is the unit of mass. It is divided into 1 000 mommes, the momme into 10 funs, the fun into 10 rins, the rin into 10 mos, and the mo into 10 shis.

Shaku is the unit of length, equal to 10 ÷ 33 (0.30303) meter, or 0.9941919 U S ft. It is decimally divided into sun, bu, rin, mo, and shi. Multiples of the shaku are: the ken = 6 shaku; the cho = 60 ken, and the ri = 36 cho, or 12 960 shaku.

The shaku (land measure) = 0.00033 are (metric), or 0.988417534 sq ft, 10 shaku = 1 go, 10 go = 1 bu or tsubo, 30 bu = 1 sé, 10 sé = 1 tan, and 10 tan = 1 cho.

The shaku (capacity measure) = 0.01804 liter, or 0.0180616 U S liquid quart, 10 shaku = 1 go, 10 go = 1 sho, 10 sho = 1 to, and 10 to = 1 koku (4.963 bushels). Metric weights and measures are recognized as legal in accordance with the above equivalents.

21. Russian Measures (E. L. Stenger)

Quantity	Equivalent	Quantity	Equivalent	Quantity	Equivalent
Vershok	1 750 in 44.45 mm	Sq mile	2 2758 sq verst 2 590 sq kilom	100 poods	1 8056 short ton 1 6122 long " 1 6380 met "
Russian ft	1 0 English ft 0 3048 meter	Sq arshine	256 0 sq vershok 5 4444 sq ft		
Arshine	16 0 vershok 28 0 in 2 3333 ft	Desiatine	24 000 sq sagene 2 7001 acre	Doli	44.435 mg 0 686 grain
Sagene	3 0 arshine 7 0 ft	Vedro	10 0 krushkar 12 299 liter 750 51 cu in 3 249 U S gal 2 7067 Imp gal	Zolotnik	0 3333 lot 96 0 doli 4 2659 gm 65 833 grain 0 13715 troy oz 0 15047 av oz
Verst	500 sagene 3 500 ft 0 66288 mile 1 06680 kilom	Funt	0 9028 lb 409 503 gm		
Meter	1 4061 arshine 0 4687 sagene 0 000937 verst	Pood	40 0 funt 36 113 lb 16 3805 kg	Cubic sagene	343 0 cu ft 2 6797 cord

22. Spanish-American Measures

Arroba = 25.4 lb av = $^1/_4$ quintál = 11.51 kg (also, in Spain, 1 arroba = 1 cántara = 4.2 U S gal approx).

Tonelada = 20 quintales = 2 032.2 lb av = 921.8 kg.

Vara = 2.75 ft (Perú), 2.841 ft (Argentina), 2.782 ft (Spain).

Estaca (Perú) = 167 meters sq = 27 889 sq meters.

Fanega (Perú) = 1.65 acre (varying locally); also = 141.43 lb av = 64.14 kg; also = 1.599 bushel (in Mex = 2.577 bushels).

Pertenencia, or mining claim, in Mexico and in general throughout Spanish America, is a solid of indefinite depth, underlying a square surface area of 100 meters on a side (Mexican Mining Law of June 4, 1892; unchanged since).

23. Miscellaneous Measures

Board measure. Commercial boards (unplaned or green lumber) are assumed to be 1 in thick, but are often less; rough, dry boards, about $^7/_8$ in. On basis of 1 in thickness, number of feet of board measure in a stick of squared timber = length (ft) × breadth (ft) × thickness (in).

Cubic measures. 1 cord fire-wood = 4 × 4 × 8 ft = 128 cu ft. 1 perch of stone = 1.5 ft wide × 1 ft high × 16.5 ft long = 24.75 cu ft. As the perch varies in different regions, it should be checked by local practice.

Structural steel. Sec 43, Art 26, contains brief tables of standard sizes and weights. For complete tables, see steel manufacturers' catalogues.

Miner's inch of water. See Sec 10, Art 123 and Sec 38, Art 20.

Ship measurements are of 5 kinds. In U S and British countries, the ton = 2 240 lb; where metric ton is used, 2 204.6 lb.

(1) *Displacement* is total wt in tons, of a vessel and contents. Displacement "light" = wt of vessel without stores, bunker fuel or cargo; displacement "loaded" = total wt, including last 3 items.

(2) *Cargo tonnage* is expressed on basis of either "weight" or "cubic measurement." "Measurement ton" is usually 40 cu ft (as in U S); in some countries, 42 cu ft.

(3) *Gross tonnage* applies to vessel itself, not to cargo, and is the contents in cu ft of its closed-in spaces, divided by 100 (assuming a vessel-ton to be 100 cu ft). "Register" states both gross and net tonnage, and is about the same under U S and British rules.

(4) *Net tonnage* is gross tonnage, less deductions for space occupied by crew, engine room and fuel, and for navigation; that is, the space available for passengers and cargo. As a ton of cargo usually occupies much less than 100 cu ft, see (2), cargo tonnage generally exceeds both net and gross tonnage.

(5) Deadweight tonnage is the number of tons a vessel can carry, of cargo, stores and fuel. It is the difference between tons of water displaced when vessel is "light" and when submerged to "load line" (which is often shown on vessel's side by the "Plimsoll mark"). Capacity for weight cargo is less than dead-weight tonnage.

Examples of relative measurements. (*a*) An ordinary freight steamer: net tonnage, 4 000; gross tonnage, 6 000; deadweight capacity, 10 000 tons; displacement, loaded, 13 350 tons. (*b*) Oil tanker, Standard Oil Co of Calif, launched 1938: net tonnage, 4 934; gross tonnage, 8 298; deadweight capac, 12 800 tons; displacement, loaded, 17 320 tons.

24. Values of $1, at — % Compound Interest, for — Years
(Adapted from tables in "Principles of Finance," by F. C. Kent, 1927)

The formula for computing the above table is: $V = A(1 + R)^n$, where V = final value, A = amount invested, R = interest rate, and n = number of years.

Example. If $1 be invested, at 3% compound interest, for a period of 15 years, $V = 1(1.03)^{15}$, whence, $\log V = 15 \log (1.03) = 0.1926$, and V = $1.56.

Conversely, to find the *present value* of an investment, the payment of which is due at the end of a term of years, at a given rate of compound interest, the above formula becomes,

$A = \frac{V}{(1 + R)^n}$ (see Table 25).

25. Present Value of $1, Due at End of — Years, at Compound Interest
(Condensed from Kent's Tables, 2nd Ed, 1927)

Years	3%	4%	5%	6%	7%	8%	9%	10%

30	4120	3083	.2314	1741	1314	0994	.0754	.0573

Formula for computing this table is: $A = \frac{1}{(1+R)^n}$, where A = present value of the investment (represented by the amounts in tables at different rates of interest), V = final value, or $1, R = interest rate, and n = number of years. Note that this formula is the *converse* of that used to compute Table 24.

Example. What sum must be invested at 3% compound interest to produce $1 at end of 20 years? A = unknown investment, or present value, V = $1, R = 3%, and n = 20; hence, $A = \frac{1}{(1.03)^{20}}$. Since $\log A = \log 1 - 20 \log (1.03) = 9.7432 - 10$, A = $0.5537.

To find the present value of any other sum, multiply that sum by present value of $1 for required number of years, as in this table.

26. Present Value of an Annual Dividend of $1, for a Term of — Years, at · · %
(Based on Inwood's Tables, 30th Ed, 1920)

Years	3%	4%	5%	6%	7%	8%	9%	10%
1	0.971	0.961	0.952	0.943	0.935	0.926	0.917	0.909

26	17.877	15.983	14.375	13.003	11.826	10.810	9.929	9.161
27	18.327	16.330	14.643	13.210	11.987	10.935	10.027	9.237
28	18.764	16.663	14.898	13.406	12.137	11.051	10.116	9.307
29	19.188	16.984	15.141	13.591	12.278	11.158	10.198	9.370
30	19.600	17.292	15.372	13.765	12.409	11.258	10.274	9.427

Formula for computing above table is: $a_n = \frac{1 - v^n}{i}$, where a_n = present value of $1 per annum for n years, v^n = present value of an investment that will produce $1, at i given dividend rate, in n years, and i = dividend rate.

Example. If n = 10 years, i = 6%, and v^n = 0.5584 (see Table 25):

$$a_n = \frac{1 - 0.5584}{0.06} = \frac{0.4416}{0.06} = \$7.36.$$

27. Present Value of an Annual Dividend of \$1 for n Years, That Will Yield $x\%$ Simple Interest, and also Provide Annual Sums Which, if Invested at 4% Compound Interest, Will Replace Original Investment (From Inwood and Kent; quoted by Hoover, "Principles of Mining" and Finlay, "Cost of Mining")

Years	5%	6%	7%	8%	9%	10%
1	.95	.94	.93	.92	.92	.91
2	1.85	1.82	1.78	1.75	1.72	1.69
3	2.70	2.63	2.56	2.50	2.44	2.38
4	3.50	3.38	3.27	3.17	3.07	2.98
5	4.26	4.09	3.93	3.78	3.64	3.51
6	4.98	4.74	4.53	4.33	4.15	3.99

30	14.74	12.85	11.38	10.22	9.27	8.49

Table 27 is computed by the formula:

$$P = \frac{R^n - 1}{r + r'(R^n - 1)}, \text{ where}$$

P = present value of annual dividend; n = number of years that the dividend is received; r = one year's interest on \$1 at 4% = 0.04; $R = 1 + r = 1.04$; R^n = value of \$1 at 4% compound interest for n years, which may be taken directly from Table 24 (thus avoiding use of logarithms); r' = one year's interest on \$1 at $x\%$.

Example. Find present value of an annual dividend of \$100 000 over 20 years at 8% simple interest, and replacing capital by reinvestment of an annual sum at 4% compound interest. Then $r = 0.04$, $R = 1.04$, $r' = 0.08$ and $n = 20$; whence

$$P = \frac{1.04^{20} - 1}{.04 + .08\,(1.04^{20} - 1)} = 8.804$$

which, multiplied by \$100 000 gives the present value required = \$880 400.

Obviously, any desired interest rate other than 4% may be used for the sinking fund, by using the appropriate values for r and R in the formula.

28. Miscellaneous Problems in Present Value Computations

(By James F. McClelland, Vice-Pres of Phelps Dodge Corporation)

1. Present value P of a deferred annuity or annual dividend of \$1, to begin at the end of p years and continue for an additional n years, allowing compound interest at $x\%$. Let r = one year's interest on \$1 at $x\%$; $R = 1 + r$. Then

$$P = \frac{1}{r}\left(\frac{1}{R^p} - \frac{1}{R^{n+p}}\right)$$

In this formula, $\frac{1}{R^p}$ and $\frac{1}{R^{n+p}}$ are the present values, at $x\%$ compound interest, of \$1 due in p years and $n + p$ years respectively and may be taken directly from Table 25.

2. Present value P of a deferred annuity or annual dividend of \$1, to begin at the end of p years and continue for an additional n years, to yield interest on capital (present value of annuity) at $x\%$ and to return capital through investment of balance of annuity at $y\%$ compound interest. Let r = one year's interest on \$1 at $y\%$; $R = 1 + r$; r' = one year's interest on \$1 at $x\%$. Then

$$P = \frac{R^n - 1}{(1 + r')^p[r + r'(R^n - 1)]}$$

In this formula, R^n is the value of \$1 at $y\%$ compound interest for n years; $(1 + r')^p$ is the value of \$1 at $x\%$ compound interest for p years. These values may be taken directly from Table 24.

3. Present value of a series of irregular annual dividends is the sum of present values of each dividend and may be computed from Table 25. Problems also arise in which it is desired to determine present value of a series of irregular annual dividends, allowing

for interest on capital at one interest rate x, and return of capital at a different rate of interest y. Then

$$P = \frac{S}{1 + \frac{r'}{r}(R^n - 1)}$$

where P = present value; r = one year's interest on \$1 at y%; $R = 1 + r$; r' = one year's interest on \$1 at x%; n = number of years over which the dividends are received; S = value of the series of irregular annual dividends at compound interest in n years at the rate y. In using this formula the value of each dividend must first be computed, using Table 24 for this purpose. S is the sum of such values.

Example. Assume irregular dividends as listed in the accompanying table, when $n = 5$ yr; interest rate desired on investment, $x = 6\%$; $r' = 0.06$; and interest rate y on sinking fund = 4%; whence, $R = 1 + r = 1.04$. S is found as follows:

$$P = \frac{\$6\,934\,070}{1 + \frac{.06}{.04}(1.04^5 - 1)} = \$5\,233\,663,$$

as proved in the table below.

Year	Dividend received	Value of \$1 at 4% at end of n years* (from Table 24)	Value of dividend at 4% at end of n years (col 2 × col 3)
1st	\$1 330 800	1.1698	\$1 556 770
2nd	1 426 100	1.1249	1 604 220
3rd	1 208 700	1.0816	1 307 330
4th	1 208 700	1.0400	1 257 050
5th	1 208 700	1.0000	1 208 700
		S =	\$6 934 070

* If dividends are received at end of each year, interest will accumulate on the first dividend for $n - 1$ years; on the second dividend for $n - 2$ years, etc.

Year	Dividend	Annual interest desired = 6% on \$5 233 663	Balance for sinking fund	Amount of sinking fund at end of 5th year
1	\$1 330 800	\$314 020	\$1 016 780	\$1 189 430
2	1 426 100	314 020	1 112 080	1 250 979
3	1 208 700	314 020	894 680	967 686
4	1 208 700	314 020	894 680	930 467
5	1 208 700	314 020	894 680	894 680
				\$5 233 242

NOTE. If the series of irregular annual dividends is deferred, first find P at end of the deferment period, as above. The present value of the deferred series is the present value of P. That is, P should be discounted for the number of years of deferment.

Estimates of future income from mining properties ordinarily involve judgment as to future metal prices, market demand and numerous variables affecting the time at which income will be produced. It should be borne in mind that present values, calculated from such estimates of income, reflect these judgment factors. A series of present-value calculations, based on estimates of future income under different assumptions as to the variable factors, is useful as an aid to judgment in determining a cash price for a mining property. Present-value calculations are invaluable in determining the relative values of two or more mining properties, especially in the case of mergers, where payment for the properties is made in capital stock of the resulting corporation. See also remarks in connection with Table 5, Sec 25.

29. Values of Foreign Monetary Units

Following equivalents, in terms of U S "money of account," were established by the Secy of the Treasury on Jan 1, 1940, for estimating the value of currencies of different countries (at par for gold units; non-gold units have no fixed par with gold). The Secretary's circulars are issued quarterly. This list comprises countries in which mining is carried on.

Country	Monetary Unit	Value in U S money	Remarks
Argentine Republic	Peso	$1.6335	Valuation is of gold peso. Paper nominally convertible at 44% of face value. Conversion suspended Dec 16, 1929
Australia	Pound	8.2397	Control of gold exports authorized Dec 17, 1929
Belgium	Belga	.1695	Decree of Mch 31, 1936; one belga equals 5 Belgian francs
Bolivia	Boliviano	.6180	Conversion of notes into gold suspended Sep 23, 1931
Brazil	Milreis	.0606	Based upon official rate for milreis as announced by Bank of Brazil. Conversion of Stabilization-Office notes into gold suspended Nov 22, 1930
British Honduras	Dollar	1.6931	Conversion of notes suspended
Bulgaria	Lev	.0122	Exchange control established Oct 15, 1931
Canada	Dollar	1.6931	Embargo on export of gold, Oct 19, 1931; redemption of Dominion notes in gold suspended Apl 10, 1933
Chile	Peso	.2060	Valuation is of gold peso; received for conversion at 4 paper pesos per gold peso. Conversion suspended July 30, 1931
China	Yuan	....	Silver standard abandoned Nov 3, 1935; bank notes legal tender under Currency Board Control; exchange for British currency fixed at about 1sh 2 1/2d, or about 29 1/2¢ U S per yuan
Hong Kong	Dollar	.2325	Treasury notes and notes of the three banks of issue made legal tender by silver nationalization ordinance of Dec 5, 1935
Colombia	Peso	.5714	Obligation to sell gold suspended Sep 24, 1931. New gold content of 0 56424 gram gold, 9/10 fine, effective Nov 30, 1938
Costa Rica	Colon	.7879	Conversion of notes into gold suspended Sep 18, 1914; exchange control estab Jan 16, 1932
Cuba	Peso	1.0000	By law of May 25, 1934
Dominican Republic	Dollar	1.6931	U S money is principal circulating medium
Ecuador	Sucre	.3386	Conversion of notes into gold suspended Feb 9, 1932
Egypt	Pound (100 piasters)	8.3692	Conversion of notes into gold suspended Sep 21, 1931
Finland	Markka	.0426	Conversion of notes into gold suspended Oct 12, 1931
France	Franc	....	Monetary law of Oct 1, 1936, providing for gold content of franc, superseded by decree of June 30, 1937, which ultimately will fix gold content of franc
Germany	Reichsmark	.4033	Exchange control established July 13, 1931
Great Britain	Pound. Demand, June, 1940, $3.75–$3.81	8.2397	Obligation to sell gold at legal monetary par suspended Sep 21, 1931
Greece	Drachma	.0220	Conversion of notes into gold suspended Apl 26, 1932
Guatemala	Quetzal	1.6931	Conversion of notes into gold suspended Mch 8, 1933
Haiti	Gourde	.2000	National bank notes redeemable on demand in U S dollars
Honduras	Lempira	.8466	Gold exports prohibited Mch 27, 1931; lempira circulates as equivalent of half of U S dollar
Hungary	Pengo	.2961	Exchange control established July 17, 1931
India (British)	Rupee	.6180	Obligation to sell gold at legal monetary par suspended Sep 21, 1931
Indo-China	Piaster	....	Piaster pegged to French franc at rate of 1 piaster = 10 francs; conversion into gold suspended Oct 2, 1936

Values of Foreign Monetary Units—*Continued*

Country	Monetary Unit	Value in U S money	Remarks
Italy	Lira	.0526	New gold content of 46.77 milligrams fine gold per lira established Oct 5, 1936
Japan	Yen (par, 0.844)	.2343	Embargo on gold exports Dec 13, 1931
Mexico	Peso	....	Decree of Aug 28, 1936 left the monetary unit to be later defined by law
Netherlands and colonies	Guilder (florin)	.6806	Suspension of convertibility of notes into gold and restrictions placed on free gold exports Sep 26, 1936; gold export prohibition repealed by decree June 28, 1938
Newfoundland	Dollar	1.6931	Newfoundland and Canadian notes legal tender
New Zealand	Pound	8.2397	Conversion of notes into gold suspended and export of gold restricted Aug 5, 1914; exchange regulations, Dec 1931
Nicaragua	Cordoba	1.6933	Embargo on gold exports Nov 13, 1931
Panamá	Balboa	1.0000	U S money is principal circulating medium
Paraguay	Peso (Argentine)	1.6335	Paraguayan paper currency used; exchange control established June 28, 1932
Persia (Iran)	Rial	.0824	Obligation to pay out gold deferred Mch 13, 1932; exchange control estab Mch 1, 1936
Perú	Sol	.4740	Conversion of notes into gold suspended May 18, 1932
Philippine Islands	Peso	.5000	By act approved Mch 16, 1935
Portugal	Escudo	*.0749	Gold exchange standard suspended Dec 31, 1931
Rumania	Leu	.010127	Exchange control established May 18, 1932
Salvador	Colon	.8466	Conversion of notes into gold suspended Oct 7, 1931
Spain	Peseta	....	....
Straits Settlements	Dollar	.9613	British pound and Straits dollar and half dollar legal tender
Sweden	Krona	.4537	Conversion of notes into gold suspended Sep 29, 1931
Thailand (Siam)	Baht (Tical)	.7491	Conversion of notes into gold suspended May 11, 1932
Turkey	Piaster	.0744	100 piasters equal to the Turkish pound; exchange control established Feb 26, 1930
Union of South Africa	Pound	8.2397	Conversion of notes into gold suspended Dec 28, 1932
Union of Soviet Republics	Chevronets	8.7123	....
Uruguay	Peso	.6583	Conversion of notes into gold suspended Aug 2, 1914; exchange control established Sep 7, 1931. New gold content of .585018 gram of gold per peso established Jan 12, 1938
Venezuela	Bolivar	.3267	Exchange control established Dec 12, 1936
Yugoslavia	Dinar	.0298	Exchange control established Oct 7, 1931

NOTE—Values in column 3 are based on present arbitrary value of gold in the U S, now (1940) approx $35 per oz.

INDEX

Light figures refer to Volume I. **Bold-face figures refer to Volume II.**
